I have already referred to the restiveness of farmers under the unremunerative prices of four successive seasons; and, speaking personally, whilst I find such restiveness amply justified, I cannot subscribe to the view that our farmers can afford to slide out of Wheat-growing, or even to curtail the area sown to any appreciable degree. Let us consider the question of prices first. I have shown below the Government Statist's mean prices realised by wheat at outports in each of these four seasons, and with these figures I have associated State Mean Yields per acre together with the calculated Mean Returns per acre.

Seasons.	Mean Price per Bushel at Outports.	Mean Yield per Acre.	Mean Gross Return per Acre = Mean Price x Mean Yield per Acre.
	s. d.	Bush.	£ s. d.
1930-31	2 3½	8.34	0 19 1
1931-32	3 2	11.81	1 17 5
1932-33	2 9¾	10.43	1 9 4
1933-34	2 8 (estimate)	9.26	1 4 8
Means , ...	2 9.28	9.96	1 7 7
At railway siding	2 3.78	—	1 3 1

The above statement shows that for the four seasons closing on June 30th, 1934, the mean price of Wheat at outports was 2s. 9¼d. per Bushel, the mean yield per acre 9.96 bushels, and consequently the mean gross return to the average farmer £1 7s. 7d. per acre for Wheat delivered at the farmer's expense to nearest shipping port; but as farmers generally sell their wheat at the nearest siding, it will be necessary to deduct from the mean price per Bushel at outports the mean railage 4d., plus usual country charges 1½d. This will reduce the average price per Bushel at the farmer's siding to 2s. 3¾d. and the average gross return per acre to £1 3s. 1d. It can be stated with confidence that neither the mean gross return of the four seasons—£1 3s. 1d. per acre—nor the individual returns of any one season could balance the corresponding costs of the average farmer. In support of this view let me quote the Mean Costs per acre of a private Mallee Farm, the accounts of which were kept by officers of the Department of Agriculture during three consecutive seasons—1929-32. These Costs can be summarised as follows:—

Mean 1929-32 *Costs of Growing Wheat on a Mallee Farm, the Mean Yield of which was* 16.92 *Bushels to the Acre.*

Preparation of Fallows	£0 12 1
Seeding Operations	0 11 3
Harvest Operations	0 11 2
Balance of Expenditure	0 14 2
Total Expenditure per Acre	2 8 8

Note.—In the above expenditure "cost" of conveying the grain to the nearest railway siding has NOT been included.

If in the above connection we should multiply the mean yield per acre —16.92 Bushels—by the mean price of Wheat at a siding during the past four seasons—2s. 3.78d. per Bushel—we should get £1 19s. 2d., which would have represented to the owner of the farm a loss of 9s. 6d. per acre per annum, plus whatever it might have cost him to convey the Wheat to the nearest siding.

IV. THE PAYING AND NON-PAYING WHEAT FARMS OF SOUTH AUSTRALIA.

But because during the past four seasons the mean price paid for Wheat has been demonstrably lower than the mean Costs of Production of the average farmer, it does not follow that such must have been the case for *all* farmers alike. In order to make this point clear, I have summarised in Table II., at the end of this statement, the mean position of Wheat Production in South Australia for the eight-year period closing on June 30th, 1933 (but excluding 1927-28, for which figures were not available). In this Table all the Wheat Farms of the State have been grouped together in accordance with their mean yields per acre, and the data given comprise—

(1) Number of Farms in each group;
(2) Total area under Wheat in each group;
(3) Total production of each group;
(4) Mean yields per acre of each group; and
(5) Mean gross returns per acre in each group, on the basis of 2s. 3.78d. per Bushel.

In this Table I have assumed—and I believe with good reason—that no Farm could be expected to meet average costs of production that does not return £2 gross or more per acre. On this basis it has been possible to separate out South Australian Farms into two divisions, comprising three groups in each. The first Division would include farms which were unable to pay their way during the four-year period ending on June 30th, 1934, and the second Division those that were able to do so. Unfortunately, the former included the vast majority of our farms, namely, 11,135, or 82.78 per cent., which averaged 7.93 Bushels per acre and 18s. 4d. per acre only in the way of gross return. These farms included 87.25 per cent. of the area under Wheat in South Australia, and 71.11 per cent. of the Wheat raised in the State. The more fortunate farmers, whom we have assumed to have paid their way during these four years of low prices, were represented by 2,316 farms, or 17.22 only of the State total. The mean area sown to Wheat on these farms and the mean quantity of Wheat harvested were 12.75 per cent. and 28.89 per cent. of the respective State totals, whilst the corresponding gross return per acre at 2s. 3.78d. was £2 11s.

Nobody can claim that results such as these were satisfactory to the State or to the individuals concerned, and however unpalatable the truth may be, it is necessary to stress the fact that unduly low monetary returns per acre are quite as much the consequence of low mean grain yields per acre as of low mean prices per bushel; and moreover, that unfavourable weather conditions are not usually the only factors responsible for these low mean yields per acre. In other words, we cannot escape the conclusion that the low farm revenues that we all deplore are frequently the natural consequence of faulty or slovenly farming practices. After almost a century of Wheat-growing and all that a century should have taught us, it is surely anomalous that during the past eight seasons there should still have been an average of 1,634 farmers, or more than 12 per cent. of the State mean total, whose mean yield per acre was 1.37 Bushels only, and whose corresponding monetary return per acre at 2s. 3.78d. per Bushel was 3s. 2d. only; or that 3,647 farmers, or more than one-quarter of the State total, should have averaged no more than 3 Bushels per acre, with a corresponding mean monetary return of 6s. 11d. per acre only. I know that it can be said that weather conditions were unfavorable during several of these eight seasons; but unfavorable weather conditions did not prevent an average of 962 farmers from reaping 23.23 Bushels per acre during the same period; 248 farmers 29.08 Bushels; and 57 farmers 35.74 Bushels.

Indeed, if we take the best of these seasons, namely, 1926-27, when the State average reached 12.84 Bushels per acre, there were still 1,513 farmers whose mean yield per acre was 4.16 Bushels only.

V. WHEAT GROWING IN SOUTH AUSTRALIA AND THE OTHER STATES.

Unfortunately, these high proportions of regrettably low yields are damaging not only to the farmers concerned but also to the prestige and material interests of South Australia as well. It should not be forgotten that with us Wheat is a National asset as well as a sectional occupation. There was a time when it was our common boast that we had taught the Sister States how to grow Wheat; and perhaps such a boast was more or less justified at the time. Latterly, however, it would seem that the pupils have bettered their instruction, in proof whereof I append a statement setting out recent mean yields of Wheat per acre in the Commonwealth and the several States:—

Australian Mean Wheat Yields per Acre, 1927-28 *to* 1932-33.

Seasons.	New South Wales.	Victoria.	Queensland.	South Australia.	Western Australia.	Tasmania.	Federal Capital Territory.	Common-wealth.
	Bushels.	Bushels.	Bushels.	Bushels.	Bushels.	Bushels.	Bushels.	Bushels.
1927-28	8·92	8·54	17·50	8·16	12·12	26·25	7·12	9·63
1928-29	12·04	12·59	11·54	7·79	10·10	20·17	11·88	10·76
1929-30	8·66	7·13	20·75	6·40	10·95	22·37	19·06	8·47
1930-31	12·83	11·70	18·76	8 34	13·53	20·49	13·73	11·76
1931-32	14·92	11·77	15·33	11·81	13·14	15·61	16·84	12·93
1932-33	16·40	14·81	9·90	10·43	12·30	20·63	18·74	13·55
Means	12·55	11·13	15·61	8·93	12 05	21·65	16·08	11·27

The statement on previous page shows that for the six-year period ending on June 30th, 1933:—

(1). The Mean Wheat Yields per acre were in the following order:—

	Bushels per Acre.
a. Tasmania	21.65
b. Federal Capital Territory	16.08
c. Queensland	15.61
d. New South Wales	12.55
e. Western Australia	12.05
f. Victoria	11.13
g. South Australia	8.93
Commonwealth	11.27

Hence, whilst Tasmania led the way with a Mean Wheat Yield of 21.65 Bushels, South Australia brought up the rear with 8.93 Bushels only.

(2). In each of the six seasons the South Australian Mean Yield per acre was less than the Commonwealth mean yield.

(3). In three of the six seasons the South Australian Mean Yields were the lowest in the Commonwealth; but in the other three they occupied the penultimate positions, with Federal Capital Territory last in 1927-28, Victoria last in 1931-32, and Queensland last in 1932-33.

This is one of the last, if not the last address, that I shall have the pleasure of delivering before Congress, and none more than myself regrets that during the course of its delivery I should have found it necessary to stress these unpalatable facts; and if I have done so at all, it is because I have always felt that whatever the legal fiction of the day might happen to be, private ownership could not abrogate the State's natural overlordship of all land within its jurisdiction, nor the implied obligation that landholders would work their holdings not only from the standpoint of private gain, but from that of the special requirements of the community as well. From such a standpoint the man who reaped 6 bushels to the acre when it was both technically and economically possible for him to have reaped twelve, was wronging not only those immediately dependent upon him, but in addition the community which had entrusted the land to his care. Let me add here that this statement is made not without full appreciation of the many difficulties that beset the man on the land, and especially of those difficulties that have almost overwhelmed him of recent years. In support of this viewpoint I propose giving a striking illustration which I hope will appeal to you.

VI. SOUTH AUSTRALIAN WHEAT AND BARE FALLOW.

If there is one practice more than any other that has enabled us to continue growing Wheat in the teeth of unfavourable conditions, both economic and climatic, it is the recognised practice of sowing Wheat on land that in the immediately preceding nine or ten months had been treated as carefully tilled Bare Fallow. There is no other practice that has had a greater influence for good on our mean yields per acre; fertilisers, quality and quantity of seed, time of sowing, treatment against disease, etc., count for little or nothing unless the land had been adequately fallowed in the preceding season. And it can be said without the slightest exaggeration that in South Australia out of every 100 acres sown to Wheat not more than one acre could be expected to be profitable if sown on stubbles or on grass land. It is not as if all this were a matter of mere

personal opinion. During the past forty years or so you have had it thundered at you from hundreds of platforms; you have seen it demonstrated on Government experimental plots and farms; you have seen it confirmed on your neighbours' farms; indeed, it has been the life-long experience of nine men out of every ten of you. How, then, is it that during the past ten years out of every 100 acres sown to Wheat in South Australia 60 acres only had been fallowed If you refer to Table III. at the back of this statement you will find the proof of my contention; you will note there, too, that whereas during these ten years the mean yield of Wheat sown on Bare Fallow was nearly 12½ Bushels per acre, that of Wheat sown on land that had not been fallowed was 5½ Bushels only. There in a nutshell we have the main cause of South Australia's recent low mean yields per acre and the inglorious position we have come to occupy among the other Wheat-producing States.

The chief sinners in this direction are to be found on Eyre's Peninsula and in the Murray-Mallee Statistical Division. On Eyre's Peninsula during the ten-year period which ended in 1933-34, for every 100 acres sown to Wheat 31 acres only had been treated as Bare Fallow; the latter yielded a mean return of 9.14 Bushels per acre, whereas the corresponding 69 per cent. of the land yielded 5.21 Bushels only.

In the Murray Mallee Division during the same period for every 100 acres sown to Wheat 47 acres only had been treated as Bare Fallow, with a mean yield of 8.68 Bushels per acre, as against 5.81 Bushels for the balance of the land that had not been fallowed.

Nevertheless, it must be admitted that there is much to be said for the attitude of Mallee Farmers in this matter, at all events to the extent that it concerns their pioneering days. The usual inadequacy of initial Capital may be said to have forced upon them rather crude, and eventually lengthy, and therefore costly, methods of scrub reclamation. In usual practice the first crop has been sown in the ashes of the first "burn" of recently rolled Mallee Scrub. This primitive treatment has, however, never sufficed to eradicate the Mallee. In subsequent years fierce stubble fires have been required to destroy Mallee Shoots that persisted in growing up with the Wheat crops, and this has meant many succeeding Wheat crops on such portions of the land as were not occupied by roots and underground stems. The man was lucky who succeeded in completing the reclamation of his farm in ten years, and by that time he had usually forgotten how to farm. It is these facts which account in some measure for the evident reluctance of Mallee Farmers to sow Wheat on well-tilled Bare Fallow even when their pioneering days are a long way behind them. Nevertheless, many a successful Mallee Farmer has told me that if he had started on a virgin Mallee Block with adequate Capital he would from the very outset have sown Wheat on Bare Fallow only.

Another unfortunate legacy of pioneering days is the obsession that as large a proportion of the farm as possible should be placed under Wheat every year. It does not yet seem to have been fully realised that on well-tilled fallow the same amount of Wheat can be harvested from one-half to one-third of the areas found necessary in pioneering days. It follows that these relatively light Mallee Lands continue to be placed far too frequently under Wheat with corresponding reduction in the mean yields per acre they might otherwise be returning. Nor does it seem to be realised that it is both simpler and cheaper to grow and handle 1,000 bags of Wheat

from 250 acres than from 500 acres. In principle, Mallee Land should not be brought under Wheat more frequently than once in three or four years, and in very light land at even greater intervals. It need not be thought that if this practice were more generally adopted there would be no economic use to which the land could be put in intervening years; every Mallee Farm should be stocked to its maximum livestock-carrying capacity, and when such was the case, grazing livestock, besides helping to maintain the fertility of land temporarily out of cultivation, should yield net returns not less than those that accrue from Wheat grown too frequently on the same area of land.

It should be unnecessary to stress the fact that the economic value of Bare Fallow before Wheat must depend very largely on the effectiveness of the tillage methods adopted by the farmer. In this connection one of the best recognised objectives of Bare Fallow is cleaning the land and preventing undesirable weeds from going to seed, and it can be added that probably no single factor exercises a more depressing influence on Wheat yields than unchecked Weed growth. It follows, therefore, that, among other things, tillage operations should be directed towards the elimination of any weeds that should appear from time to time on well-tilled Bare Fallow. It came, therefore, as a shock to my old-fashinoed ideas to learn at a recent Conference of Branches of the Agricultural Bureau that a farmer had no time for "pretty ploughing," but preferred to see the furrows standing on edge, only partly inverted, with stubble and rubbish showing on the surface. In the first place the gibe against "prettiness" seems to be misplaced, since it is a gibe against the symmetrical regularity of well-laid furrows, which in turn is an indication that not a foot of soil has escaped adequate tillage. There is many an acre of Wheat in South Australia, the mean yield of which has been appreciably reduced because of the patchiness and lack of prettiness of the ploughing. As to the incomplete inversion of the furrows and the retention on the surface of stubble and rubbish, the object would seem to have been to check the tendency of the soil to drift. Without wishing to discuss the effectiveness of the practice in the latter direction, it can be definitely stated that if adopted the control of weeds is bound to be defective, and that succeeding Wheat yields are bound to suffer accordingly. Moreover, if the main object in view is not to plough, but to check drift, then why make use of a plough at all? Why not fall back upon a cultivator which proportionally to area covered is of lighter draught, and correspondingly cheaper to work? After all, our benighted forefathers wasted a good deal of thought and effort in the progressive evolution of the Mouldboard, which eventually has been mathematically designed to slip under the furrow slice, to lift it progressively, and finally to invert it completely, in the course of which operations weeds and surface rubbish are completely turned under and left to decay beneath the inverted furrow slice. If modern ideas should suggest that the turning of the furrow was a work of supererogation, then let us scrap mouldboards ruthlessly, but in doing so, let us not imagine that our fallows will be well tilled, in the usual acceptance of the terms.

There is another popular saying anent fallowing to which I also take exception, namely, that Farmer Brown, let us say, lived on his fallows between ploughing and seeding time. It seems to me that all that can be said in the matter is that whilst Farmer Brown should no doubt be commended for his misdirected energy, it is probable that portion of his time and that of his teams might have been more profitably occupied elsewhere. Is it necessary to remind you that from the technical standpoint it is quite

as easy to over-work as to under-work land, particularly land relatively light in texture? Moreover, whilst it is true that the mean yield of a Wheat crop will depend very largely upon the adequacy of the tillage that preceded it, it is also true that every tillage operation in excess of what is strictly necessary tends to raise costs of production, and in these days of low prices this is a luxury which farmers can ill-afford. If we suppose fallows to have been cultivated once more than was strictly necessary, this would mean that unnecessary expenditure to the extent of 2s. 6d. to 3s. 6d. per acre would have been incurred, representing 2d. to 3d. per Bushel on a 15-Bushel crop!

In my judgment, unless weather conditions render field operations out of the question, there should be no holidays for horses between Seeding time and Fallowing; nor should they need them if they had been adequately tended and fed in the late summer, and during the course of seeding operations. Those who delay fallowing operations because of the bits of feed they are afraid of ploughing under are usually doing so at the expense of the succeeding year's Wheat Crop. Whether the land should be harrowed immediately after ploughing, or whether it should be left in the rough state throughout the winter, is more or less a matter of opinion depending probably upon local conditions. There are soils which heavy winter rains tend to beat down to a hard, impermeable crust whenever the surface layers have been broken down too fine; such soils had probably better be left in the rough state until Spring. Early harrowing no doubt prepares a better seed-bed for the early germination of weeds. and as such presents certain advantages: but speaking generally I would prefer completing the ploughing before calling in the harrows; and would not use the latter unless I thought they were required, which generally would be after the first cultivating. After all, harrowing costs in the neighbourhood of 1s. per acre, representing ¾d. per bushel on a 15 Bushel crop.

In the great majority of cases ploughing should be completed in the month of August and followed almost immediately afterwards by cross-cultivation. Any undue delay in this first cultivation will generally mean that over portion of the fallows, at all events, rising Spring temperatures will stimulate weeds into growth too vigorous to be dealt with effectively by cultivators; hence the ultimate consequences of this kind of delay would usually be increased costs of combined tillage operations, or abundant seeding of weeds on the fallows, or both. As to the number of tillage operations that should be given between ploughing and seeding, much will depend on circumstances; but usually three to four should suffice. The requisites that should guide our decisions in the matter can be summarised as follows:—The importance of breaking up the surface crust that forms over tilled soils following on appreciable falls of rain; the urgent need of preventing undesirable weeds from scattering their seed over the fallows; and from the standpoint of the subsequent healthy development of young wheat plants, the necessity to build up progressively an adequate seed-bed, consisting of 1½in. to 2in. of loose soil mulch, resting upon a firm, well-consolidated sub-surface layer. It remains to be added that the tillage of soils that are in dust-dry condition should be avoided as much as possible, and particularly so, if the soils are light in texture. Technical efficiency in the performance of these various operations will frequently depend upon the correct choice of time and way of giving effect to them, and errors of judgment in the matter will usually be reflected in increased costs of production, or reduced mean yields per acre, or in both.

There is one important point which I have hitherto deliberately avoided, and that is the question of depth of ploughing; and if I have done so, it is because I hoped that the subjects upon which we are in moderate agreement would pave the way for a single subject in which we might possibly find ourselves in complete disagreement. I have attended a sufficient number of country Conferences to know that I am addressing an audience of convinced exponents of ultra-shallow ploughing; nor can I altogether blame you for the faith that is in you, although I might at times think that with you the wish is father to the thought. In order to satisfy you that I am not approaching this question in an unreasonable frame of mind, I propose committing myself to a preliminary statement with which we shall all be in agreement. We all know that for every increased inch in the depth of the furrow we have to face a corresponding increase in draught, and consequently to a corresponding increase in costs of tillage; and in the circumstances one cannot imagine any person increasing his depth of ploughing unless he were first satisfied that such increase would presently or subsequently lead to improvement in mean crop yields sufficiently great to make adequate compensation for increase in mean costs of production.

It is generally recognised that the progressive improvement of the natural fertility of arable land was one of the main aims of the art of farming; and that among the factors that affect natural fertility depth of soil occupied an important position. If, on the other hand, we consider that in the majority of instances "Soil" as distinguished from "Sub-soil" can be described as that darkened surface layer with which organic matter has gradually become incorporated, then it would be correct to say that in the majority of instances the depth of the soil would be the depth of the deepest furrow usually adopted by the farmer. It follows, therefore, that if you were to cling unduly to a policy of unchanging shallow ploughing—say 2in. to 3in.—you would be declining to take advantage of one of the simplest methods of progressively improving the natural fertility of your farms. Every additional inch that is won from the subsoil would represent an additional layer of soil 1in. thick to which organic matter would be added; in which Bacterial Life would find more congenial environment; and over which the delicate roots of plant seedlings would roam more freely and to greater advantage; there would be progressive increase in the soil stock of available plant food; and increase in the powers of moisture absorption and moisture retention of the surface soil layers.

I recollect discussing this very same question many years ago with one of the most successful hay growers of my acquaintance—the late Mr. A. G. Both, of Roseworthy; he attributed his success, among other things, to the fact that he made it a practice to break up his fallows on a deeper furrow in alternate years; and this, I feel, is a policy which I can safely recommend to you. I realise, of course, that no man should be asked to break up land beyond the mean depth of penetration of the yearly rainfall; there can be no life activity, no mechanical reactions favourable to plant growth in the absence of adequate soil moisture, nor can you bring about that sub-surface consolidation so essential to young Wheat growth; but I cannot consider land in which the mean penetration of the annual rainfall does not exceed 2in. to 3in. as land that is adapted to ordinary farming operations. Let it go back to bush, and to Sheep and Cattle grazing.

VII. THE "STORY" OF RECENT LOW WHEAT PRICES.

But, if inadequate mean grain yields have been important causal factors of the unprofitableness of recent Wheat Crops, so, too, both directly and indirectly, have been the abnormally low prices of the same seasons. I have said "both directly and indirectly" advisedly, because apart altogether from the "direct" arithmetic result of such prices, their "indirect" but continued depressing influence on the temperaments of much harassed individuals, must also be taken into consideration. I can conceive of nothing more discouraging, more conducive to slackness, or more wasteful of honest, human effort, than the unescapable seasonal routine of land preparation, of putting in and taking off crops by those whose sub-consciousness must tell them that little can come of all this expenditure and effort. Hence, it seems inevitable that a succession of wastefully unprofitable seasons of this character must eventually sap the pride of work of human beings, and to this extent I agree that it can be said quite fairly that abnormally low Wheat prices extending over four consecutive seasons have been contributory factors in the regrettable decline of our recent State Mean Yields of Wheat per acre.

The story of these low prices is more or less known to you; nor do I propose dwelling upon it at any great length. In ultimate analysis it is to the Great War, together with the psychological and economic factors that came in its wake, that we can be said to owe this long period of unprecedently low prices. Within modern pre-war times Europe had always been the greatest Wheat-producing and Wheat-consuming Continent, and since the spread of industrialism, the greatest Wheat-importing Continent of the World. But the intensity of the 1914 War conditions had the effect of progressively depressing Europe's normal rural output, and eventually its pressing food requirements were met by the expansion of rural production in North and South America, and to a less extent in Australia as well. Unfortunately, in the years that immediately followed the Armistice Wheat prices rose to quite abnormal heights, and naturally led to further expansion in the production of extra-European countries; unfortunately, too, when between 1921 and 1924 Wheat prices began to drop to normal, American interests sought to recall the earlier high prices by a process they described as "orderly marketing"; in effect this process meant that the owners of the major portion of the World's exportable Wheat, would ration the depleted European markets, and check the arrival of any Wheat that might tend to reduce prices. Impoverished Europe was at the time still nursing her War Wounds and unable, therefore, effectively to counter this attempt to impose a dear loaf upon her people; hence, in the matter of prices, the American policy of "orderly marketing" may be said to have succeeded up to 1929-30. But as Europe could not afford to buy all the exportable Wheat available, and was, moreover, from year to year expanding her own output, and as no other purchasers were in sight at the time, "orderly marketing" came gradually to mean that whilst a moderate proportion of the season's supply was sold at a high figure, the unsold balance went to swell the carry-over of preceding seasons, until such time as these flouters of the law of Supply and Demand were no longer able to stand the financial strain involved, and prices crashed to undreamt of levels, from which they have not yet recovered.

It is, of course, true that under the influence of World-wide Economic Depression the prices of Wheat, in common with those of other commodities, would have fallen in any case from the abnormal heights of the early post-war years; but in the absence of so-called "orderly marketing" the fall would have been more gradual, nor would it have reached the depths we know of, and recovery would have been more rapid; because if the Law of Supply and Demand had been allowed to operate freely it would have checked the useless seasonal carry-over of unsaleable grain and prevented the expansion of new areas sown to Wheat under the stimulus of artificial high prices; nor, indeed, would European countries have gone to the extreme of encouraging the growth of Wheat on their own lands under what must be considered as wastefully uneconomic conditions.

VIII. PROBABLE WHEAT PRICES OF THE IMMEDIATE FUTURE.

But, whilst it is to be hoped that as a nation we shall endeavour to avoid the mistakes of the past, it is with the present, and the immediate future, that we are in the main concerned. From the latter standpoint, what are the price prospects that the future holds for us? My own impression is that we have at last come to the turning of a long and exceedingly disagreeable lane; it cannot be denied that prices have already improved appreciably since last harvest; and this notwithstanding the fact that Wheat has again become the plaything of gamblers and speculators. There is good reason to believe that whilst 1934 Harvest prices should be higher than those of the immediately preceding Season, the 1935 prices should tend to approach normal, unless, indeed, some new World stupidity should tend to interfere with the normal process of recovery.

In support of this statement it may be pointed out that the World price of Wheat is usually influenced by the following main factors:—

1. The magnitude of the Carry-over of Exportable Wheat (including Wheat afloat) on the 1st of August in any given season. This carry-over has been as follows of recent years:—

	Bushels.
1926-27	249.000,000
1927-28	319,000,000
1928-29	512,000,000
1929-30	502,000,000
1930-31	564,000,000
1931-32	588,000,000
1932-33	683,000,000
1933-34	661,000,000
Means of 1926-34	510,000,000

In these eight successive seasons the only August World carry-over of *Exportable* Wheat that was not appreciably in excess of World requirements was that recorded in 1926-27, namely, 249 million Bushels; but the carry-overs of the seven succeeding seasons were progressively

added to the accumulation of preceding seasons, and reached a climax in 1932-33 with a carry-over of 683 million Bushels. The effect of so huge a carry-over upon the price of Wheat in 1933-34 may be gauged by the following facts:—The estimated 1933-34 import requirements of Europe were assessed at 375 million Bushels, and those of extra-European countries at 150 million Bushels, *i.e.*, total World import requirements for the season of 525 million Bushels only. It follows, therefore, that with an August, 1933, carry-over of 683 million Bushels of *Exportable* Wheat, should the main Wheat-exporting countries—Canada, United States of America, Argentina, and Australia—have had not a surplus bushel to dispose of abroad from their 1933-34 crops, then the carry-over would still have sufficed to supply World 1933-34 import requirements, and to leave a carry-over of 158 million Bushels on August 1st, 1934. It will be realised, therefore, how much 1933-34 prices must have been depressed by the threat of this huge accumulation of Wheat. On the other hand, the slight difference between the 1932-33 carry-over and that of 1933-34, namely, 22 million Bushels only, might seem to justify the belief that the 1933-34 carry-over might exercise an equally sinister influence over 1934-35 Wheat prices; and this, no doubt, would be true but for counter influences operating in the opposite direction, to which reference will be made later on.

The mass effect of these favourable influences can be shown from the September, 1934, calculation of the probable carry-over of Exportable Wheat on August 1st, 1935. The figures upon which this estimate has been built have been supplied by the International Institute of Rome, through the kind offices of the Department of Commerce:—

	Bushels.	Bushels.
World exportable carry over, including Wheat afloat on August 1st, 1934	661,200,000	
1934-35 New Exportable Wheat, including 220,400,000 Bushels estimated for Southern Hemisphere	312,200,000	
		973,400,000
1934-35 Estimated Import requirements of Europe .	440,800,000	
1934-35 Estimated Import requirements of extra-European countries	128,600,000	
		569,400,000
Estimated World carry over of Exportable Wheat on August 1st, 1935		404,000,000

A glance at the immediately preceding statement will show that if the anticipated August, 1935, carry-over, namely, 404 million bushels, should prove approximately correct—and it can be added that the forecasts of the Institute of Rome have hitherto proved accurate—it would be the lowest recorded since 1927-28; it would, too, be sufficiently close to normal to warrant the belief that 1934-35 Wheat prices would be appreciably higher than those of 1933-34.

2. The relative magnitude and quality of the harvests in the Northern Hemisphere, which in August should be in full swing, is another factor influencing mean prices offered for Wheat in any season. Although definite figures on the subject are not yet available for 1934, it is known that both in Europe and in North America, but particularly in the latter Continent, the 1934 harvest returns will be considerably below those of recent years; and it has already been officially announced that U.S.A. would not be an exporter in 1934-35. How great must have been the deficiency in U.S.A. and Canada may be gauged from the figures given

in relation to the calculation of the probable August, 1935, Carry-over of *Exportable* Wheat. It is shown in this statement that the combined *Exportable* surpluses from 1934-35 Harvests of the Northern and Southern Hemispheres would aggregate 312,000,000 Bushels, in which 220,000,000 Bushels had been estimated as the probable contribution of the Southern Hemisphere. This means that 91,800,000 Bushels of new Wheat only was anticipated from U.S.A. and Canada; compare this figure with 584 million Bushels which was the corresponding figure for 1933-34. A drop of 492 millon Bushels in the matter of available new wheat, or 84 per cent., is a factor which is bound eventually to tell in favour of improvement in Wheat prices.

3. The relative magnitude and quality of the Harvests in the Southern Hemisphere will also, in due course, have its influence on the prices of Wheat. Argentina and Australia are the only two countries that count much in this aspect of the question; although at times India has made herself felt.

It is too early as yet to make even a rough guess as to the extent to which the Southern Hemisphere is likely to influence the position in 1934-35. We do know, however, that there will be appreciable reduction in areas sown; probably more than 10 per cent. relatively to 1933-34. It is equally certain, too, that seasonal conditions have not hitherto been as favourable as in 1933-34; and it may be concluded that the 1934-35 exportable surplus of the Southern Hemisphere will probably be less than that of 1933-34; hence, another factor favouring improvement in current Wheat prices.

4. The prospective requirements of importing countries, and particularly of Europe taken as a whole, must exercise an important influence on the trend of future Wheat prices. In a measure this factor is more or less related to, and frequently a direct consequence of the relative magnitude of the Harvests in both Hemispheres. Nevertheless, it calls for special comment, since importing countries themselves, from misadventure or miscalculation, may find themselves with August carry-overs above or below natural requirements, and their prospective imports would be calculated accordingly; again, according to political views in the ascendant at the time, special measures might have been adopted to encourage or to discourage the importation of Wheat.

In this connection it should be noted that several European countries, which hitherto had been looked upon as important importers of Wheat, such as France, Germany, Italy, &c., have within recent years turned towards self-sufficiency in the matter; and so successful have they been that some of them are nursing embarrassing surpluses to-day. Take France, for instance, with a surplus above national requirements of 80 million Bushels, for which the French farmer has been paid at the rate of 8s. 1½d. sterling per Bushel (10s. 2d. Australian currency), but the London value of which is not more than 2s. 6d. per Bushel. Unfortunately, the French Government. in order to encourage the growing of Wheat on the national soil, had not only guaranteed an absurdly high "home" price to local farmers, but in addition had undertaken to pay the difference between the home value and the export value of any Wheat grown in excess of home requirements. It is stated that this rash guarantee is likely to cost the French Government something

like £22,000,000; but the London Corn Trade Association considered that this was an expenditure which the French Government was unlikely to incur.

How long policies of this character are likely to endure it is difficult to say; but it is certain that if 8s. to 12s. per bushel be guaranteed to growers everybody will soon be growing Wheat in their back yards. At such prices, however, reaction is likely to come from the workers who, in industrialised countries, will no longer be able to afford a white loaf, and the economics of the position must in the end kill self-sufficiency in Wheat production for thickly populated countries with high land values. Hence, it can be considered that eventually common sense will overcome the difficulties which the policy of "self-sufficiency" in wheat is imposing upon World Wheat trade to-day.

In the matter of 1934-35 prices it seems probable that European requirements will be in excess of those of the immediately preceding year owing to less favourable Harvests.

5. The relative magnitude of other cereal crops in the Northern Hemisphere, chiefly Rye and Maize, must also be taken into account. The most recent information on the subject tends to show that neither crop is as good as in preceding years.

6. There are finally such minor factors as the slowly increasing consumption of White bread in rice-consuming countries; the gradual supersession of the black loaf by the white loaf in the rye-eating countries of Central and Eastern Europe; the progressive increase in population of white-loaf-eating countries, &c.; all these factors will tell gradually in favour of improvement of wheat prices. But against them, and of corresponding influence in the opposite direction, are the numerous restrictions against the free circulation of Wheat from country to country; the legal compulsory admixture of other ingredients with Wheat Flour, such as Potatoes, &c.; the reduced consumption of Cereal Foods in some countries, notably the United States of America, &c.

Such, then, is the general position to-day, and on the whole it seems to me that the prospects are favourable to improved Wheat prices for 1934-35.

IX. THE WHEAT GROWERS' CLAIM TO PROTECTION AGAINST APPARENTLY UNREMUNERATIVE WORLD WHEAT PRICES.

If in a moment of aberration I should protest that 35s. for a pair of locally made Boots was considerably more than reasonable costs of manufacture and distribution, I should probably be told that costs of manufacture and distribution had nothing to do with retail sales; that prices asked were usually those that average customers were prepared to pay and rivals to respect. On delving further into the matter I should find that the price of 35s. for a locally made pair of Boots would probably be determined as follows:—

The price of a similar pair of Boots in equal quality and value would be worth in London, say, 16s. in English currency, or 20s. in Australian currency; to the latter figure would, however, be added the following interesting items:—

	s.	d.
London value of Boots in Australian currency	20	0
Cases, Packing, Freight, &c.	0	11
Tariff and Primage charges	6	9
Sales Tax	1	4
Port Adelaide charges	0	2
	29	2
Add Retailer's charges	5	10
	35	0

That is why costs of manufacture and distribution count for nothing in the retail price of a locally made article; it is one of the consequences of attempted national "self-sufficiency" and one of the blessings of a "home price," which, however, is the main causal factor of high costs of production in Australia.

If, on the other hand, in order, let us say, to pay for these boots, I go to a miller with a good F.A.Q. sample of Wheat, he would probably offer me 2s. 8d. at the railway siding (September, 1934); but if I should protest that 2s. 8d. was considerably below my costs of production, he would say—like the boot-seller before him—that costs of production had nothing to do with the price paid to farmers for Wheat; that the latter was based upon London parity and determined upon the following lines:—

Let us suppose the value of Wheat in London to have been 27s. per quarter, 3s. 4½d. per Bushel in British currency, or 4s. 2½d. in Australian currency; but, in order to arrive at the price paid to the farmer for Wheat intended for home consumption, the following deductions would have to be made from the London price of Wheat expressed in Australian currency (Note—In a similar calculation relative to Boots the intermediate charges were *added, not deducted,* from the London price):—

	s.	d.	s.	d.
London Value of Wheat in Australian currency			4	2½
Less London charges	0	0¾		
Freight and Insurance	0	9½		
Port Adelaide charges	0	2¾		
Country Agent	0	1½		
Mean Rail Freight	0	4		
			1	6½
Farmers' Price for Wheat at average siding			2	8

Here, then, we have two examples of commodities the local prices of which were to all intents and purposes based upon London parity; in the one case the intermediate charges were added to the London "spot" price—Boots and all our protected industries—and in the other these charges were deducted from the London price—Wheat and our few unprotected industries. To add to the irony of the situation there is another characteristic difference between these two classes of industries, namely, our protected industries, lacking the stimulus of external competition, have been unable to acquire that degree of efficiency that should enable them to compete on even terms on the markets of the world; whereas our unprotected industries, the costs of production of which have been unduly swollen in order to pay the costs of inefficient

secondary industries, have had to carry the burden of producing the greater proportion of our exportable commodities, and to face the rigour of World Prices, not only abroad, but on the Home Market.

Observe that if Wheat were Boots or any other protected industrial commodity, its local consumption price, with London "spot" price at 4s. 2½d. (Australian currency), would not be 2s. 8d. per Bushel as at present, but not less than 5s. 9d. at the average railway siding.

A comparison of mean prices paid for Wheat in New Zealand, a country that does not produce enough Wheat for home consumption, and in South Australia, with a large export surplus, should not be without interest:—

	New Zealand.	South Australia.
	s. d.	s. d.
1924-25	6 7	6 1
1925-26	6 9	6 2¼
1926-27	6 2	5 3½
1927-28	6 4¼	5 5¼
1928-29	6 1½	4 8¾
1929-30	6 3¾	4 4
1930-31	5 10¼	2 3½
1931-32	4 10½	3 2
1932-33	4 4	2 9¾
Means	5 9	4 3

Consider that in 1930-31 the South Australian Farmer did not receive for his Wheat more than the equivalent of 2s. 3½d. per Bushel at outports; in the same year the New Zealand Farmer received the equivalent of 5s. 10¼d. Similarly, during the period of nine years which ended in 1932-33 the South Australian Farmer received for his Wheat the mean equivalent of 4s. 3d. per Bushel at outports, whereas over the same period the New Zealand Farmer received 5s. 9d. Nor has the New Zealand Farmer owed this premium of 1s. 6d. per Bushel to the higher intrinsic value of his Wheat, which on the World's Markets would probobly have brought a lower average price per Bushel than Australian F.A.Q., but to the fact that in New Zealand Wheat production is a relatively unimportant matter, and the industry has therefore been given the advantage of a protected market.

However much we might believe that in a country of vast unoccupied spaces and small scattered population primary production should be the main occupation of its inhabitants and the main concern of its Government; that *everything* should be done to foster its progressive development and to facilitate the access of its surplus products to suitable overseas markets; that *nothing* should be done, either directly or indirectly, that would tend to increase unduly its costs of production and to hamper primary production in its competitive struggles on the markets of the World; that tariffs, in short, should be used exclusively for revenue purposes and not for bolstering up exotic industries that can render but little service to the community, but which inevitably add to the burden of costs of primary production; however much one might believe in all these things, one is bound in the end to recognise

that in a World gone—temporarily one may hope—"self-sufficiency mad," and in a country that has groaned under high tariffs for 34 years, there is very little chance of adequate relief in the near future. And yet we cannot escape growing Wheat though the heavens should fall; and it is therefore satisfactory to know that a Royal Commission is inquiring into the disabilities of Wheatgrowers, and will shortly suggest special measures for their relief. Bounties have been announced in the past towards harvest time, and frequently without adequate consideration; but they may be excused on the grounds that those responsible do not seem to have grasped the fact that mean costs of rural production to-day are altogether out of keeping with current World prices. Hence, it is to be hoped that the Commission will suggest something better than periodical Bounties, something more in the nature of permanent relief and not of gratuity. Personally, I know of nothing more suitable in a country in which everything else is protected than a Home Price for Wheat used for local consumption.

It is, of course, true that the granting of such a price must lead to a rise in the cost of Bread until such time as the overseas parity of Wheat equals the guaranteed home price; and much sentimental talk on the subject has been indulged in, notwithstanding the fact that in Australia the Basic Minimum Wage is made to fluctuate with the rise or fall of prices of necessaries of life, and of these Bread is obviously one. Moreover, many other countries with far more important industrial populations than Australia have not hesitated to make provision for a special national price for Wheat, to which increases in the price of Bread have naturally corresponded. The examples set in this direction by both France and New Zealand have already been indicated; and quite recently the German Minister for Agriculture was reported to have boasted that he had doubled and quadrupled World prices of rural products. It can be pointed out, too, that in 1930-31, at a time when Australian Farmers were realising the equivalent of 2s. 3½d. per bushel at outports, the price of Wheat in Germany rose to 26 Reich marks per metric quintal, which corresponds to 14s. 2d. per Bushel in Australian currency. Similarly, in 1931 the price of Wheat in Spain was made to rise to the equivalent of 10s. per Bushel, Australian currency. Again in 1931 tariff duties on Wheat imported into Italy rose to 8s. 10¾d. (Australian currency) per Bushel, and on Wheaten Flour to £22 4s. 1d. (Australian currency) per short ton; whilst in 1933, in spite of a record harvest in the immediately preceding season, No. 2 Manitoba wheat was being quoted on the Milan market at 14s. 9d. (Australian currency) per Bushel, and ordinary Italian soft wheat at 10s. 7¼d. (Australian currency). In Switzerland of recent years the Government has guaranteed to farmers 17s. 2d. to 20s. 4d. per Bushel (Australian currency) on their farms. In the United States a special home price has been paid to farmers from the proceeds of a processing tax. And, finally, Great Britain—the protagonist of Free Trade since the Repeal of the Corn Laws in 1847—has guaranteed to her farmers 45s. per quarter, which in Australian currency represents about 7s. per bushel.

These examples should suffice to show that apparently Australia, although raising the cost of most other commodities by means of tariffs that are all but prohibitive, is among the few that hesitate to pay for

Wheat a price that will yield something more than mean inclusive costs of production. One can imagine that the Royal Commission has had this question under consideration; and in the circumstances an examination into what a home price for Wheat can do for farmers is advisable.

In the first place we should note that the home price cannot very well be less than 5s. per Bushel, which, after all, approximately represents the mean price paid for Wheat for the past seventy years (*vide* Table I.), and upon which the average price for Bread in Australia must have been built up. What would 5s. per Bushel paid for Wheat used in Australia for home consumption represent to the farmer, if we assume the balance of Marketable Wheat to realise no more than London parity?

During the five-year period closing in 1932 the mean quantity of Wheat exported annually from Australia was approximately 110 million Bushels, and the mean quantity gristed for human consumption about 32 million Bushels. If in this connection we assume the mean price of export wheat to be 3s. per Bushel and the "home" price 5s., then the average price collected by every Wheatgrower in the Commonwealth should be about 3s. 5½d. at outports; but if the "home" price were raised to 6s. per Bushel wheatgrowers should realise 3s. 8¼d. at outports. In contrast with the prices quoted for other countries, the suggested Australian prices do not appear particularly attractive; they should, however, permit us to live, which is perhaps all that we can expect at the present time.

There are good reasons for believing that the prices quoted above, namely, 5s. and 6s. respectively for Wheat to be gristed for home consumption, should not lead to Bread prices exceeding 5d. to 5½d. per 2lb. Loaf.

X. CONCLUDING REMARKS.

It is much to be feared that I have allowed this address to run away with me; and that it can now be said to have roamed from Dan to Beersheeba, having touched upon many topics, and having done justice to none. I realise, too, that you were already familiar with much that I have had to say, even with the least palatable portions of the address. I would like now to add that throughout the preparation of this address, I have tried to keep steadily before me what seemed to be the best interests of Australia and its farmers. Australia, in my opinion, cannot do without Wheat; and, notwithstanding recent talk to the contrary, we want not less, but more Wheat; but Australia should not expect Wheat to be grown under conditions that are unfair to those responsible for its growth. I recognise that latterly farmers have performed their tasks in times of considerable difficulty; that the majority of them and their dependants have had to face four unspeakable years; and if some should have done justice neither to themselves nor to the State, it can be said in extenuation that the progressive dwindling of hard-earned assets, the increasing pressure of intolerable debt, the association of low prices and unfavourable seasons, the utter futility of routine tasks that led nowhere, are so many factors that must eventually destroy the moral fibre of the stoutest-hearted; and I rejoice to think that definite signs of improvement are already in sight, and in the coming good days I trust that all will benefit.

PASTURE SPECIES FOR THE NON-IRRIGATED GRASSLANDS OF SOUTH AUSTRALIA.

[Paper read by R. C. SCOTT, R.D.A. (Supervisor of Experimental Work), at the 45th Congress of the Agricultural Bureau.]

Cereal cropping is the most important division in the agricultural practice of South Australia, but at the same time grassland products also occupy a prominent position.

There are large areas of relatively high rainfall country which are not well suited to the production of cereals, whilst in a number of districts the regular planting of wheat is simply being adopted as an economic means of cleaning and developing the land. Frequent wheatgrowing in these localities is only a temporary measure, and as soon as the scrub conditions permit or the provision of water, fences, &c., allow for the carrying of livestock so will wheat be relatively widely spaced in the cropping rotation planned.

Therefore, the future advancement of the State lies more and more in the direction of livestock husbandry, and this implies that increased attention must be given to pastures, grassland management, and the problems associated with this branch of agriculture.

However, it does not necessarily mean that there will be any reduction in the quantity of wheat produced in South Australia but, on the other hand, whilst the area planted may be less the acre yield should be greater, since it is generally admitted that the building up of the organic content of many soils, and of the Mallee soils in particular, is essential for maximum grain returns, and in this connection the development of satisfactory pastures will fit in well with the optimum cropping rotation for the district.

IMPORTANCE OF GRASS PRODUCTS.

Considerable development in the grasslands may therefore be anticipated in the future, but even to-day pastures contribute very largely toward the monetary wealth of the State. Examination of the statistics dealing with overseas exports shows that for the five-year period 1928-1932 produce to the value of £13,922,410 has been shipped annually. Of this amount £4,339,984 or 34 per cent. represents wheat and cereal products, £3,668,700 or 26 per cent. grassland products, £3,515,073, or 25 per cent. mining products, and £1,998,653 or 15 per cent. vineyard, orchard, and other products.

However, whilst South Australia is credited with exporting mining products to the above value the great bulk of the material included under this section is obtained from Broken Hill, and is not directly produced in this State. Therefore, if only South Australian products are taken into consideration about 46 per cent. of the total value of our overseas exports is derived from wheat, and approximately 35 per cent. from the grasslands.

From the foregoing particulars it will be realised that the grazing areas are of great importance to South Australia, and any experimental work indicating lines of improvement and profitable extension will result in appreciably increasing the general wealth of the community.

RAINFALL BELTS IN SOUTH AUSTRALIA.

Over large areas of South Australia the mean rainfall recorded is the limiting factor so far as the establishing of pastures is concerned, and in the table following, the areas receiving varying amounts of rain are shown.

Average Annual Rainfall.	Square Miles.
Over 40in.	96
30-40in.	1,036
25-30in.	3,258
20-25in.	8,620
15-20in.	19,940
10-15in.	36,460
Under 10in.	310,660
Total area	380,070

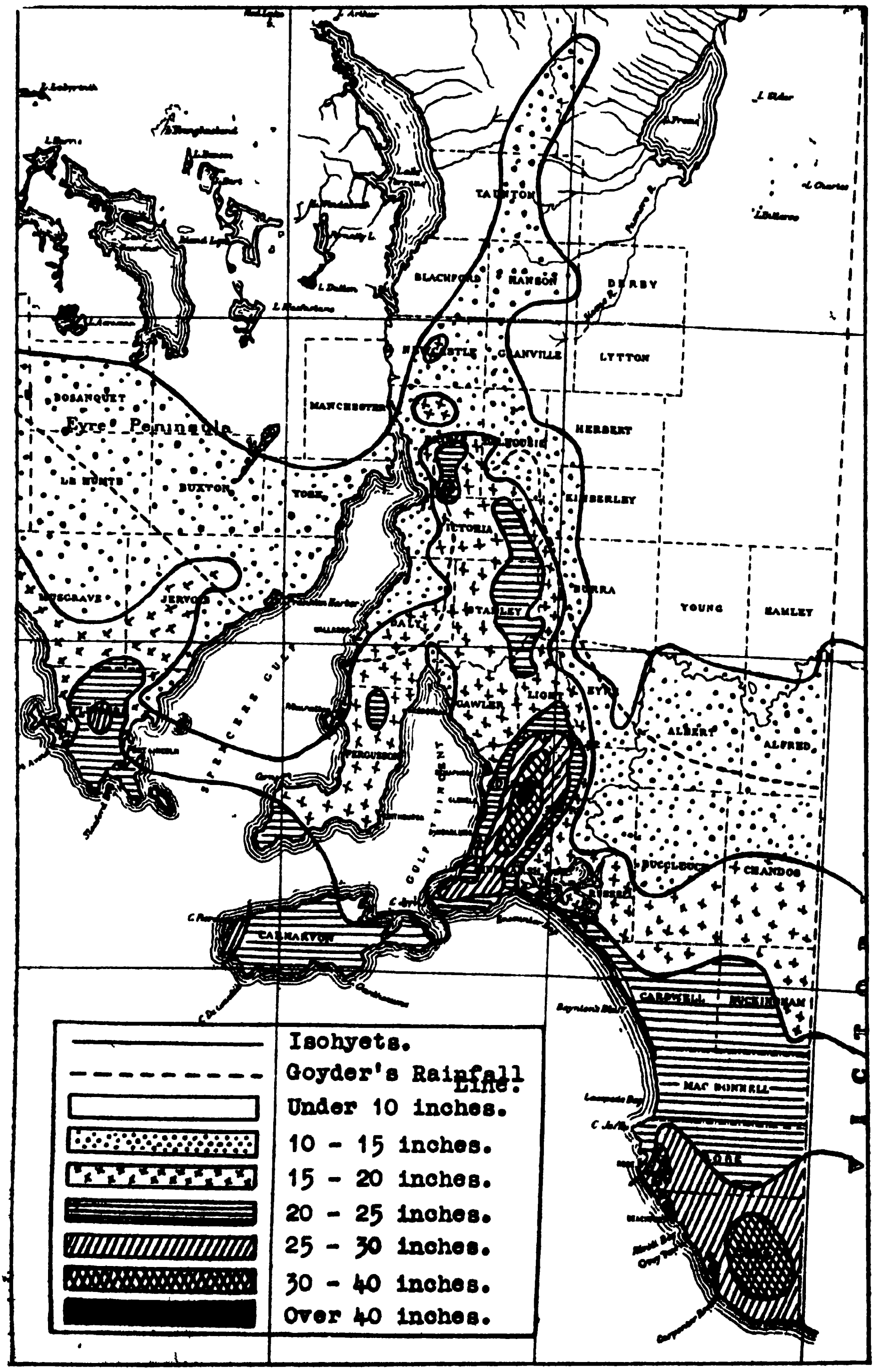
It will be noted that in this State 347,120 square miles of land receive less than 15in. of rain annually. This represents approximately 91 per cent. of the total, leaving only about 9 per cent. with which from a pasture point of view we are mainly concerned. On the other hand, however, 9 per cent. of the total area of South Australia equals nearly 22 million acres, and therefore there is considerable scope for pasture improvement. Included in this area of 22 million acres is wheat-growing land, vineyards, orchards, &c., with the result that only about one-third can be regarded as essentially grassland country. Over the balance pastures will be associated with the cultivation of other crops, and consequently be of a more or less temporary nature. The accompanying map on page — will show where these varying rainfall areas are situated.

The area of maximum rainfall is situated within the vicinity of Mount Lofty, reaching as high as 47.08in. at Stirling West, whilst over the adjoining areas of the Mount Lofty Ranges and the land surrounding Mount Gambier and Glencoe in the South-East the mean fall exceeds 30in. per annum. The 25 to 30in. belt covers the greater portion of the lower South-East, together with the boundaries of the Adelaide Hills and isolated spots at Green Patch on Eyre's Peninsula and Mount Remarkable in the North. The 20-25in. area includes practically all of the upper South-East, the lower levels of the Adelaide Hills, Kangaroo Island, and Southern Eyre's Peninsula, whilst as we get further inland, and therefore away from the westerly winds which strike the southern shores, so does the annual fall become less and less, until in the far-distant portions of the State a mean fall of less than 10in. of rain per annum is recorded.

THE POSITION OF NATIVE PASTURE PLANTS.

Since these are the natural conditions of the country it may be asked are there not native pasture species which could be isolated and utilised to advantage? It would appear reasonable to expect that plants which had developed and flourished under these conditions of soil and climate would respond to grassland management. However, on the whole, that does not appear to be the case, mainly because of the vastly different grazing conditions occurring at the present time comparatively with those obtaining prior to this land being inhabited by white men. In those days Australian herbivorous animals were neither particularly numerous nor very heavy grazers, with the result that the native vegetation was rarely severely checked. However, with the introduction of sheep, cattle, &c., and particularly the infestation of the country with hard-grazing vermin such as rabbits, the plant life was subjected to intense depasturing conditions for which it was not specially fitted. The result has been that a number of useful indigenous varieties have practically disappeared, whilst so far as cultivated pastures are concerned very few of the remainder exhibit marked promise. It may be that in the course of time special strains of Wallaby Grass, Saltbush, &c., will be isolated which will fill the requirements of certain localities, but it would appear that in the main we must look to successful introductions together with selections of desirable types from within these introductions for improvement in the pasture species available for planting on the grasslands of South Australia. Such being the case it is

necessary to examine the climatic conditions of the State and determine what types are likely to be of value to us, that is to say, can the best varieties of the chief grass-producing countries of the world be utilised, or will we be largely dependent upon our own efforts for building up satisfactory strains of pasture?



METEOROLOGICAL CONDITIONS.

Tables showing the mean monthly rainfall and temperature at various places in South Australia comparatively with those obtained at various stations in England and New Zealand.

The South Australian stations included in the foregoing table illustrate the climatological conditions in different portions of the State.

The rainfall in England also varies within wide limits, that for much of the eastern coast beng less than 25in. per annum, whilst parts of the western areas average almost 100in.

Kent is situated in the south-eastern corner, and as this is a county with a fairly light rainfall the details recorded show the conditions for an area which in England is regarded as relatively dry.

On the other hand, the rainfall in Wales varies between 26in. at Flint to 97in. at Merioneth, but the two stations given represent a fair average for that municipality, and the conditions may be regarded as more or less typical both in respect to annual rainfall and mean temperature. They may also be accepted as being very similar to those obtaining in the chief grassland areas of England. In the same way the data recorded for Wellington and Auckland represent average conditions for the good pasture areas of New Zealand.

Examination of the rainfall figures indicates that the monthly falls at the stations shown for England and New Zealand are much more regular than those received at the South Australian stations. For example, if three centres with approximately equal annual rainfall, namely, Stirling West, 47.08in.; Wellington (N.Z.), 48.11in.; and Brecknock (Wales), 48.03in. are compared, it will be noted that at the first-named station the extremes are 1.22in. for Februray, and 8.06in. for June; for Wellington, 3.69in. for January, and 5.55in. for July; and for Brecknock 2.65in. in May, and 5.13in. in September.

Therefore, even in the highest rainfall district in South Australia pastures are subjected to monthly periods of much lower rainfall conditions than those in the average grassland areas of England and New Zealand. But more than this, in South Australia these droughty conditions extend over several months of the year, and at Stirling West the six-monthly period of May to October only shows a mean fall of 12.03in. or 26 per cent. of the total, whereas at Wellington for the same period 20.32in. is recorded, or 42 per cent. of the mean annual fall, whilst corresponding figures for Brecknock are 19.07in. and 40 per cent. respectively.

In the matter of mean temperatures the differences between the readings of the wetter districts of South Australia and those obtained at the New Zealand stations are not appreciable, but at the same time the periods of low temperature and heavy rainfall, or high temperature with low rainfall, occur to a much greater degree in this State than in New Zealand.

So far as England is concerned South Australia is considerably warmer, whilst within the State the mean temperature increases as the annual rainfall becomes less or according to the distance inland that the area is situated.

EFFECT OF CLIMATE ON PLANTS.

From the preceding discussion it is evident that South Australia must be included in the group of countries which enjoy what is known as a "Mediterranean type" of climate, and as these countries have not had extensive experience in the development of valuable pasture species such work in South Australia is made correspondingly more difficult.

With a "Mediterranean type" climate, that is to say, where the period of winter rainfall and low temperatures alternates with summer drought and high temperatures, perennial pasture plants must be able to exist for a considerable length of time during which evaporation will be very great and the rainfall almost negligible. On the other hand, in the chief pasture lands of Great Britain and New Zealand the rainfall is high enough and well enough distributed throughout the year to produce abundant crops of grass, whilst moreover such production is assisted by the mildness of the climate and humidity of the atmosphere.

The more important native grasses of Australia are perennials, but the introduction of fodders with improved grazing capacities means that such plants expose increased leaf growth to evaporation, and therefore lose a greater supply of moisture. The consequence is that unless the species or strain possesses a particularly extensive root system and drought-resisting habits it rapidly succumbs to the conditions.

Whilst there are certainly some areas in South Australia where high rainfall, coupled with location and moisture supplies, soil fertility, &c., render the conditions favourable for the planting of the chief pasture varieties of the world, yet on the whole these areas are relatively small, and it would appear that the development of special types whether they be perennials or annuals is necessary in the same way as plant breeders have had to evolve cereal varieties able to meet the varying soil and climatic conditions of Australia. This fact has been realised for a considerable time, and throughout the Commonwealth much work has already been done in the introduction and testing of both perennial and free seeding annual pasture plants.

There is another aspect of pasture improvement which of late years has received appreciable attention, and that is the selection and development of pasture strains. As a rule within each pasture species there exists a considerable variation in type, and it is possible that amongst these variations there may be some which are specially suited to particular soil and climatic conditions, yield a greater quantity of leaf, are more persistent, possess superior re-seeding habits or other desirable characters, thus, from a pasture point of view, making such strains superior to the other types included in the species.

It is the work of the agrostologist and experimentalist to isolate these strains, test them out in various localities, and ascertain their value for special conditions.

CHOICE OF PASTURE SPECIES AND STRAINS.

In connection with the question of planting pasture species it is necessary to consider whether it is possible to secure varieties which given normal climatic conditions and efficient management will economically supply a greater quantity of fodder than the spontaneous herbage which naturally springs up.

However, so far as the latter is concerned, it should be remembered that it includes many varieties which have been accidentally introduced from countries possessing somewhat similar climatic conditions. Weeds imported in this way which are widespread throughout the State are Burr Medic (or Burr Clover as it is frequently termed), Barley Grass, Geranium, Cat's Ear, and many others of lesser grazing value. Consequently, any new variety must be tested to determine its relative importance for the widely differing soil and climatic conditions which exist in South Australia.

Much has been done in the past, and of recent years upwards of 60 trials including pasture varieties have been conducted in various districts extending from Upper Eyre's Peninsula to the Lower South-East. In these tests many varieties have been shown to be quite unsuitable, some must be regarded as unproven, whilst a few have definitely established themselves as valuable pasture types for different conditions in the State. It is with this latter group that the practical man is mainly concerned, and therefore it is only proposed to discuss those varieties which have been definitely proved to have value and can be confidently recommended for planting. There are a number of others which are still in the experimental stage, whilst work in the way of introducing and the testing of strains is still in progress.

SUBTERRANEAN CLOVER (*Trifolioum subterraneum*).

This is far and away the best clover for general planting in South Australia. In fact, because of its ability to provide an abundance of fodder and at the same time act as a soil renovator it must be regarded as the most important

pasture plant in this State. Much poor land has been built up by the encouragement of heavy crops of Subterranean Clover until in the course of time the soil has become so improved in fertility that the introduction of other grasses to make a better pasture mixture is rendered possible. The foregoing statements could only be submitted if the characteristics of Subterranean Clover fitted in well with the rainfall and climatic conditions which obtain over large areas of the State. This is the case, as being an annual it does not have to struggle for existence during the period of high temperatures and low rainfall, but given efficient management, and when planted in favourable districts sets its seed in early summer, thus making provision for carrying on in the following year. These seeds are buried underground, and therefore the plant is practically permanent in nature. Further, the grain is large in size allowing for relatively strong early growth after germination in the following autumn.

One of the chief advantages of this clover is the fact that it can be economically established—a most important point in the development of new country and relatively low yielding pasture areas. The soil preparation does not necessarily have to be complete, whilst it will withstand competition, and in a number of cases has been successfully seeded in conjunction with another crop. Subterranean Clover will naturally respond to good soil tillage, but provided that the seed is covered by some means or other good stands have been established with comparatively little soil preparation.

So far as soils are concerned Subterranean Clover thrives in practically all classes, the only exception in the series of experimental plots being at Hatherleigh in the South-East where the plants failed to develop on heavy black soil which contained an appreciable amount of lime. Other landowners have experienced similar results in this class of country, but as clovers such as Strawberry respond to these conditions the area apparently unsuitable for Subterranean Clover is not particularly important.

The credit of developing and demonstrating the value of this clover, which occupies such an important position in the pasture world of the Commonwealth, is due to the late Mr. A. W. Howard, of Mount Barker. Whilst it is regarded as more or less a weed in Southern Europe, where it originated, Mr. Howard took it in hand some 30 years ago, and to-day it may be classed as the most important fodder plant in this State, if not in Australia.

The strain built up by Mr. Howard and generally planted throughout the Adelaide Hills and the South-Eastern areas is a succulent, leafy, high fodder-producing type, which requires mild and moist early summer conditions for full development of its seed. Consequently, it is not persistent in districts where dry weather and high temperatures are regularly experienced in early summer. Under such conditions the plants fail to set seed and quickly disappear. As a result the annual rainfall limit for this variety is 22in., although where the locality enjoys cool weather during November and early December this amount may be reduced to approximately 20in. per annum.

However, of recent years other strains possessing earlier ripening characteristics have been developed, and to-day seed of a variety known as Dwalganup Subterranean Clover has been placed on the market. This strain originated in Western Australia. Seed has been imported to this State and planted at a number of centres. From the results obtained it appears likely to prove valuable in districts receiving as little as 16in. of rain annually. On sandy soil at Narrung, in the Lakes district, where the rainfall recorded since the crop has been planted is less than 16in. per annum a really good mat of fodder has been secured. It is now three years since the plot was seeded, and plants are appearing in various places over the remainder of the field where the grain has been carried by grazing animals.

Satisfactory results have also been obtained at Saddleworth, Eudunda, Keith, and other places where plots have been established, and it is therefore probable that this clover will occupy a definite place in the 16in. to 22in. rainfall areas of the State.

In addition to the strains of Subterranean Clover already on the market several others have been selected by different plant breeders, and at Kybybolite Experimental Farm seven strains in all are being seeded in small plots for comparative purposes.

However, provided that the climatic conditions will permit of the planting of the Mount Barker strain there is no reason for departing from this type. Lack of leaf development proportionately to the amount of stem appears to be a characteristic associated with early maturity of Subterranean Clover, and therefore the later ripening strain is definitely superior from a fodder point of view.

Subterranean Clover is therefore recommended for general planting in all the wetter pasture areas of the State, and the Dwalganup strain for other districts in which the rainfall is not less than 16in. to 17in. per annum.

However, in this connection there is one point which must be kept prominently in mind, namely, that full pasture returns cannot be anticipated unless adequate phosphatic manurial dressings are applied to the soil.

A promising Wimmera Rye Grass Selection.

WIMMERA RYE GRASS (*Lolium subulatum*).

Both Subterranean Clover and Wimmera Rye Grass are annuals, and are regarded as the most valuable pasture plants for average grassland conditions in South Australia.

In neither case were they considered of particular importance in their country of origin, and it remained for Australian workers to demonstrate their value for local conditions. It is recorded by Mullett (H. A. Mullett, *Journal of Agriculture*, Victoria, 1919) that the seed of the grass which is now known as Wimmera Rye Grass was imported from Europe by Mr. McNicholl, a Wimmera farmer, toward the end of last century. Apparently it was purchased as Italian Rye Grass, as it was known by that name for many years. On planting on Mr. McNicholl's farm the seeds made strong growth, and the plants were ultimately harvested. The grain so obtained was distributed throughout the district, and thus the grass became firmly established.

However, beyond spreading locally not much headway was made until about 1919, when the variety was definitely identified and given the name of Wimmera Rye Grass. Harvesting of seed became general, and it was distributed throughout Victoria and the other States. The Wimmera farmers had long recognised its grazing value, and when introduced into other districts its importance was quickly realised.

The outstanding features of the grass are hardiness, persistency, and palatability. It will thrive in practically all soils, and good stands have been established on poor, shotty, ironstone country, light sandy soil, and extending through the different classes to the rich volcanic soil in the vicinity of Mount Gambier.

In addition to the main pasture areas, Wimmera Rye Grass can be grown in all districts in which wheat is successfully cultivated, and possesses the advantage of being established at very little expense. The seed can be drilled in at the same time as the wheat, when the only additional cost would be approximately 1s. per acre for 2lbs. of Wimmera Rye Grass.

The original strain of Wimmera Rye Grass collected in the Appila district from which the selection in the preceding photo. was made.

On the pasture areas planting may be relatively rough, but in any case every effort should be made to bury the seed. Satisfactory grazing of this grass has been secured in districts with as low as 12in. of rain per annum, whilst at the same time it responds to wetter conditions.

Wimmera Rye Grass is most persistent in its efforts to produce seed, and so carry on in the following year. Except if very heavily overgrazed late in the growing season or inefficiently managed even very small plants will form seed heads close to the ground and produce grain.

As a rule it is eaten readily by stock when in either a green or dry state, but in this connection the variety should not be confused with Hard or Rigid Rye Grass which is common in some districts and of very little grazing value.

Considerable variation of type exists in Wimmera Rye Grass, some plants being much more leafy than others, and consequently of superior fodder value. Others possess heavy fibrous stems and a minimum amount of leaf, thus rendering them undesirable. There is therefore work for the plant breeder to do with this fodder, and at the present time that marketed as the McDougall strain is fairly satisfactory so far as good type plants are concerned. The Department has tackled the question of building up a superior and uniform Wimmera Rye Grass selection.

In 1932 individual good-type plants were collected from various districts, and the seed from these sown separately in the Pasture Strain Experimental Plots at Kybybolite. Throughout the series quite a variation in type and rate of maturity appeared, and from these variations a further selection was made. The results secured this season are very encouraging, and there is a possibility that one or two strains will ultimately prove of distinct value.

It is with the utmost confidence that Wimmera Rye Grass can be recommended for general planting throughout South Australia. In fact, with but rare exceptions, seed of this variety should be included in every pasture mixture sown. In this way the provision of a grass in the fodder crop is insured notwithstanding the character of the summer weather experienced.

PERENNIAL RYE GRASS (*Lolium perenne*).

The results obtained from the various plots have indicated that high rainfall, favoured situations, and good soil fertility are necessary for this fodder to be truly persistent. Unless such conditions exist the stand tends to rapidly thin out, and even if these natural advantages are available it is essential that seed possessing truly perennial habits should be planted. In some plots where uncertified seed was utilised the stand practically disappeared in the course of three years. This was because the strain was of the short-lived type, and unless it is certified the buyer is always liable to be supplied with poor seed. Therefore, although guaranteed seed may be a higher price per bushel it is much more economic than any other unless the type of plant in the crop from which the seed is harvested is known to the purchaser.

The best crops of Perennial Rye Grass have been obtained on the rich, dark-coloured pockets of soil in the Adelaide Hills and the black lands of the South-East. Where the soil and climatic conditions are favourable this grass possesses distinct advantages. Being a perennial it makes rapid growth in the early autumn, whilst it provides green picking throughout the summer should the rainfall conditions permit. Consequently, it is a very valuable pasture plant in the chief grasslands of the world, and is the most important grass in England and New Zealand, but in South Australia the areas favourable for its cultivation are relatively limited. However, it is possible that in the course of time some strain may be developed which is able to withstand severer weather conditions than the type now regularly planted. For example, there are small areas of Perennial Rye Grass situated in various places in the Adelaide Hills which have been established for many years, and which are capable of withstanding the periodic summer droughts experienced. It is possible that in this way regional strains of Perennial Rye Grass have developed which are specially suited to the local climate, and if seed were available the area over which the variety could be successfully planted would be considerably increased.

In order to provide information on this question seed has been collected from various sources and grown in comparison with the best New Zealand, Victorian, and English strains. Last year 14 strains of South Australian origin were selected for further observation, and in the course of time it is hoped to isolate a productive and persistent type which will prove satisfactory for planting on the better-class pasture land of the State. However, to-day the planting of Perennial Rye Grass can only be recommended under the most favourable conditions offering in South Australia, and if any doubt exists as to the suitability of the locality Wimmera Rye Grass should be substituted or in any case constitute portion of the grass seed mixture to be planted.

PHALARIS TUBEROSA.

Phalaris tuberosa has proved the most drought resistant of the perennial grasses included in the trials. It has survived extremely dry and hot summer conditions in many districts, and although exhibiting very limited above-ground growth at the end of summer, the plants have invariably made rapid development following

the autumn rains and provided a bulk of early feed. This variety of grass, therefore, has distinct possibilities, but there is one important feature in connection with its cultivation which must be emphasised, namely, that the young plants are very susceptible to competition in the first few weeks of their existence. Consequently, proper soil preparation is absolutely essential for a good stand. Weeds or other strong-growing pasture varieties are likely to crowd out the weakly *Phalaris tuberosa* plants, but on the other hand as soon as the root system of these plants is developed they become markedly resistant to such competition.

The best results have been obtained by sowing the *Phalaris* seed alone on well-prepared land, and in the following year adding Subterranean Clover to make a satisfactory pasture mixture. In some cases where the land has previously carried good Subterranean Clover crops sufficient seed remains despite the preparatory cultivation to provide the clover mixture in the second year, but the important point is to endeavour to give the *Phalaris tuberosa* plants every chance in the first month or so after germination.

The 17in. rainfall belt appears to be the limit for moisture, whilst it prefers heavier and more fertile soils to those of a sandier and lighter nature. Owing to the manner in which the crown expands the plant tends to crowd out other weeds and provided that precautions are taken in insuring favourable seeding conditions the cultivation of *Phalaris tuberosa* can be recommended for many areas in South Australia. When once established a stand including this pasture should be regarded as practically permanent, and therefore it is not suitable for planting in a short-term rotation on a wheatgrowing farm. On the other hand, in some of the wheatgrowing areas its drought-resistant qualities render *Phalaris tuberosa* useful for seeding in the grazing fields.

LUCERNE (*Medicago saliva*).

So far as Lucerne is concerned, in this report it is regarded as a purely grazing crop. It is a fodder which has given really good results in many districts whilst there is still room for expansion over much wider areas in South Australia. Its wonderful root system renders Lucerne extremely drought-resistant, and some thousands of acres have been successfully seeded in the Mallee areas of the State where the annual rainfall is approximately 15in. per annum.

Another advantage for such conditions is the fact that it can be readily seeded with the wheat crop and dressings as low as 2lbs. to 3lbs. of seed per acre have yielded satisfactory grazing. However, as a rule better results have been secured where Lucerne has been sown alone, although in land which tends to drift a cover crop is necessary.

Lucerne is one of the best pasture plants for the wheatgrowing areas of South Australia, whilst it is the chief pasture variety for the sandy land of the Lakes District. It is a crop demanding certain requirements of soil and drainage, with the result that it cannot be generally grown throughout the Adelaide Hills and South-East. Lucerne can only make satisfactory growth on land which is well drained and contains ample supplies of lime. Therefore, these requirements must be kept in mind when planting is being considered, and soils which become saturated for relatively long periods or overlie an impervious raw clay subsoil should not be seeded with Lucerne.

WHITE CLOVER (*Trifolium repens*).

So far as the soils and climate of South Australia are concerned White Clover may be placed in the same category as Perennial Rye Grass. Where conditions permit of its successful cultivation White Clover makes an excellent perennial pasture plant, but unless the prospects are favourable for satisfactory growth it is better to sow Subterranean Clover in preference to this variety. Another factor militating against White Clover is the prevalence of lucerne flea in the moister

localities, as these pests attack the smooth-leaved legumes much more readily than those with hairy leaves, and consequently tend to destroy young White Clover plants. There are several strains of White Clover on the market, the best type appearing to be the New Zealand Certified, but except for limited areas and irrigated lands the seeding of White Clover cannot be recommended in South Australia.

OTHER VARIETIES AND CONCLUSION.

Among the other pasture plants which under special circumstances have yielded satisfactory grazing are Cocksfoot, Strawberry Clover, Clustered Clover, Primrose, Wallaby Grass, King Island Melilot, Creeping Saltbush, &c. However, from the point of view of the grasslands of the State as a whole, none of these is very important.

Consequently, when it is proposed to sow down a pasture field the varieties which have been discussed should be the first considered, since experience has shown that they will respond to the conditions stated. From time to time new fodder varieties are widely advertised, and their valuable qualities prominently set forth, but until their importance under local conditions has been fully demonstrated by comparative trials, purchase of seed or plants for other than a small experimental plot is not recommended.

It is unwise to depart from the proved types, and prospective planters of pastures in this State should rely upon the tested varieties, particularly Subterranean Clover and Wimmera Rye Grass, which have shown to advantage in numerous trials extending throughout many districts in South Australia, and leave the search for superior types to the Commonwealth and State officers directly associated with pasture improvement experiments.

ANNUAL REPORT ON PASTURE WORK, KYBYBOLITE, 1933-34.

[By L. J. Cook, R.D.A., Manager

(*Continued from page* 596.)

SOWN PASTURES—SUBTERRANEAN CLOVER AND WIMMERA RYE GRASS.

The 15 plots of this pasture mixture established during 1924 are being maintained and fully grazed each season. This year they were again grazed in rotation, using 245 ewes including 52 aged half-breds, 62 Comebacks (1929 drop), 50 Comebacks (1930 drop), 48 Comebacks (1931 drop), and 33 Comebacks (1932 drop). They were proportionately divided into four flocks on the 65 acres of manured plots, and grazing has been continuous on the plots for the whole season 1933-34.

Table 7 shows the fertiliser given to various plots with the rate and time of application, and Table 8 shows the grazing results for the past nine years.

These results show that Subterranean clover pasture that has been receiving continued applications of phosphatic fertiliser is increasing its carrying capacity annually. For the past seven seasons the average number of sheep carried over all the plots has shown a steady increase from 2.88 per acre in 1927 to 4.11 in 1933, and the average for nine years has been 3.38 per acre. This latter figure is one sheep better than the average carrying capacity of 2.39 sheep per acre, secured from well fertilised natural pasture previously discussed.

Considering the individual plots, No. 4, dressed with 90lbs. 45 per cent. superphosphate annually, has had a very productive season, carrying approximately 6½ sheep per acre for the season, and is the highest return from any plot during the nine-year period. Plot No. 5, dressed with 180lbs. 45 per cent. superphosphate annually, also exceeded six sheep per acre for this season, and No. 7, dressed with lime and superphosphate carried 5.84 sheep, which is also the greatest return received from this plot. Twelve of the 15 plots during this season exceeded their average carrying capacity. The three plots that failed to do so were No. 9 (no manure plot), No. 12 (dressed only with potash), and No. 8 (dressed with Ephos phosphate nine years ago).

For the nine years Plot No. 7 (lime and superphosphate) has been the most productive with 4.53 sheep per acre per annum, and No. 5 (heaviest dressed superphosphate plot) is second in productivity with 4.37 sheep,

closely followed by No. 4 (90lbs. superphosphate) with 4.27 sheep. Plots No. 15 (1cwt. superphosphate) and No. 3 (gypsum and superphosphate) have also exceeded four sheep per acre per annum.

For the immediate past six years, however, Plot No. 5 (180lbs. superphosphate) has yielded greatest return with 5.17 sheep per acre per annum, very closely followed by No. 7 (lime and superphosphate) with 5.12 sheep. For the same period No. 4 (90lbs. superphosphate) has carried 4.76, No. 3 (gypsum and superphosphate) 4.73, No. 15 (1cwt. superphosphate) 4.23, and No. 8 (Ephos phosphate) 4.11 sheep.

As a comparison of the quantity of superphosphate test Table 9 shows the results from 180, 90, and 45lbs. dressings compared with no manure:—

These results are the average annual returns over six consecutive seasons, and indicate the value to be obtained from the use of superphosphate on a sown pasture of Subterranean clover and Wimmera Rye grass, combined with systematic rotational grazing. For this grazing the fertilised plots have been fed off monthly in rotation with approximately 16 sheep per acre, whilst the unfertilised plot was grazed monthly with approximately three sheep per acre. The table shows that when sheep are valued at 15s. each per annum the increased return per acre per annum due to the fertiliser has been 51s. 7d. from the 180lbs. dressing, 49s. 10d. from the 90lbs. dressing, and only 27s. 9d. from the 45lbs. application. It appears that the 90lbs. annual application is very suitable and economical under local conditions.

Referring further to Table 8, the averages for the nine seasons show clearly that lime and superphosphate are the most productive of the fertilisers tried. The two combined have given the greatest yield, whilst superphosphate on its own has yielded almost as well in quantity of feed. Lime has an advantage, however, in producing quicker early feed, and more during the colder months of the year.

Summarily the average results of the principal plots for the past six years are compared in Table 10 in order of productivity and value.

With reference to the variety of growths now appearing on these plots monthly estimations were taken throughout the growing period of the season by reading six indiscriminate quadrat sections on each plot. The following table shows the average percentage of annual grasses, Subterranean clover, Cape weed, thistles, &c., on the various series of fertilised plots taken during the seven months of growing pasture.

TABLE 11.—*Botanical Analysis of Clover Pasture Plots, Kybybolite,* 1933.

Bare Space	1·46	0·68	0·36	0·27	1·10	3·67	0·90	4·41

In making the estimation of pasture plants no attempt was made to separate the various species of grasses. The grasses consisted wholly of annual types, principally Barley grass, with some Wimmera Rye, Silver, and Sterile Brome grasses. Wimmera Rye was not much in evidence, providing not more than 5 per cent. of the pasture on the best plots.

An interesting factor shown by the above table is the variation of amount of grass to clover in the different manurings. The percentage

of grass is highest on the lime and superphosphate plot with 60.7 per cent., and next highest on gypsum and superphosphate plot (50.9 per cent.). The same pasture fertilised with superphosphate only has yielded 43.1 per cent. of grass, and significantly the plot with the heaviest dressing of superphosphate has yielded the heaviest proportion of grass—180lbs. dressing shows 47 per cent. grass, 90lbs. dressing shows 45 per cent., and 45lbs. dressing shows 43 per cent.

When fertilised with acid soluble phosphate the percentage of grass shows at 31.5, fertilised with potash only 30.6 per cent., fertilised with both potash and acid soluble phosphate 35.7 per cent., whilst on unmanured pasture the percentage of grass has only been 14.8.

The percentage of Subterranean clover on the plots has been reversed being only 26.4 per cent. of the pasture on the lime and superphosphate plot, and 79.4 per cent. of the pasture on the unfertilised plot. It is necessary to state that these plots were established on old cultivated land in 1924, and consequently there was a certain residue of phosphate present on the check plot, which has enabled the Subterranean clover to persist throughout the 10-year period, and although it has made cover over the plot to the extent of 79.4 per cent., the clover has made scarcely any growth, and provided very little feed.

Thistles have appeared on most fertilised plots in comparatively small numbers, except on the lime and superphosphate plot, which contained over 8 per cent. thistles, principally of the Scotch and Slender varieties.

Cape weed was less consistent on the plots, and although the plot dressed with Ephos phosphate contained 7.27 per cent., and the one dressed with 1cwt. superphosphate contained 2.97 per cent., none of the others carried any appreciable quantity.

Miscellaneous plants were rather plentiful on plot No. 12, dressed with potash only, 4.56 per cent. of this pasture being designated miscellaneous, and consisted principally of rooted cat's ear.

Naturally the unmanured plot contained the greatest amount of bare space, namely 4.4 per cent., and this amount of bare space was reduced consecutively with the heavier dressings of fertiliser, no bare space being recorded at all on the plot dressed with 180lbs. superphosphate, and only 0.27 per cent. noted on the lime and superphosphate plot. The average amount of bare space for all plots fertilised with phosphate has been less than 1 per cent.

THE BREEDING OF ENGLISH LEICESTER-MERINO-COMEBACK LAMBS ON SUBTERRANEAN CLOVER AND WIMMERA RYE GRASS PASTURE.

For the past five seasons separate flocks of ewes have been grazed on the different series of fertilised plots, and careful records kept of the lambs produced. The flocks used on these plots this season were constituted as follows:—

	Aged. Halfbreds.	Comebacks. 1929. Drop.	1930. Drop.	1931. Drop.	1932. Drop.	Total.
Flock E, grazed on plots Nos. 4, 5, 6, 15, fertilised with superphosphate only ..	15	19	15	15	10	74
Flock I, grazed on plots Nos. 3, 7, 8 fertilised with lime, or gypsum, and superphosphate	13	17	13	13	9	65
Flock G, grazed on plots Nos. 10, 11, 13, fertilised with rock phosphate	11	13	11	11	7	53

All of the above ewes, excepting the aged half-breds, were born and reared on their respective plots, and are daughters of these half-bred English Leicester x Merino ewes by Merino rams. They have known no other type of feed throughout their life.

Table 12 shows the percentage of lambs marked for the immediate past five seasons from these three flocks, and includes also for comparative purposes the results from Flock KI, similarly constituted of 1929, 1930, 1931, and 1932 Comeback ewes, but grazed on fertilised natural pasture.

TABLE 12.—*Lambing Percentages of English Leicester-Merino Ewes x with Merino Rams,* 1929-33.

KI—Ewes born, 1930	—	—	—	75	—	38	67	
KI—Ewes born, 1931	—	—	—	—	62	62		

The lambs were sired by Merino rams, and the percentages are satisfactory, this season's results comparing favourably with previous years. For the five years under review it is interesting to note that the aged half-bred ewes in Flocks E, I, and G have averaged 115 per cent. of lambs per season, but there has been no marked differences between the individual flocks on the average.

The younger Comeback ewes have naturally not been so prolific, although it is pleasing to note that the six-tooth ewes, Flocks EA, IA, and GA have this season averaged over 105 per cent. There has been a distinct reduction in lambing percentages obtained from young Comeback ewes on the fertilised natural pasture, as the results from KI flock show an average of only 67 per cent. from all flocks, against 77, 83, and 85 per cent. from similar ewes on clover pasture.

It appears also that the ewes grazing on clover pasture fertilised with superphosphate and rock phosphate have been more prolific than those on similar pasture fertilised with lime or gypsum, and superphosphate; the results in table showing 85 per cent., 83 per cent., and 77 per cent. respectively for the three forms of fertilising for Comeback ewes, and 92 per cent., 90 per cent., and 86 per cent. when the half-bred ewes are considered as well.

For the first occasion this season a definite check was kept of the actual number of lambs born dead or alive in each flock, and this revealed that all the flocks on the clover pasture gave birth to approximately equal percentages, and varied only from 115 per cent. in Flock I to 119 per cent. in Flock E. The percentages of deaths between birth and marking were greater in some flocks than others. Consequently, for this season,

no variation in fertility of stock can be traced to the various manures, but the fertility has been definitely greater from sown pasture than natural pasture This fact is, no doubt, due to the better development of ewes obtained on the sown pasture.

The next table, No. 12A, shows the average weights of Comeback lambs at weaning time from each flock, and each age and grade of ewe.

TABLE 12A.—*Weights of Comeback Lambs at Weaning*, 1930-34.

Average	66·7	54·4	57·9	62·8	49·5	54·4	

This table shows that there has been considerable variation in weights of lambs from season to season, the 1929 and 1932 drops weighing over 60lbs. each, whereas this season's were only 49.5lbs. This is possibly due to the variation in quality of feed, the heavy November rains this season tended to wash valuable food ingredients from the matured plants. Also the percentage of clover in the pastures was light, and this would appear to be a governing factor. The pastures of the plots fertilised with rock phosphate contained a higher proportion of clover than the other plots, and it is perhaps significant that the lambs reared on the former were considerably heavier at weaning time, namely, 56lbs. on average, as against 48lbs. and 45lbs. on the other series of plots. More annual grasses with their objectionable seeds and less clover amongst the dry feed had a decided detrimental effect on the lamb development.

DEVELOPMENT OF COMEBACK EWES ON SUBTERRANEARN CLOVER AND WIMMERA RYE GRASS PASTURE.

The Comeback ewes in the above flocks have been grazed on their respective plots from birth, excepting for a few weeks at weaning and mating times, when they were pastured on similar type of pasture.

It is significant that in each season there has been a marked difference in the rate of development. Each flock has increased in weight during the growing period of pastures, and decreased during the dry or autumn period.

On the sown pasture every season, with all ages of ewes, the development has been greater, and has been maintained by the ewes throughout their life.

The 1929 ewes have in their four seasons on the sown pasture averaged 113lbs. live weight, and on the natural pasture 94lbs., a maintained increase of 19lbs. (20 per cent.) in live weight in favour of the sown pasture.

The 1930 ewes have in their three seasons on the sown pasture averaged 109lbs., and on the natural pasture 93lbs., an increase of 16lbs. (17 per cent.)

The 1931 ewes have in two seasons on the sown pasture averaged 98lbs., and on the natural pasture 82lbs., also an increase of 16lbs. (19 per cent.).

Similarly the 1932 ewes for their initial season as hoggets have averaged 83lbs. on sown pasture, and 73lbs. on natural pasture, an increase of 10lbs. (14 per cent.).

Increase sown over natural pasture	1 2 (15%)	0 15 (11%)	1 1 (13%)	0 12 (9%)

Table 13 shows the average wool production per sheep each season for the life of the sheep grazing on the variously fertilised Subterranean clover and Wimmera Rye grass plots (Flocks G, I, E) compared with Flock KI that has been bred on top dressed natural pasture. The wool production in the majority of flocks was a little below the average during 1933, and it is noticeable that those on top dressed natural pasture have averaged better during the past two seasons than in 1930 and 1931. However, for the four seasons the ewes on clover pasture have averaged 9lbs. wool per head per year, whilst those on natural pasture have averaged 7lbs 15ozs. per head, a difference of 13 per cent. in favour of sown pasture.

The lower section of the table gives the wool produced per year from the ewes at their respective ages. For four seasons two-tooth ewes on sown pasture have yielded 8lbs. 9ozs. each, 15 per cent. more than on top dressed natural pasture, which yielded 7lbs. 7ozs. per head. For

three seasons four-tooth ewes have yielded 9lbs. 7ozs. each on sown pasture, 11 per cent. more than on natural pasture with 8lbs. 8ozs. per head. For two seasons six-tooth ewes have yielded 9lbs. 4ozs. each on sown pasture, 13 per cent. better than 8lbs. 3ozs. yielded on natural pasture; whilst for one season eight-tooth ewes have produced 8lbs. 9ozs. on clover and 7lbs. 13ozs. on natural pasture, 9.6 per cent. better.

It is therefore quite apparent that sown pasture of Subterranean clover and Wimmera Rye grass definitely increases the wool production per head over well fertilised natural pasture.

There is, however, not much difference in production shown from the various types of fertilisers used on the sown pasture. Those ewes grazing on the pasture fertilised with rock phosphate have yielded 9lbs. 3ozs. wool each per annum, those on pasture fertilised with superphosphate have yielded 8lbs. 15ozs., whilst those on that fertilised with lime or gypsum and superphosphate have yielded 8lbs. 13ozs.—a difference of only 6ozs. per head between the highest and lowest averages.

HEALTH OF SHEEP.

With reference to the health of sheep in these flocks, the following table shows the deaths and percentages that have occurred during the four seasons under review.

TABLE 14.—*Deaths of Comeback Ewes*, 1930-33.

Total KI	0 (%)	0 (0%)	1 (4·17%)	1 (3·23%)	1·85%

It is noted that most deaths occurred during 1931 amongst the flocks grazing on sown pasture. The loss was 7.78 per cent. that season—more than double the loss of any other year—and these deaths were due almost entirely to entero-toxaemia, which affected the sheep during the late winter and early spring.

For the four seasons the average loss on the sown pasture has been 4.3 per cent. per year, and on the top dressed natural pasture 1.85 per cent., showing that where the system of rotational grazing has been observed

throughout the growing periods the losses have not been unduly high, but have been somewhat higher on sown pasture than natural pasture. This fact is verified by referring to an earlier portion of this report, in which it is shown that the losses amongst 87 ewes in Flocks A, B, C, and D on natural pasture has only been 0.92 per cent. per annum over a period of five seasons. The deaths on natural pasture have occurred more amongst six and eight tooth ewes, whereas the deaths on sown pasture have been greatest amongst two and four-tooth ewes. The losses on sown pasture have been slightly greater when the pasture has been fertilised with lime and superphosphate than when fertilised with rock phosphate, and somewhat less when fertilised with superphosphate only.

Amongst the ewes born in 1930 the losses have been 5.98 per cent., which is 2 per cent. greater than those occurring amongst ewes born any other season. After allowing for losses the following wool per acre per annum has been produced by the various aged ewes:—

During four seasons the 1929 ewes have yielded 32.8lbs. on sown pasture, and 23.4lbs. on natural pasture.

During three seasons the 1930 ewes have yielded 33.5lbs. on sown pasture, and 22.6lbs. on natural pasture.

During two seasons the 1931 ewes have yielded 31.3lbs. on sown pasture, and 25.9lbs. on natural pasture.

For one season the 1932 ewes have yielded 34.1lbs. on sown pasture, and 26.9lbs. on natural pasture.

These results distinctly show an increased production of 34 per cent. in wool per acre due to the cultivated pasture.

SOWN WINTER GRASSES.

Four seasons' results are now available of the grazing of five-acre plots comparing *Phalaris tuberosa* with Wimmera and Perennial Rye grasses. The ryes were established with 8lbs. seed per acre, and the *Phalaris tuberosa* with 2lbs.; each plot has received 1cwt. 45 per cent. superphosphate per acre annually, and they are all growing in conjunction with Subterranean clover, and were established on virgin non-top-dressed land.

Table 15 shows the grazing yields of these plots:—

Sown Grasses and Subterranean Clover, 1930-34.

Season.	Grazing in Sheep per Acre.		
	Wimmera Rye and Subt. Clover.	Perennial Rye and Subt. Clover.	*Phalaris tuberosa* and Subt. Clover.
1930-31	2·47	2·05	1·64
1931-32	1·70	1·48	3·52
1932-33	2·41	2·50	3·82
1933-34	3·70	3·62	3·52
Mean	2·57	2·41	3·12

These results show that for the four seasons *Phalaris tuberosa* and Subterranean clover has carried 3.12 sheep per acre—a half sheep per acre more than the Wimmera Rye and Subterranean clover—although for the immediate past season the Wimmera Rye produced slightly more feed than the *Phalaris tuberosa*.

The Perennial Rye plot was established with ordinary commercial seed, and has practically died out; the high grazing result for 1933 was due to the heavy growth of annuals on the plot which have superseded the Perennial Rye grass. Further plots of *Phalaris tuberosa* and Wimmera Rye grass will be established in 1934, and a definite comparison between the two species made under rotational grazing.

HAWKES BAY PERENNIAL RYE GRASS.

Hawkes Bay Certified Rye grass has been sown in three two-acre fields, No. 9D was sown in 1931, and Nos. 9C and 9B in 1932, the former with Alsike clover, and the latter two with Subterranean clover. Some *Phalaris tuberosa* was included with the 1932 seedings, but this made very little headway against the early vigorous growth of rye plants. Consequently the bulk of the grass growth produced has been rye grass, and it has proved definitely inadvisable to sow *Phalaris tuberosa* in conjunction with rye grass.

The grazings received from the three fields since seeding to pasture have been as follows:—

TABLE 16.—*Hawkes Bay Rye Grass Grazing Results*, 1931-33.

Field.	Season.	Grazing in Sheep per Acre.
No. 9D	1931-32	1·43
"	1932-33	3·57
"	1933-34	2·21
No. 9C	1932-33	2·12
"	1933-34	2·36
No. 9B	1932-33	3·00
"	1933-34	2·39
Mean		2·44

The grass seeds were sown on stubbles in Fields Nos. 9D and 9C, but in 9B the seeds were sown on well-prepared fallow. Consequently the first season's result from the latter was much greater than from the former field. The average of 2.44 sheep per acre per annum is a good comparative return from the grass, which gives a very useful bite of green following summer and autumn rains, but does not provide as good winter growths as the annual grasses. It is noticeable that the plants appear to be persisting better than those in previous trials of ordinary commercial Perennial Rye grass strains, but nevertheless the percentage of rye grass in these pastures has been about 15 per cent. less this season than the previous, and the amount of annuals has increased. Careful readings of counts and estimations of plant species are being recorded, and at the conclusion of several more seasons' work definite results on the life of Perennial Rye plants will be available.

SUBTERRANEAN CLOVER.

The grazing results of general fields of the Farm, that is, those outside the purely experimental pasture areas, have been recorded. Those established with Subterranean clover have been grouped together, and the following table shows the results for the past 10 seasons.

TABLE 17.—*Subterranean Clover Grazing, Kybybolite,* 1924-34.

Season.	No. of Fields.	Area.	Total Feed Days.	Sheep per Acre.
		Acres.		
1924-25	1	29·50	29,469	2·74
1925-26	3	109·00	100,794	2·53
1926-27	5	181·50	141,041	2·13
1927-28	6	231·80	208,635	2·47
1928-29	7	267·66	234,378	2·40
1929-30	7	263·71	220,071	2·29
1930-31	5	155·70	138,417	2·44
1931-32	7	237·40	238,234	2·74
1932-33	6	181·26	181,900	2·75
1933-34	8	205·62	210,492	2·80
Mean		1,863·15	1,703,431	2·50

The above table represents the grazing taken from all general clover fields that have not been cut for meadow ensilage or hay, but does not represent their full grazing capacity, as it has not been practical to completely graze all fields every season. It is necessary to hold back fields to provide reserve of feed during April and May, causing a consequent loss of feed which varies with the seasons. The result from these pastures for the immediate season of 2.80 sheep per acre is the best so far recorded —a slight increase on the previous two. The average of 2.50 sheep for the past 10 seasons shows a useful and marked consistency.

Of individual fields under clover this season several yielded over four sheep per acre—No. 6E (9.14 acres) carried 4.45, No. 12 (27 acres) carried 4.15, and No. 6F (11.06 acres) carried 4.02 sheep. Some of the older established fields have not been top dressed regularly of recent years, and their yields have been below average.

TOP DRESSING OLD CULTIVATED LAND.

For the past nine years some areas that have been cultivated for a period of from 15 to 20 years have been left out of the cropping area, and to enhance their grazing they have been top dressed with superphosphate, but no grasses or clovers have been sown. This has had the effect of greatly increasing the growth of naturalised grasses and clovers. The following table summarises the grazing received from this class of pasture each season:—

TABLE 18.—*Grazing of Top Dressed Old Cultivated Land, Kybybolite,* 1925-34.

Season.	No. of Fields.	Area.	Total Feed Days.	Sheep per Acre.
		Acres.		
1925-26	1	50·00	30,097	1·65
1926-27	4	140·47	68,764	1·34
1927-28	3	102·47	76,196	2·04
1928-29	3	121·07	102,089	2·31
1929-30	4	151·83	144,242	2·60
1930-31	4	151·83	134,629	2·43
1931-32	4	151·83	123,491	2·22
1932-33	3	93·38	83,588	2·45
1933-34	2	76·31	93,827	3·37
Total		1,039·19	856,923	2·26

Similar land left out of cultivation but not top dressed has, during the past six seasons, carried 1.41 sheep per acre.

As a comparison to the above the following two tables are included to show the grazing received from similar land that has never been cultivated.

Table 19 shows the combined results of all such land that has been top dressed, whilst Table 20 shows the results from a fair area of unimproved natural land, that is, land that has neither been cultivated nor top dressed:—

TABLE 19.—*Grazing of Improved Natural Land by Top Dressing Only, Kybybolite,* 1921-34.

Season.	No. of Plots.	Area.	Total Feed Days.	Sheep per Acre.
		Acres.		
1921-22	5	17·5	9,971	1·56

Total		747·04	190,290	0·70

In summarising the grazing results of the Farm the areas that have been subjected to the different treatments for a number of years are collected and averaged over the various periods in the following table.

TABLE 21.—*Summary of Grazing Results at Kybybolite.*

Type of Grazing.	No. of Years Tested.	Area Acres.	Sheep per Acre per Annum.	Increase over no Manure. Sheep.	Increase over no Manure. Per Cent.
Subt. Clover and Wimmera Rye Grass (Expl.)	9	70·5	3·38	2·68	383
Subt. Clover and *Phalaris tuberosa*	4	5·0	3·12	2·42	346
Subt. Clover (large fields)	10	186·32	2·50	1·80	257
Hawkes Bay Rye Grass and Clover	3	6·0	2·44	1·74	249
Improved Natural Land (Topdressing only) .	13	35·58	2·39	1·69	241
Topdressed old cultivated land	9	115·47	2·26	1·56	223
Non-topdressed old cultivated land	6	32·08	1·41	0·71	101
Natural land (unimproved)	13	57·46	0·70	—	—

The results in Table 21 can be looked upon as a fair comparison, although it must be remembered that all large fields have not been fully grazed amongst items 3, 6, and 7. However, as they are averaged over a number of years, the table is useful and interesting, and continues to show the advantages to be gained from Subterranean clover, Wimmera Rye grass, and top dressing with phosphates.

NITROGEN FERTILISER TEST.

During the past two seasons work carried out in conjunction with the Nitrogen Fertilisers Proprietary Limited has been confined to two four-acre plots. These were ploughed in February, 1932, worked well, and sown to the following pasture mixture per acre at the end of April in that season:—

10lbs. Certified Perennial Hawkes Bay Rye grass.
4lbs. *Phalaris tuberosa.*
2lbs. White Dutch clover.
1lb. Subterranean clover.

Both plots were given a dressing of ½ ton lime and 1cwt. 45 per cent. superphosphate per acre, the dressings of lime and superphosphate being applied one month apart. During August, 1932, 1cwt. 20 per cent. sulphate of ammonia was broadcasted per acre on Plot No. 1. Superphosphate at the rate of 1cwt. per acre was again applied to both plots during April, 1933, and sulphate of ammonia (1cwt. per acre) was also applied to Plot No. 1 in late July, 1933. Both plots were harrowed in June, 1933.

The following table shows the grazing results from the plots for the two seasons:—

TABLE 22.—*Nitrogen Fertiliser Test, Kybybolite,* 1932-34.

Plot.	Grazing in Sheep per Acre. 1932-3.	1933-4.	Mean 1932-4.
N1. Lime, super, and nitrogen ..	4.26	3.76	4.01
N2. Lime and super	3.26	3.24	3.25

These plots produced a very nice stand of pasture, which consisted principally of Perennial Rye grass, which thrived well the first season, 1932. During the winter of 1933 the rye grass, however, made only poor

growth, and was in marked contrast to annual grasses and clovers growing on adjacent plots. The rye grass recovered well in the spring, and finally produced quite a good average throughout the season. As the table shows, the nitrogen fertiliser caused an increase of approximately $\frac{3}{4}$ sheep per acre per annum, but the difference in the second season was only half of that secured during the first season.

Counts of plants revealed that there was a greater death of rye grass plants during the second season on the nitrogen dressed plot than on the No. 2 plot, which received no artificial nitrogen fertiliser. There was, however, 40 per cent. more plants of rye established on the former plot at the close of the first season, and consequently a greater death on the thicker stand was not unexpected. Also the *Phalaris tuberosa* grass was able to establish a little better amongst the thinner stand of rye of No. 2 plot.

The experiment once again demonstrates the necessity of maintaining good healthy clover growths amongst the perennial grasses to enable the latter to secure sufficient fertility.

TRIALS OF GRASS AND HERBAGE STRAINS.

By the aid of grant made to us by the Australian Dairy Council, work was commenced in 1932 to test various strains of grasses and clovers with the view of selecting the more persistent and productive strains for ultimate seed production.

A collection of perennial rye grass strains were secured from New Zealand, Victoria, and South Australia from various sources, as well as available strains of *Phalaris tuberosa.* These were sown under field conditions in 1932, and have since been maintained under good grazing conditions. Periodically notes have been taken on the growth and health of plants in the strains, and prominent individual plants have been pegged and noted both as prolific winter growers and also those that have shown to advantage in the summer months. Particular attention has been given to the health of Perennial rye grass plants during the mid-winter months

Sufficient result has been obtained at present to show that there is a marked variation between strains, and also that many types of plants exist amongst the individual strains themselves.

Similarly some strains of *Phalaris tuberosa* have shown marked superiority to others, and in one or two cases the advantage has been sufficient and the type sufficiently definite to warrant transplanting to isolated positions with a view of seed collection.

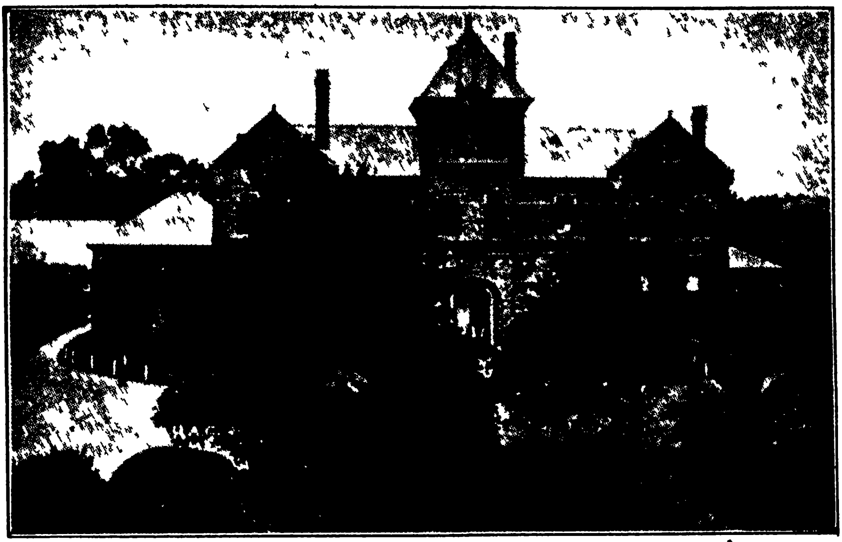
Some progress has been made with the selection of types of Annual Rye grasses, and isolated plots of these selected strains are being grown this season. The accompanying photos. show quite a 100 per cent. increase in early leaf and stem growth secured from selected strains above that of the parent plants.

Very little success has as yet been obtained with strains of other species of grasses, although several are under close observation.

Also, so far, little success has been secured from the latest strains of white and red clovers under our conditions.

Quite distinctive results have been recorded from various strains of Subterannean clover under trial, and the behaviour of these during future seasons will be carefully recorded.

Finally I wish to record valuable assistance and diligence to duties given by the staff of the farm throughout the season.



INVESTIGATION DESIGNED TO IMPROVE CULTURAL PRACTICES IN CURRANT VINEYARDS LOCATED IN NON-IRRIGATED COASTAL DISTRICTS IN SOUTH AUSTRALIA BEGUN JULY, 1932.

[In our March, 1934, issue Mr. Geo. Quinn (Chief Horticultural Instructor) presented the First Progress Report of the above Investigation and the Second Report is appended below. The work undertaken consists, briefly, as follows:—

(1) *Methods of re-organising old debilitated vines in low yielding and unprofitable currant vineyards.*

(2) *Testing the comparative values of various systems of pruning in relation to the productivity of normal vines and of the quality of the fruit borne by them.*

(3) *Gauging the crop yielding capacities of groups of normal currant vines in selected vineyards with a view to initiating manurial trials.]*

In addition, certain growth and fruit cropping studies were conducted in minute detail during the growing season of 1932-33 on vines selected at random in the plots devoted to the above. The data accumulated from these studies were passed over to officers of the Council for Scientific and Industrial Research for statistical analysis and comparison with data similarly obtained in the Currant vineyards grown under irrigation in the Murray Valley. With the exception of certain measurements taken of the development of the Currant berries at intervals from setting until harvest time, the work during the period under review, viz., 1933-34, has been confined to the continuation of the three above-mentioned field operations.

A local committee of Currant growers has been formed in each district (Clare, Barossa, and McLaren Flat) to watch the progress of the investigational work, and considerable interest in the work has been displayed.

That portion of the work designed to re-organise old non-profitable vines has made considerable and substantial progress, thanks largely to the prompt assistance rendered by the owners of the respective plots in removing the old dilapidated trellises and replacing them with newer and more up-to-date types, and attending to other cultural and drying operations. The owners of these vineyards have entered into the renovating procedure with enthusiasm, and it is hoped that from the figures kept of the work and the crops harvested the officials of the investigation may soon be in a position not only to demonstrate the practicability of re-organising these old plantations, but to show what the exact cost may be to the owner of inaugurating the change and bringing the vineyard back to a highly productive condition. The method adopted in the first instance, when the old vines were cut off at ground level and new shoots arising therefrom led up to the trellis, is being supplemented by several methods of layering these growths in the establishment of the new vines. The writer's experience leads him to the opinion that this will prove the most satisfactory procedure for securing permanently healthy vines, as it will ultimately eliminate the old stumps, into which the entrance of decay cannot be wholly prevented.

Although it is premature to arrive at definite conclusions at this stage of the investigation, there is at present some indication that certain methods of pruning have a direct influence on various phases of fruit production in the Zante

Currant. Observations of the growth reactions displayed by the vines, which are spur pruned in winter and disbudded of all surplus sprouts, other than from the spurs, in the spring, indicate during the two seasons that the work has been in progress a great improvement in the size and texture of the canes arising from such spurs. Studies made elsewhere have shown a direct correlation—within certain limits—between the strength of the cane and the weight and quality of the fruit borne thereon.

In this respect the figures given in this and the previous report show that whilst the gross weight of fruit borne by the disbudded spur pruned vines has not yet in all cases equalled that on the spur pruned plants which have not been disbudded, the quality of the dried Currants has excelled it to an appreciable degree. Owing to this increased strength of the individual canes produced by them, an additional number of spurs has been retained on the spur pruned disbudded vines for the coming season. This procedure has partially been instigated by the greater loss of sprouts from these vines by wind breakages during the earlier and more brittle stages of their development.

Another feature which has been emphasised from data obtained by harvesting and drying the fruit borne by shoots arising from the various parts of the vines pruned by these three methods is that spur pruned Currant vines, when grown in the richer soils and cooler conditions of these non-irrigated areas, produce, in comparison with those which are rod and spur pruned, a greater number of seed bearing berries known as "bucks." On the other hand, the rod and spur pruned Currant vines, whilst thus far producing a greater weight of fruit, have, at the same time, given definite evidence that it is done to the detriment of the quality of the dried product. As this investigation has been designed for the purpose of improving the quality of the Currants grown in the coastal areas, the results thus far obtained may be claimed to be distinctly encouraging to the prosecution of further efforts in that direction.

It may be recorded here that the weather conditions, which have such an important bearing on each season's results in investigational work such as this, and particularly in non-irrigated areas, have been very diverse during the two years it has been in progress. The winter of 1932 was an extremely wet season, followed by an unusually cool summer. The foliage on the Currant vines, even into the harvesting period, showed no lack of moisture in the soil, and the fruit, in consequence, displayed a tendency to lag in sugar formation. The winter of 1933, though not lacking in rainfall, turned suddenly dry in September, and the Adelaide Weather Bureau records show that from the end of that month until 26th March, 1934, only 206 points of rain fell. These were spread over 23 readings, showing how superficial the individual falls were. The average annual rainfall in Adelaide over the same period for the past 95 years was 458 points. In addition to this lack of moisture, two heat waves were experienced. One in January lasted 11 days, on nine of which the temperature ranged from 100° to 110° Fahr. in the shade. This did not appear to affect the vineyards, but the second was an unprecedently late burst of heat, beginning on 4th March and lasting 12 days, during which seven consecutive days ranged between 102.2° to 110.5° Fahr. in the shade. This great heat, coming when the land was at its driest stage, burned the foliage and shrivelled and semi-dried the already fully ripened Currant berries. Hence the very high Baumé readings and drying ratio to be seen in the data given herein.

The following tables of figures set out the position in respect to the results of the work done during the season ending with the Currant harvest of 1934.

THE RE-ORGANISATION OF OLD CURRANT VINES.

Clare District—Stanley Flat (Mrs. A. Dolan), Season 1934.

As described in the first progress report (see *Journal of Agriculture*, March, 1934, page 965), in this vineyard two rows consisting of 121 vines were cut off in 1932 season and reconstructed on lines described therein.

In the season under review, these young vines bore their first crop of fruit, viz., 1,307lbs. fresh Currants. The owner also harvested the crop from a corresponding number of old vines in the rows immediately north of those reconstituted. The results of the cropping of the reconstructed vines and the old control vines during the 1934 harvest are as under:—

Reconstructed Vines.

No. of Vines Recorded.	Total Yield Fresh	Average Yield Fresh per Vine	Total Yield Dried	Drying Ratio.	Average of Four Baume Readings	Rate per Acre. Fresh.	Rate per Acre. Dried
	Lbs	Lbs	Lbs.			Lbs.	Lbs.
112 planted 10 x 11 896 p.a.	1,307	11 67	413	3 16	14 87	4,021 = 2T 1C 1Q 1L	1,460 = 13C 4L

Old Check Vines.

121 planted 10 x 11	2,495	20 62	880	2 83	14 37	8,165 = 3T 12C. 3Q. 17L.	2,888 1T. 5C. 3Q. 4L.

Barossa District—Angaston (Mr. G. L. Wishart), Season 1934.

In this 60-year old vineyard three rows, consisting of 124 vines, were also cut off in 1932 and 116 responded, and are undergoing reconstruction. These young vines bore a small crop for the first time, viz., 848lbs. of fresh Currants. A crop yield record is being taken from the next adjoining three rows for purposes of comparison. The harvest of 1934 yielded the following results:—

Reconstructed Vines.

No. of Vines Recorded	Total Yield Fresh.	Average Yield Fresh per Vine	Total Yield Dried.	Drying Ratio	Average of Four Baume Readings	Rate per Acre Fresh.	Rate per Acre Dried
	Lbs.	Lbs.	Lbs.			Lbs.	Lbs
116 planted 8' 6" x 16' 136 p.a.	848	7 31	316	2 68	13 5	994 8C 3Q 14L	368 3C. 1Q 4L

Old Check Vines.

124	1,380	11·1	412	3 35	14 5	1,513 13C. 2Q. 1L.	452 = 4C. 4L.

When graded into commercial grades, the following results were obtained by the Angaston Fruitgrowers' Co-operative Packing Shed:—

Reconstructed Vines—

64lbs. 3 Cr. large.
242lbs. 3 Cr.
10lbs. Mfs.

Old Check Vines—

132lbs. 3 Cr. large.
274lbs. 3 Cr.
6½lbs. Mfs.

McLaren Flat (Mr. R. G. Bell), Season 1934.

In this 30-year old vineyard two rows, equalling 76 vines which had been cut off during winter of 1932 and reconstructed on a new trellis, cropped for the first time. These vines were not cinctured and the berries were uniformly small,

but quite good. By request, Mr. Bell also harvested and recorded the crop from the next adjacent two rows of old vines. The following are the results of the croppings:—

Reconstructed Vines.

No. of Vines Recorded.	Total Yield Fresh.	Average Yield Fresh per Vine.	Total Yield Dried.	Drying Ratio.	Average of Four Baume Readings.	Rate per Acre. Fresh.	Rate per Acre. Dried.
	Lbs.	Lbs.	Lbs.			Lbs.	Lbs.
76	639	8·40	226	2·82	—	—	—
Old Check Vines.							
78	1,425	18·27	469	3 03	—		

These dried fruits were graded by Mr. Bell, with the following results:—

Reconstructed Vines—

194lbs. 3 Cr. small.
32lbs. 2 Cr. small.
— Bucks.
6½lbs. waste.

Old Check Vines—

440lbs. 3 Cr.
24lbs. 1 Cr.
5lbs. Bucks.
14½lbs. waste.

TESTING THE SYSTEMS USED IN PRUNING CURRANT VINES.

Clare District—Sevenhills (Mr. W. H. Penna), Season 1934.

This test, which embodies 33 groups, each containing three Currant vines, and in each of which groups three different pruning treatments are repeated, was continued. The results of the 1934 harvest are given below:—

Method of Pruning.	No. of Vines.	Total Yield Fresh	Average Per Vine	Total Dried.	Baume Reading.	Drying Ratio.	Total Yield Per Acre Rate. Fresh.	Total Yield Per Acre Rate. Dry.

Barossa District—Light's Pass (Mr. P. B. Boehm), Season 1934.

This test plot also contains 99 vines, divided into 33 groups of three vines each, thus presenting 33 replications of each method of pruning under comparative test. The results given below have no doubt been much reduced owing to a spring frost occurring in this vineyard shortly after bud burst. In the spring of 1932 a similar frost was experienced, but its ill-effects were not so severe as from that of 1933. The following is a summary of the results obtained from the 1934 Currant harvest.

Method of Pruning.	No. of Vines.	Total Yield Fresh.	Average Per Vine.	Total Dried.	Baume Reading.	Drying Ratio.	Total Yield Per Acre Rate.

SUMMARY OF DRIED FRUIT WEIGHTS.

No. of Vines Recorded.	Total Yield.	Average Yield per Group.	Average Yield per Vine (Dried).	Drying Ratio.	Total Dried per Acre Rate (including Stems and blowouts).
134 (Planted 10′ x 12′)	Lbs. 605	Lbs. 24·2	Lbs. 4·51	Lbs. 2·88	Lbs. 1,639 = 14C. 2Q. 15L.

This dried fruit was graded into [illegible] 2 Cr.; [illegible] 2 Cr.; 6lbs. 31 Cr.; 47lbs. Bucks; 33½lbs. stems and blowouts.

NOTE.

From close observations made of the Currants at harvesting time from the pruning plots at Mr. W. H. Penna's vineyard at Sevenhills and from Mr. P. B. Boehm's vines at Light's Pass, Mr. Quinn formed the opinion that in processing and grading the dried samples the Angaston Co-operative Shed applied the grade designation of 3 Cr. L. to a different type of fruit from that selected at the Clare Co-operative Shed. The latter was a much larger and bolder Currant, and if graded on the Clare basis, most of the Light's Pass fruit would have been included in the 3 Cr. It should be more satisfactory for purposes of comparison if steps could be taken to secure greater uniformity in this matter in future lots.

SEED WHEAT FROM CROP COMPETITIONS.

In Wheat Competitions conducted in the undermentioned Districts the following Competitors exhibited crops which, in the opinion of the judge at the time of inspection, should produce grain suitable for seed purposes:—

Competition. Competitor. Address. Variety.

Matters and McCabe, Wasleys—Sword.
W. K. Oliver, Wasleys—Sword.
N. J. Griffiths, Salisbury—Bencubbin, Ghurka, Dundee.
Dawkins and Aunger, Gawler—Sword.
Kerr and Cliff, Waratah—Waratah.
W. F. Leak, Willaston—Pine Vale, Quality, Nabawa.

JERVOIS—

W. Jericho, Cleve—Waratah.
J. Brus and Sons, Mangalo—Sword.
L. H. and D. H. Hogg, Darke's Peak—Nabawa, Waratah, Sword.
M. H. Burton, Rudall—Waratah.
F. I. Kestel, Rudall—Bencubbin.
D. C. McCallum, Rudall—Waratah.

BUXTON—

H. Cant, Kimba—Sword.

SOUTHERN—

S. Wachtel, Palmer—Sword.
M. Wachtel, Palmer—Nabawa.
L. H. Wachtel, Palmer—Nabawa.
J. O. Bottroff, Palmer—Sword, Nabawa.
G. W. Faehrmann, Palmer—Nabawa.
H. B. Scheer, Mannum—Sword.
C. A. Whittlesea, Langhorne's Creek—Late Gluyas.
J. Rzeszskowski and Mattner Bros., Finniss—Sword.
Rankine Bros., Strathalbyn—Nabawa.
H. A. Eckert, Belvidere—Sword.
C. Brook, Woodchester—Petatz Surprise, Nabawa.
H. H. Cross, Woodchester—Ford.
E. T. and L. Jaensch, Hartley—Ghurka, Bencubbin.
Mrs. E. Hartmann, Monarto South—Dan, Sword.
Thomas Bros., Monarto South—Nabawa, Sword.
P. B. Frahn, Monarto—Currawa.
Frahn Bros., Monarto—Sword, Nabawa.
J. F. C. Paech, Callington—Dan, Nabawa.
C. Brook, Woodchester—Comeback.

JUDGE'S NOTE.—*"Sword" contains the mixed strains typical of this variety, but because of its prominence and the demand for seed, it has been recommended until such time as a more fixed type is available.*

Seed Wheat—*continued.*

ALBERT—

G. H. Sutherland, Copeville—Ranee.

ALFRED—

W. Paull & Sons, Alawoona—Gallipoli, Ranee.
A. C. Webb, Paruna—Sword, Nabawa, Baringa.
G. J. Zimmermann, Meribah—Sword.
E. M. Edwards, Paruna—Ranee.

BALAKLAVA—

Jas. Campbell, Barabba—Sword and Ford.
J. A. Campbell, Barabba—Sword.
R. P. Anderson, Upper Wakefield—Sword.
W. Ryan, Halbury—Sword.
Bowyer Bros., Owen—Sword.
G. Uppill, Balaklava—Sword.
E. Munday, Barabba—Sword.
D. Wilson, Barabba—Ford.

WESTERN—

L. C. Roberts, Port Pirie—Currawa.
H. G. Munday, Merriton—Waratah.
E. T. Franks, Box 157, Port Pirie—Currawa.
J. H. Holman, Telowie Creek—Carmichael's Eclipse and Gallipoli.

SOUTHERN YORKE PENINSULA.

H. Polkinghorne, Minlaton—Sword.
W. G. Boundy, Minlaton—Ford.
A. E. Brechin, Curramulka—Sword.

MID-NORTH—

A. Maitland, Rochester—Nabawa.
F. J. Pedler, Koolunga—Sword, Rance, 4H, Bencubbin.
F. A. Wheaton, Redhill—Nabawa.
J. T. Clothier, Redhill—Sword.
A. H. Bentley, Redhill—Sword.
H. J. Crouch, Crystal Brook—Waratah.
J. D. Dennis, Redhill—Rance 4H.
J. L. Norman, Gulnare—Sword.

NOTHERN YORKE PENINSULA—

T. Rodda, Boors Plains—Sword.
J. H. Bussenchutt, Paskeville—Sword.
G. E. & H. M. Meier, Paskeville—Sword.

FAR NORTHERN—

H. G. Kupke, Morchard—Free Gallipoli.
A. Piggott, Morchard—Ford.
D. J. Crocker, Orroroo—Waratah.
W. G. Gregurke, Wepowie—Felix.
T. F. Orrock, Wepowie—Ranee 4H.
E. H. Hampel, Terka—Ranee 4H, Currawa.

LE HUNTE—

T. L. Nottle, Yaninee—Ford, Merridin.
E. H. Edmonds, Pygery—Nabawa.
S. C. Billinghurst, Minnipa—Felix, Faun, Early Gluyas, Merridin, Nabawa.
W. P. Bartley, Wudinna—Nabawa.

NORTHERN—

H. C. Jaeschke, Yandiah—Nabawa.
M. H. Burgess, Laura—Nabawa.
J. C. Kleinig, Laura—Sword.
W. F. Wurst, Laura—Nabawa.
J. W. Prior, Gladstone—Free Gallipoli, Nabawa, Sword.
W. S. Ballantyne, Gladstone—Sword.
W. M. Neate, Caltowie—Ford.

CROPS RECOMMENDED FOR SEED.

W. H. Prior, Hampden—Sword and Dan.
E. A. Pfitzner, Buchanan—Ranee.
E. J. Williams, Tothill's Creek—Ranee and Gallipoli.
S. Garrard, Farrell's Flat—Gallipoli.

Seed Wheat—*continued.*

H. Miller, Farrell's Flat—Ranee.
W. T. Ley, Farrell's Flat—Gallipoli.
J. L. C. Freebairn, Owen—Sword.
E. V. H. Wilsdon, Spalding—Dan.
T. Vogt, Saddleworth—Ranee 4H.
G. and C. Frost, Manoora—Gallipoli.
H. N. Pearson, Tarlee—Sword.
D. L. Clarke—Waratah and Sword.
R. Wake, Tarlee—Dundee.
F. Coleman, Saddleworth—Gallipoli and Ghurka.
H. Behn, Saddleworth—Sword.
W. H. R. Branson, Hamley Bridge—Sword.
R. and N. Hughes, Kapunda—Gallilopi.
Mrs. M. E. Glynn, Rhynie—Dan.
L. J. Harvey, Hilltown—Dan.
J. Ross, Mintaro—Waratah.
Molinaux Bros., Tarlee—Sword.
W. R. Woods & Sons—Gallipoli and Kerley's Early.
R. L. Blatchford, Mintaro—Waratah.
A. J. Jones, Manoora—Gallipoli.
W. J. Cornwall, Hilltown—Turvey and Dan.
L. A. Martin, Farrell's Flat—Dundee and Ranee 4H.
R. Roebuck, Buchanan—Mogul and Nugget.
J. H. Torr, Farrell's Flat—Gallipoli.
Geo. Hazel, Kapunda—Gallipoli and Ranee 4H.
C. J. H. Behn and Son, Riverton—Waratah and Nabawa.
L. V. Bell, Marrabel—Nugget.

Mr. Johnston also reports that he inspected the following crops which were not in the Competition, but have been recommended for seed:—

W. J. Branson, Hamley Bridge—Ford.
L. J. Harvey, Hilltown—Turvey.
L. V. Bell, Marrabel—Clarence, Waratah, Ranee 4H.
C. H. Behn and Sons, Riverton—Ghurka, Dundee, Sword, Baringa, Florence.

TATIARA—

L. Y. Langdon (Kongal), Bordertown—Gallipoli and Ranee.
H. C. M. Pilgrim, Wolseley—Gallipoli.
G. D. Butler, Wolseley—Ranee 4H.
Fisher Bros., Bordertown—Ranee.
F. V. Staude, Kongal—Gallipoli.
D. R. Milne, Bordertown, Ranee.
S. Pitcher. Bordertown—Ranee.
J. Smith, Bordertown—Ranee.
A. Klien, Mundulla—Bobin and Ranee.
C. Gall, Wolseley—Gallipoli.

Oats.

Mr. W. C. Johnston advises that he inspected a crop of New Zealand Cape Oats on the farm of Mr. F. H. Wolf, of Rosedale, which he reports as being suitable for seed.

Messrs. C. H. Behn and Son, Riverton—Calcutta Cape.
Kelly Bros., Wolseley—Algerian.
C. Gall, Wolseley—Algerian.
J. A. Sudholz, Kalangadoo—Algerian.
H. W. Walsgott, Mount Gambier—Mulga.
A. A. Sassanowsky, Mount Gambier—Algerian.
C. Mitchell, Mount Gambier—Algerian.
W. M. Harfull, Mount Gambier—Algerian.
F. L. Koop, Glencoe West—Algerian.
H. M. Kennedy, Glencoe West—Algerian.
Hilton Hinze, Mundalla—Sunrise.

Barley.

A. H. Allen, Mount Gambier—Plumage Archer.
V. Pettingill, Mount Gambier—Plumage Archer.
Smith Bros., Mount Gambier—Plumage Archer.
D. O. Norman, Mount Gambier—Plumage Archer.
Fisher Bros., Bordertown—Prior.
S. Pitcher, Bordertown—Prior.

EXPERIMENTAL FEEDING TESTS CONDUCTED AT PARAFIELD POULTRY STATION.

[By C. F. ANDERSON, Poultry Expert.]

A series of feeding tests are being conducted at Parafield Poultry Station with a view to ascertaining if suitable foods which are obtainable on the majority of our farms can be satisfactorily fed to poultry. The tests are each of 50 White Leghorn pullets, and commenced on April 1st, 1933.

The feeding is as follows:—

No. 1 *Test.*—Morning—Wet mash composed of 1 part crushed barley, 2 parts wholemeal (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 2 *Test.*—Dry mash composed of same proportions as No. 1 Test.
Midday—Greenfeed. Evening—Wheat.

No. 3 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts pollard (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 4 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts wholemeal (by weight), ½ lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 5 *Test.*—Morning—1½ozs. wheat per bird.
Evening—1½ozs. wheat per bird. Greenfeed in season.

The following are the numbers of eggs laid by each pen from April 1st, 1933, to December 31st, 1934.

Definite conclusions, however, cannot be given at this juncture with regard to the various methods of feeding. It is necessary for the tests to complete the 24 months before any satisfactory opinions can be formed.

	No. Eggs Laid April 1st, 1933, to Nov. 30th, 1934.	No. Eggs Laid Month of Dec., 1934.	Total Eggs Laid April 1st, 1933, to Dec. 31st, 1934.
No. 1 test	12,101	676	12,777
No. 2 test	11,308	617	11,925
No. 3 test	10,960	591	11,551
No. 4 test	12,197	574	12,771
No. 5 test	6,296	415	6,711

IMPORTANT WEEDS OF SOUTH AUSTRALIA.

[By G. H. CLARKE, B.Sc., Botanist at the Roseworthy Agricultural College.]

No. 10.—WILD ONION, OR ASPHODEL.

Asphodelus fistulosus, L.

The Wild Onion is an extremely common weed of roadsides, pastures, and other uncultivated ground. It occurs in all States of the Commonwealth, but is particularly well established in South Australia, where it forms some very dense growths, and in which it is a proclaimed noxious weed for the entire State. There are, however, within a short distance from Adelaide some large areas occupied by the weed to the almost complete exclusion of other pasture plants. The name "Wild Onion" is due to resemblances in habit and leaf-form to species of the true Onion (*Allium spp.*), and especially to the Shallot (*Allium Ascolonicum,* L.), which plants, since they belong to the same monocotyledonous family *Liliaceae,* further resemble the Asphodel in many structural details of the flower and fruit. Nevertheless the Asphodel is not a true Onion. The Onion-like habit of growth, in fact, is to be found in many members of the *Liliaceae* besides species of *Allium,* from which *Asphodelus* is easily distinguishable by the absence of bulb formation, by the arrangement of the flowers in racemes or panicles instead of in umbels, and by the absence of the characteristic odour and taste of onion or garlic present in most species of *Allium.* The Asphodel may be readily recognised by its very numerous, radical, dark-green, and cylindrical leaves, and by its erect racemes or panicles of white or pinkish flowers, each one of which has a pink or brownish stripe down the centre of each petal.

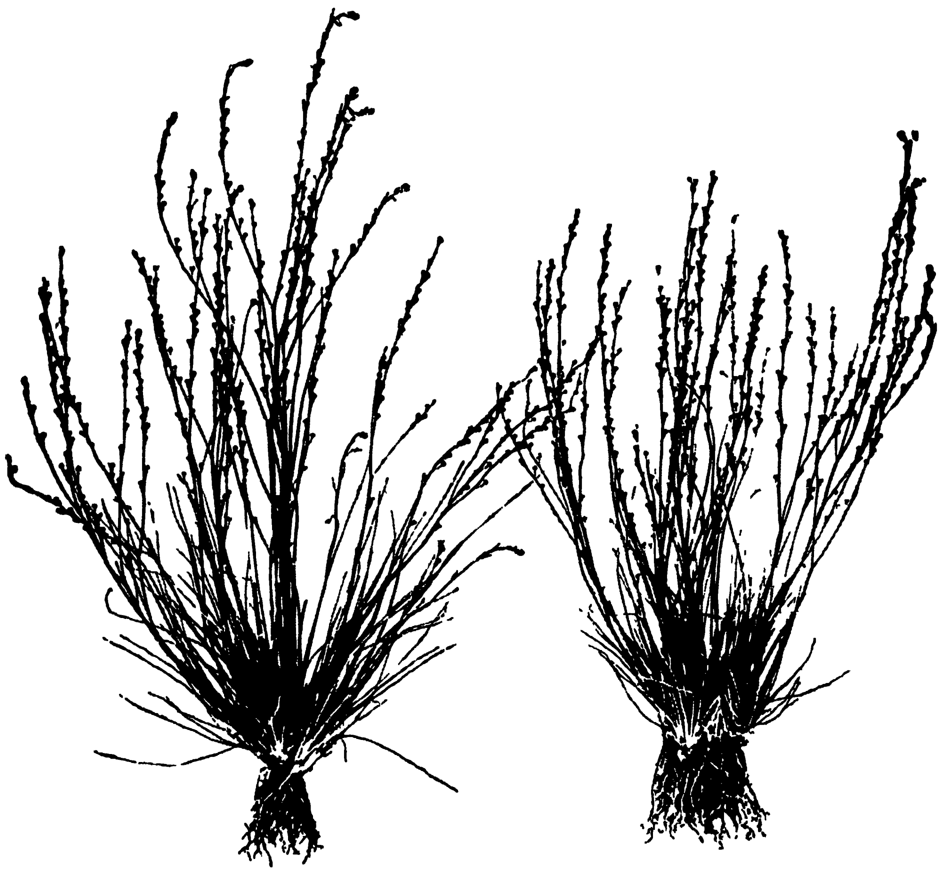
Botanical Name.—The name *asphodelos,* meaning "the head of a pike," was applied by the Greeks to some plant with awl-shaped leaves and belonging, probably, to the family *Liliaceae.* The species name *fistulosus* means "hollow," and is on account of the hollow stems and leaves of this species.

The Family.—The family *Liliaceae,* to which *Asphodelus* belongs, derives its name from the contained genus *Lilium,* and its members are often referred to as "Lilies," *e.g.,* Lily of the Valley (*Convallaria majalis*), &c. But the term "Lily" is more commonly applied to Arum Lily (*Zantedeschia aethiopica*), which belongs to the entirely different family *Araceae.* Similarly the Water Lilies (*Nymphaea* and its allies) are quite unrelated to Liliaceous plants.

The family includes a large assemblage of plants (about 250 genera and nearly 4,000 species), among which is to be found considerable diversity both as regards habit and habitat. The great majority are herbs with bulbs or underground stems, but there are some climbing members, a few large-leaved succulents, and a number of shrubs and trees. The Australian genus *Xanthorrhoea,* which includes the plants popularly known as "Black-boys," "Grass-trees," and "Yacca-gums," belong here. In fact, the family is rather well represented in Australia, there being no less than 40 genera and about 120 species native, of which 15 genera and 35 species occur in this State. In addition there are a number of introduced species, such as the plant under discussion, *Asphodelus fistulosus,* which belongs to the Mediterranean region.

The economic importance of the *Liliaceae* is, on the whole, small, but some genera, *e.g., Allium* and *Asparagus,* are food plants; certain others are of medicinal value, *e.g., Smilax* (Sarsaparilla), *Urginea* (Squills), *Aloe* (Aloes), *Colchium,* and *Veratrum; Phormium* (New Zealand Flax) and *Yucca* yield fibre, while resin is obtained from *Xanthorrhoea.*

Despite the range of variation in habit there is a remarkably uniformity in the structure of the flower throughout the *Liliaceae*. With very few exceptions it is a radially symmetrical structure with an attractive perianth and nectar arrangements indicative of insect pollination. The parts of the flower are in threes, and there are five whorls, each whorl consisting of three segments. There are two whorls of perianth segments (petals), two of stamens, and a single one of three united carpels, the latter forming a superior pistil, of which the ovary contains three spaces or loculi, with a pair or double row of ovules arising from the inner angle of each. The fruit is in some cases a dehiscent capsule, and in others a succulent berry.



Wild Onion—Showing general habit and mode of branching at the base. A coloured plate of this weed is shown opposite.

An anatomical peculiarity which is found in certain tree-like types is the occurrence of secondary increase in the amount of conducting tissue in the stems, a process analogous to the cambial growth of other woody-species. Though a cambium in the strict sense is not present, there is formed in the outer part of the stem a layer of meristem which forms additional conducting strands outside those more centrally placed. Such meristem formation is unusual among *Monocotyledons* to which Liliaceous plants belong; a further departure from the usual monocotyledonous structure is seen in the climbing genus *Smilax*, which has net-veined instead of the more typical parallel-veined leaves.

H E POWELL GOVERNMENT PHOTOLITHOGRAPHER, ADELAIDE G H CLARKE, Direxit

The Genus.—The genus *Asphodelus* comprises about 12 Mediterranean species characterised by a non-bulbous habit and the possession of white, or reddish-white, flowers with the main vein of each petal conspicuously coloured. The stamens have their filaments expanded and curved at the base in such a way as to cover over the ovary (see coloured plate) and enclose it in a kind of sheath in which nectar accumulates. The ovary is superior and trilocular, and matures to form a capsular fruit with one or two seeds in each loculus. The *Asphodelus* flower is *protogynous,* that is to say, the pistil matures before the stamens, the ovules being already fertilised by the time the latter shed their pollen. Cross-pollination is thus assured. The species *fistulosus* is distinguished from other species by the relatively slender roots, which in other species are more or less swollen and tuberous, by the hollow and shorter stems, the narrow cylindrical leaves, three-lobed stigma of the flower, and by the small size of the fruit.

Description of A. fistulosus.—A glabrous perennial herb 20-60 cm. high, with numerous long only slightly thickened roots; stem hollow, simple or branching dichotomously towards the summit; leaves slender (1-3 mm. thick), semi-cylindrical, dark-green, inserted spirally at the base. Flowers white or flesh-coloured, small, in loose racemes; bracts whitish; perianth of six spreading segments, 8-12 mm. long, each with a pinkish or brownish stripe along the main vein; stamens six, filaments lanceolate and papillate at the base where they curve over the ovary; stigma three lobed; capsule globular, 4-6 mm. in diameter, wrinkled transversely, opening loculicidally; seeds 1 or 2 in each loculus, black, triangular, covered with irregular elevations and depressions. In flower, July-November.

Properties.—The Wild Onion is of no use, and, though not actually poisonous, is not eaten by stock. It is apt to take possession of large areas of uncultivated ground, so that these become practically useless for grazing purposes. Being perennial it holds its ground from year to year, and, besides forming large quantities of seed, it spreads by a method of branching suggestive of the tillering of cereals and other grasses, the stems branching at the base and so giving rise to the tufted habit which is so characteristic of older plants. The latter thus continue to grow each year, while new plants spring from seed formed each season, and if eradication measures are not undertaken the ground becomes densely covered with the weed in the course of a few years.

Yet the Wild Onion is not a difficult plant to eradicate, at least from small areas. It can be got rid of by hoeing or hand-pulling prior to the formation of seeds, the plants being easily uprooted since the root system does not penetrate the soil to a great depth. But if neglected it may become a serious pest on vacant land, as is actually the case in some areas where the land has been untouched for years. But once the weed has been got rid of by hoeing or cultivation, it only needs a little attention from time to time to keep the land free from it. On large areas it can be controlled by cultivation, though this, of course, means expense, especially when the earning capacity of the land is small.

Earning Capacity of Land and the Problem of Noxious Weed Control.—The subject of the earning capacity of land is important when considered in relation to the problem of controlling noxious weeds, and a few remarks thereupon may not be out of place here, since we are dealing with one of the commonest weeds to be found growing on vacant ground in and around the suburbs of Adelaide.

Legislation for the suppression of noxious weeds exists because we know that the unrestricted growth of such plants means financial loss both to individual farmers and pastoralists and to the State as a whole. This is obvious enough to the man on the land, who knows from his own personal experience that the trouble and expense incurred in preventing the growth of weeds is more than compensated for by the resulting improved earning capacity of the land. But

noxious weed control, in order to be effective, calls for concerted action, and so legislation is enacted to ensure that negligence on the part of a few is not allowed to undo the work of the many. So far so good. Unfortunately, however, legislation cannot accomplish miracles; and though such measures may be effective enough where economic conditions permit of their being carried out, there are, in certain situations, economic factors which operate in precisely the reverse way. This is particularly true in the case of land of which the earning capacity is small or none. Where the land is earning money, either as rent or from the sale of produce, the cost of weed eradication is recoverable and can be borne without pecuniary loss to the owners; in such cases the provisions of a Noxious Weeds Act are easily enforced and willingly carried out. But where the land is quite unproductive the cost of ridding it of weeds is not so recoverable; it becomes a tax on income from other sources, and so a financial burden which the owners are naturally unwilling, or perhaps unable, to bear. That legislation is far from being effective in such cases is evident from the often luxuriant growth of noxious weeds on this type of land.

It may be contended that the land in question should be made productive, and that legislative compulsion provides the necessary stimulus to this end. Such a view, however, is doubtless quite mistaken, even if it be conceded that such land can be made productive, which is not always the case. Apart from the circumstance that much of this land might be quite unsuitable for the growth of useful crops owing to high salinity or other causes, the important fact is that there will always be, on the outskirts of a growing city, a certain amount of land with a very small earning capacity. Such land constitutes a "wide border" between the agricultural area, which is continually receding, and the suburban or manufacturing area, which is continually advancing in its wake. Only rarely does a single line of fence separate a farm from a suburban garden, or from a factory; the border is not narrow, nor is it of uniform width; there is usually a perceptible interval, several miles perhaps in width, between the advancing lines of suburbs and the retreating line of farms, and it consists of land which has gone out of cultivation and which will eventually become incorporated in the suburbs as the city area expands.

It is easy to visualise what happens; the initial settlement is surrounded by farms, and, as the village grows into a town, the agricultural area gradually spreads outwards, pushing before it the pastoral areas, the land nearest the town being that longest in cultivation. With further growth of the town the adjacent land becomes too valuable for agricultural purposes and goes out of cultivation, the process extending outwards; moreover, the land, as a result of repeated cropping, becomes deficient in certain mineral nutrients, and, with improved facilities and reduced costs of transport, it becomes more profitable for farmers to move further afield and to take up virgin land than to recondition the more or less exhausted land near the city, in the face of the rising capital value of the land due to its proximity to the city and its prospective value for residential purposes. For various reasons, therefore, this land, exhausted of much of its mineral nutrients, comes to lie idle. Such land now has a prospective value only; it has no present earning capacity, but will have such capacity in the future. Its future worth is purely conjectural, and it may have to lie idle for

10 or 20 years or longer before it becomes capable of earning anything more than a few shillings annually for agistment purposes. Land of this type is purchased as an investment pure and simple, and it is held until such time as it becomes possible to subdivide and sell for residential or manufacturing purposes.

Large areas of such land will be found on the outskirts of any growing city, and will be connected by more or less radial strips with smaller areas situated in the more densely populated suburban parts. These lands form veritable nurseries for the growth of noxious weeds, and they present a serious obstacle in the way of the State-wide control of such plants. And what is true of capital cities is true, in diminishing degree, of larger and smaller country towns, so that there are similar, though smaller, "nurseries" dotted throughout the length and breadth of the State. The eradication of noxious weeds from such areas is obviously a matter of vital importance for the successful control of weeds on a State-wide basis, but it presents some very difficult problems which have their origin in the simple fact that the cost of weed eradication is not recoverable from the land itself, since the latter has only a prospective value and is devoid of present and actual earning capacity. And it would be difficult to find a weed more at home in such situations than the Wild Onion, or *Asphodelus fistulosus.* Here is a plant declared to be noxious for the entire State; yet, in spite of the legislative strictures placed upon it, and in spite of the conscientious efforts of landholders and district councils to check its growth on farms and roadsides, it is to be found growing in the greatest abundance on the outskirts of the suburbs of Adelaide, where it continues to reign supreme over hundreds of acres of land of the type referred to.

THE VALUE OF HEDGES AND THE KAFFIR APPLE (*Aberia Kaffra*) AS A HEDGE PLANT.

[By E. W. PRITCHARD, Dip. Econ., Agricultural Botanist].

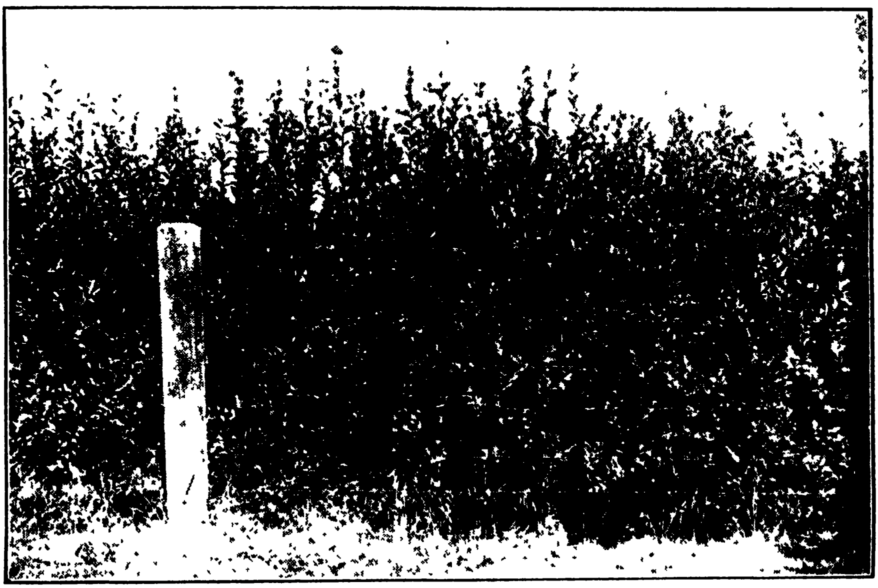
It does not seem to be generally recognised in Australia that the hedge has a very definite place in farm economy. In older countries it has always had its special uses. Among these are, first, the saving of fencing, a very valuable consideration in the days before fencing wire was invented, and still of considerable practical importance. Second, perhaps, comes the matter of shelter for stock

A single shoot of Kaffir Apple, 2ft. long, showing dark, shining leaves and long, sharp prickles.

from cold winds. And, third, the beautifying of the countryside with green shrubs and their flowers. Then as a subsidiary advantage, which has only recently been recognised, there is the provision of cover and nesting places for insect-eating birds.

Notwithstanding that Australian conditions are in most cases very different from those of England, all these reasons for the growing of hedges apply, more or less, to our own country. Indeed, in the early days of settlement, when farm operations were conducted on a small scale, hedges were extensively planted, as seen at Glenelg and Brighton and in the older hills districts, such as Mount Barker. But when through the invention of large and efficient wheat-producing machinery, farming in Australia became extensive instead of intensive, the hedge was more or less dropped out of farming practice.

Let us take the uses enumerated above and apply them to Australian conditions. The first matter of saving fencing was not of great importance in the early days because timber was plentiful and only the wire had to be bought. But even then labour was an expensive item, and again posts have a regular and incurable habit of wearing out. To-day, on the other hand, both wire and posts have usually to be bought, and labour for erecting is still dear. So, if with a little more expense, a permanent hedge can be established which will effectively restrain stock and will not need renewing, it should surely be a good proposition, even from the econmic point of view.



A young Kaffir Apple Hedge, showing dense, strong growth.

The question of shelter is even more important. For while the winter winds which sweep across our bare, open plains may not be so cold as in England, they are drier and, therefore, just as effective in reducing the temperature of the animal's body. Thus a larger amount of the food of farm stock is consumed in keeping the body warm and less goes towards productive uses. Also young stock of all classes are stunted and weakened and even killed by such conditions.

Besides this winter result, there is to be considered in Australia the annual drift of the fallows in all dry farming districts. How well we know the South Australian "brick-fielder," when some of the most valuable constituents of our northern wheat fields are lifted high in the air to be deposited away out at sea or on the shining cups and saucers of the exasperated city housewife. Surely, properly placed hedges could prevent a great deal of this irreparable waste.

The third use is, of course, a sentimental one, but yet important in making country life more refined, more varied, and more enjoyable. What can be more

dreary and uninviting than a farm which consists merely of a group of buildings surrounded by bare fallow or crops in winter, and fallow and dry grass in summer, with wire fences and iron gates for ornament. Such things were excusable, no doubt, in the early days when every farmer was busy getting his land cleared and in working order, but surely they should no longer be tolerated.

As for the last use, there is surely no country in the world which needs to conserve its bird population more than Australia. Few of our native birds were fitted to survive under the entirely new environment which had been so suddenly thrust upon them, giving them no time to adapt themselves to the new conditions. So we should surely make the best of what insect-eating species we have left and also of the few useful introduced varieties, such as the Blackbird.

A single Kaffir Apple Bush about 5 years old and 8ft. high.

Suitable Plants.

Coming now to the many varieties of plants which have been tried for hedges, there are not many which are suitable for economic planting on farms in South Australia. The properties required for general and extensive planting from a utility point of view, I would enumerate as follows:

The plant should be hardy; it should be easily propagated and quickly established. It should be strong growing and should be protected from stock by spines or prickles and should require little cutting. And perhaps, most of all, it should not have the power of spreading spontaneously.

For the cooler and moister parts of the State, notably, the Mount Lofty Ranges, the plant which fulfils these conditions best appears to be the Hawthorn. This plant is so generally known and so widely used that it needs no description here. Its only disadvantage is that it does spread in uncultivated land to some extent, but not nearly so quickly as some others, such as the Furze.

The case is quite different, however, on the plains and in the wheatgrowing areas generally. The African Boxthorn was first tried and proved quite suitable, excepting for one point; it spreads rapidly on all uncultivated lands, the seed being carried far and wide by birds, which feed on the berries. It has indeed spread so quickly that it has been necessary to place it on the list of Declared Noxious Weeds.

It is as a substitute for the Boxthorn that the Kaffir Apple should find a place on all farms in the wheatgrowing areas and on much of the pasture country. It has been grown in South Australia for at least 30 years and has proved itself to be entirely suited for the purpose. It exhibits all the desirable qualities stated above. The plant is a strong growing shrub, which reaches a height of about 15ft., the shoots giving off at intervals strong, sharp, woody spines. The leaves are dark green and shining, giving it a fresh, bright, pleasing appearance throughout the whole year. It also produces a yellow "apple," about 1in. in diameter and a perfect sphere in shape, which is edible and makes quite good jam. It is easily propagated by extracting the seeds from these fruits, planting them in drills in the autumn about ½in. deep, and covering with leaf mould. The young plants will come through the soil in early spring and should be watered occasionally during summer. Most of them will be ready for planting out in the autumn following and should be set out about 3ft. apart. The soil round the young hedge should then be kept cultivated for two or three years, and it should also be protected from stock until the plants are well grown. There are many old established hedges round the city from which a supply of the "apples" could be obtained, or the seed can be bought from city seedsmen.

Thus we have, in a few years, a dense hedge, not too broad, even if left uncut, spreading well at the bottom and quite high enough for protection from wind and beating rain, and for most of the day from the sun. As to the danger of spreading, I have never seen a specimen anywhere that has not been planted by hand.

In conclusion, let me emphasise the need for providing some such shelter for all farm animals. A beginning could be made by planting a short line of hedge along each of the two fences in four corners of the paddock. By this means some shelter would always be available which ever way the wind may be blowing. From such a beginning planting could be gradually extended until the whole farm is, shall we say, fully "hedge conscious."

SOUTH AUSTRALIAN COMMITTEE OF AUSTRALIAN DAIRY COUNCIL.

REPORT OF SOUTH-EASTERN PASTURE COMPETITION, 1934.

[Judged by E. S. ALCOCK, R.D.A., District Agricultural Instructor.]

The South Australian Committee of the Australian Dairy Council again arranged a Pasture Competition for dairymen who milk seven cows or more. The idea of these competitions is to encourage dairymen to pay more attention to the management of their pastures.

This year seven (7) entries were received and these were judged between the 15th and 23rd November, 1934. The entries were situated at Hynam, Robe, Hatherleigh, Rendelsham, Allandale, and Mil Lel, the land in these districts varying from

ironstone, gravelly loam to light limestone loam and peaty soils, which are found in reclaimed swamps. With such differences in soil type and also considerable variation in the climatic conditions, it is not easy to inspect all of the entries when they are in their best stage of development, since those at the lower end of the South-East and in lower lying situations are not at their best early in the season.

The closing date for the entries was rather late for those at the northern end of the district and probably a little too early for those in the later districts. All entries, however, were sown with different forage crop seeds and had been top dressed with phosphatic manures. These entries were judged according to the following schedule of points:—

	Points.
Bulk of pasture available per unit of area	30
Quality of pasture	25
Freedom from useless plants	20
General care and management	15
Area	10
Total	100

The points awarded to each competitor in detail are given below:—

Name and Address.	Position.	Bulk of Pasture Available. 30	Quality of Pasture. 25	Freedom from Weeds. 20	Care and Management. 15	Area. 10	Total. 100
A. C. Kemp, Hatherleigh	1	29	24	19	13	10	95

W. K. Chambers	With	drawn.					

HILLS DISTRICT, 1934.

[Judged by R. Hill, R.D.A., District Agricultural Instructor.]

Judging this year was made very difficult by the entries and particulars being submitted so late in the season, and in future judging should be made possible two months earlier. The late rains caused extraordinary growth in pastures which made the economical handling of pastures very difficult, and many of them were left to be cut for hay. In fact, some of the entries were actually being cut when inspected. Growth was so rapid late in the season that unless the pastures were in very small fields it was impossible with the livestock available to keep them grazed down as they should be to obtain maximum results.

There is need for more attention to subdivision in a district such as this competition embraces and many of the fields could be considerably reduced in area, which would make more economical grazing possible and subsequently allow the carrying of more livestock on more even and nutritious pastures. With the exception of Strawberry Clover in selected patches, the base of the best pastures has undoubtedly been Subterranean Clover and Perennial Rye Grass, and on the types of soil generally being made use of for pastures in the Hills district there seems to be nothing better.

Phalaris tuberosa was found in small quantities in some pastures, and much more of it could be used because of its ability to provide earlier feed than any other perennial pasture plant under these conditions.

One difficulty experienced with pastures is to control the inferior annual grasses that so readily appear once clover has been well established. The practice of clipping the high growth of these plants and preventing their seeding has proved to be effective and is strongly recommended. The cutting of fields occasionally for silage will also help materially in keeping such grasses under control.

That pastures have been improved considerably during the last few years is certain, but the handling of pastures after they have been established has not improved at the same pace, which means that there is too much wastage, and the quantity of livestock carried is below what it should be. Finance and not the lack of knowledge is usually the reply when this error of management is discussed with those concerned, but is it economical to continue when it can be overcome by storing reserves in the form of Silage and Meadow Hay and by subdividing the pastures into smaller fields to allow some form of rotational grazing to be carried out?

Liberal annual applications of superphosphate are essential to maintain high production in pastures, and those who felt that they could break away from that practice have, after the experience of one or two seasons, quickly realised their mistake.

The results of the judging are given in the following table:—

Competitor's Name and Address.	Position.	Density of Sward. 30	Quality of Pasture. 25	Freedom from Useless Weeds. 20	General Management. 15	Area Submitted. 10	Total. 100
H. A. Woolley, Mt. Barker J. .	1	28	22	20	13	5	88

PASTURE COMPETITION—IRRIGATED AREAS.

[Judged by R. HILL, R.D.A. (District Agricultural Instructor.]

Unfortunately the shortage of feed during winter and early spring forced settlers to graze the pastures far too severely, but they had made quite good recovery. Although judged late in the year the majority of the pastures inspected were in really good heart.

There is much to be learnt in the handling of permanent pastures under irrigation, and it was very evident that subdivision, frequent light waterings, good drainage, the selection of the correct types of plants, and liberal applications of superphosphate are to be important factors in producing maximum results from that type of fodder.

Any permanent pasture required for milk production needs the presence of a leguminous plant and White Clover adapts itself so well to the reclaimed swamp areas that no other need be sought for this purpose, but the grasses are a much more difficult problem.

Perennial Rye Grass had not given the results expected of it in any cases under a system which applications of water are too far between. Cocksfoot has only persisted well on the higher or better drained points, but where it had managed to remain, splendid feed was produced. Prairie Grass, which is a very palatable grass, makes rapid growth and produces earlier autumn feed than the other grasses; does not persist under grazing like Perennial Rye Grass but, as mentioned in Mr. Wise's No. 2 entry, it had reseeded well where the pasture has been cut for hay.

It appears that Prairie Grass should be taken very much more into consideration as a mixture in pastures and steps taken to experiment with the hope of establishing a satisfactory method of retaining it in pastures. Paspalum had produced high yields of feed during the warm months, but should only be considered as a pasture to grow on the low-lying areas in conjunction with clover and in small fields which can be kept well under control. It was rather disappointing that where there is such a large area of permanent pastures under irrigation more entries were not presented for judging.

TESTS TO DETERMINE THE EFFECT OF DIGGING OR DEEP PLOUGHING CLOSE TO FRUIT TREES WHILE IN FULL BLOOM.

[By R. Fowler, Manager Government Experimental Orchard, Blackwood.]

The question whether deep ploughing or digging operations close in to fruit trees while in full bloom would result in a diminished crop owing to root injury by implements used at this time was raised by Mr. H. N. Wicks in a paper on "Some Observations on the Cultivating of a Non-irrigated Orchard," read at a Conference of Fruitgrowers at Tanunda on 1st November, 1932. It was then decided to ask through the Advisory Board of Agriculture that experiments to determine this matter should be carried out at the Blackwood Orchard.

These tests were started in 1933-34 on peach and apple trees in the Barrier Rows in the Manure Test. The ground was ploughed in the ordinary way on 4th September, 1933. Using a single-furrow plough, the ground was worked right up to the stem of the trees to a depth of 3in. for the first three furrows, and then down to 5in. for the remainder of the land. During summer the soil was further worked with the spring-tine cultivator and harrows.

When the Elberta Peaches were in full bloom on the 21st September, each alternate tree in the three Barrier Rows was deeply and roughly dug with a four-pronged digging fork, the ground being stirred to the full depth of the fork, approximately 8in., in many instances bringing to the surface the underlying clay subsoil.

Many small fibrous roots were broken and numerous others exposed in the surface soil, where they were allowed to remain and dry out. The area dug extended out to the distance covered by the full spread of the branches, thus covering that portion of the soil adjacent to the tree, where many of the small fibrous roots are usually located.

Observations made during the growing period, which was an unusually dry one—only 316 points of rain being recorded for the five months—did not seem to indicate any loss of vigour in the trees roughly treated, nor was the quality of the fruit in any way impaired. There was no apparent difference regarding the length of annual growth or colour of foliage as between treated and untreated trees.

The crop was harvested between the 6th and 12th of February and carefully weighed. The results were as follows:—

Row.	No. of Trees in Row.	Mean Average per Tree in lbs. from Treated Trees.	Mean Average in lbs. from Untreated Trees.
1	12	101·29	78·96
2	12	92·79	90·00
3	12	72·21	68·71

In all 18 trees were treated and 18 left untreated, the average return per tree being respectively 88.76lbs. for trees cultivated during blossoming and 79.22lbs. for trees not cultivated during bloom, the difference being 9.53lbs. The observed differences are palpably insignificant and do not suggest any immediate adverse effect as a result of deep digging during bloom.

In the tests with Apples, 12 trees each of Dunn's Seedling, Jonathan, and Cleopatra were used. The routine treatment was the same as with the Peaches, the work being done in the same manner and at the same time.

In each plot six alternate trees were treated and six left untreated while the variety was in full bloom. The Cleopatras received attention on 14th October, 1933, the Dunn's Favourite on 18th October, and the Jonathans on 23rd October. With the Apples, as with the Peaches, the rough deep digging fractured many small roots and brought others to the surface, mostly in the clay subsoil. At the time of digging the soil was hard and compact as the result of heavy winter rains and two or three weeks of hot, dry weather just before the work was done. This soil condition resulted probably in greater injury to the small rootlets than would have been the case had the soil been in better physical condition. Observations did not reveal any outstanding differences in the trees during the growing period. The number of annual shoots and their length appeared to be much the same under each treatment.

The Apple trees are all the same age and are fairly even in size and development. All blossomed heavily and set good crops which were harvested before the end of April, with the following results:—

Variety.	No. of Trees in Tests.	Mean Average Crop per Tree from Six Treated Trees.	Mean Average Crop per Tree from Six Untreated Trees.	Decrease.	Increase.
		Lbs.	Lbs.		
Dunn's Seedling	12	346 83	302·42	-	44·41
Jonathan	12	185·87	168·83	—	17·04
Cleopatra	12	301·83	252·87	—	48·96

The average return per tree from the whole of the treated and untreated trees respectively being 278.17lbs. and 241.37lbs., a difference of 36.80lbs.

After allowing for crop variations due to outside factors, there would appear to be no significant difference revealed by the figures, so that apparently no serious injury resulted from the treatment. The experiment is being repeated.

DAIRY AND FARM PRODUCE MARKETS.

MESSRS. A. W. SANDFORD & Co. reported on 1st January, 1935:—

BUTTER.—Trading throughout December was satisfactorily maintained and the fact of the weather being fairly cool was responsible for a greater consumption than would otherwise have been the case. Production is falling back rapidly, but there is still a surplus of first and second grades going forward to London each week, but all the choicest now being manufactured in this State is required for home consumption. The London market showed some improvement during the Christmas week and at date of report the range was 72s. to 74s. per cwt. for choicest Kangaroo. Local rates at present are:—Choicest creamery fresh butter in bulk, 1s. 3¼d. per lb.; prints and delivery extra. (These prices are subject to stabilisation levies). Store and collectors' lots, 5d. to 5½d. per lb. according to quality.

CHEESE.—The South-Eastern factories kept markets well supplied and turnover was maintained. There was a better inquiry towards the end of the month for matured cheese and rates continued steady throughout at:—Large and medium, from 8d. per lb.; loaf, from 8½d. per lb. at store door, delivery extra; semi-matured and matured, 8½d. to 9d. per lb.

EGGS.—Supplies kept up well, although the quality, as is usual at the end of the season, depreciated. With export packing finished there are greater supplies available for local market, but at present interstate market is dull, so that heavy quantities are being manufactured into egg pulp. Rates are:—Ordinary country eggs, fair average quality, 5d. per dozen net; long distance rail or shipping eggs, lower; selected new laid clean eggs, 1¾ozs. and over, up to 7d. per dozen net.

BACON.—Trade in hams for the Christmas season was better than for a number of seasons past, but in anticipation of this curers marketed sufficient supplies to meet all requirements. Bacon sales were also satisfactory. Rates are steady at:—Best quality sides, 9½d. to 9¾d. per lb.; middles, 10½d. to 11d.; heavy middles, 9d. to 9½d.; rolls, 8½d. to 9d.; hams, 1s. 1d. to 1s. 2d.; cooked, 1s. 3d. to 1s. 4d. per lb.

ALMONDS.—The sales of almonds in shell and also kernels were very satisfactory up to within about a week of Christmas, when there was a lull in demand. However, it is expected that trading will revive again this week and that all consignments will be cleared. Rates are:—Softshells and brandis, 9½d. to 10d. per lb.; hardshells, 5½d. to 6d. per lb.; kernels, 1s. 11½d. to 2s. 0½d. per lb.

HONEY.—Sales of this commodity continued very dull, and unless new markets can be obtained in some of the Continental countries the outlook is not at all promising, as there are very heavy stocks carried over and prices are only nominal at:—Prime quality clear extracted, 2½d. to 3d. per lb.; lower grades, 1½d. to 2d. per lb.

BEESWAX.—Sold readily from week to week and values are steady at 1s. 4d. to 1s. 4½d. per lb., according to quality.

LIVE POULTRY.—Sales are held every Tuesday, Thursday, and Friday, and our salerooms are the best equipped in the State. As is usual at the Christmas markets, very heavy quantities of live poultry were submitted, but, unfortunately, a large proportion of the birds to hand were poor and medium in condition and rates obtained for such were disappointing. For prime quality heavyweight table poultry, however, good prices were realised. It is expected that markets will be short throughout January and clients would be well advised to forward any surplus stock. Crates loaned free on application. The following are prices realised:—Prime roosters, 4s. to 5s. each; nice conditioned cockerels, 3s. 3d. to 3s. 11d.; fair conditioned cockerels, 2s. 3d. to 3s. 2d.; chickens, lower; heavyweight hens, 2s. 3d. to 3s. 2d.; medium hens, 1s. 7d. to 2s. 1d.; light hens, 1s. 3d. to 1s. 6d.; couple of pens of weedy sorts, lower; prime young Muscovy drakes, 5s. to 6s.; young Muscovy ducks, 3s. 3d. to 4s.; ordinary ducks, 1s. 3d. to 2s. 6d.; ducklings, lower; geese, 4s. to 5s. 3d.; goslings, 3s. to 3s. 6d.; turkeys, good to prime condition, 11d. to 1s. 2d. per lb. live weight; turkeys, fair condition, 8d. to 10d. per lb. live weight; turkeys, poor and crooked breasted, lower; pigeons, 4d. to 6d. each.

POTATOES.—New seasons, 13s. per cwt.

ONIONS.—New season's, 9s. 6d. per cwt.

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying.	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilizers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator *v.* Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

SOUTH-EASTERN DISTRICT.

With the aid of a microphone connected with an amplifier on a motor car, officers had no difficulty in making their addresses heard at the Kybybolite Experiment Farm Field Day on November 9th.

MIDDLE NORTH DISTRICT.

(PETERBOROUGH TO FARRELL'S FLAT.)

KOONUNGA.

November 1st.—Attendance, 14.

HOW TO OBTAIN GOOD WELL OR BORE WATER.—Mr. A. H. Falkenberg read the following paper:—"This is a matter of great importance to the man on the land. It is one of the first questions to consider whenever a person acquires a property. A place without a good supply of water is always a worry to the man who is managing it. If searching for water, get into touch with someone who is good with a divining rod. With this it is possible to locate any underground veins, although it is never safe to say that they are all water-bearing or whether it is good or bad. Well sinking is a job which requires great care on the part of the men doing it. Only a good and sound rope or wire rope is good enough for the purpose. If a chain is used next to the bucket, this should be strong and have no split links, which are a great danger to the man in the well; they are likely to go sideways and break. Nor should a hook be used on the bucket; this should be fastened tight. As the work progresses and wet soil is noticed, a supply of bricks should be there in readiness for setting the walls of the well. I prefer to do it with bricks right to the top even if it is fairly rocky. Boring for water can be done by a simple method or with engine and plant. The simple method is to procure a handy bore for the soft soil, a rock drill in case rocks are encountered, and a slush pump to suck out the drilled rocks. The bore is screwed to pipes of the same size, adding more pipes as the hole gets deeper and a pair of strong tongs are used for turning the pipes and bore. When the bore is full it must be removed and emptied. In case the rock drill is used, this is worked in a jumping action, turning at the same time. Water is poured down in the pipe. It is for this that the slush pump is used to suck out the drilled rock. Boring for deep water should be let to an experienced man. Dry wells, or wells containing too salty water, should either be filled with soil or fenced off and covered. This applies not only to wells, but also to any other pit or tank. If a good underground supply is not available, then a dam in a higher position than the homestead will be useful, but it is likely to go dry in a late summer. A good water supply is a wonderful aid to success." (Secretary, H. Mibus.)

December 19th.—Attendance, 14.

THE DAIRYING INDUSTRY.—Paper read by Mr. F. Collins:—"The dairying industry is worth about £40,000,000 per year to Australia, and will be worth considerably more in the very near future. There are several well known breeds of dairy cattle, and it depends on the ability of the man in charge of which particular breed he fancies. It is important that a dairyman devote his ability and time to the breed that he thinks is most fitted to his own conditions, but if he is to be successful he must be sure that his heart is in the interests of that particular breed. Most successful dairymen now know that they must test regularly, 'cull the cows that you have to keep, and breed from the cows that keep you,' using a pure-bred bull from a proved producing cow. Pasture improvement involving the sowing of suitable grasses and clovers, regular use of fertilisers, and harrowing, are also necessary. The modern dairy cow has come to be regarded as a machine. However, it requires much more consideration than most machines. It must be managed with sound judgment and a great deal of commonsense. Its health must be safeguarded and good water is essential. A cowshed with its east side open is most suitable. In making a choice of dairy cattle, there are several breeds to pick from, the Shorthorn, Red Poll, Friesian, and Guernsey are somewhat large cattle, requiring heavier feeding than the lighter Ayrshire and Jersey breeds. On lighter grazing and in hilly country the smaller breeds will prove the better stock to handle. At present the dairying industry is going through a hard time—it is even harder for the inefficient dairyman, who still uses the 'scrub' bull: it clearly shows that the 'scrub bull' is one of the dairyman's enemies, as every pure breed society has substantially increased its membership since the drop in butter prices. It is not within the power of the average dairymen to raise the price of butterfat, but it is in every dairyman's power to get better returns from every cow. A good, pure-bred cow whcih is a heavy producer is not so costly to keep as the cow from the 'scrub bull'." (Secretary, H. Mibus.)

PIG RAISING.—The following paper was read by Mr. R. Roebuck:—"Pig raising combines with most phases of agriculture, and in these times of depression is a valuable sideline. The pig is able to convert into profit many products that would otherwise be wasted. The pig is a clean animal if housed in clean quarters. Of late years the most popular pig has been the progeny of the Tamworth boar crossed with the Berkshire sow, and for the export trade in particular, the Large White or the Large White crossed with the Mid-York sow. Export buyers prefer the white breeds because of the better colour and conformation of the dressed carcass. *Breeding*: To make pig raising fully profitable, it is essential to breed the right type of pig. The average breeder of pigs cannot, at a moment's notice, dispose of his mongrel sows and replace them with better animals, but he can adopt a policy of gradually improving his stock, and the first step in this direction is to obtain a boar of the selected breed and mate him with the sows. To improve the sows, the breeder should select from his flock those pigs which nearest approach his ideal and breed from them, and if this practice is followed with each litter, much will have been done to improve the standard of the pigs. If at any time it is desired to start cross-breeding, then a pure-bred boar should be introduced." (Secretary, L. V. Bell.)

SOUTH AND HILLS DISTRICT.

CHERRY GARDENS (Average annual rainfall, 35.03in.).

December 15th, 1934.

The December meeting was held at the residence of Messrs. A. R. Stone and Sons, there being present 13 members and 15 visitors, including representatives from the Blackwood Branch. The afternoon was spent looking over the orchard. In the evening items of interest that had come under notice during the afternoon inspection were discussed.

It is with regret that the Branch reports the death of Mr. Caleb Lewis, a life member of the Agricultural Bureau, a foundation member of the Cherry Gardens Branch, and one who, until comparatively recently, had taken an active part in the work of the Bureau since he first became a member in 1892. He will long be remembered by local members as a man who gave of his best to the Bureau. His advice could always be relied upon, and regretting his death, members look back on the influence for good his life had on the tillers of the soil of the Cherry Gardens district.

FRAYVILLE.

November 20th.—Attendance, 10.

The Crop Competition results were announced by the judge, Mr. R. Hill (District Agricultural Instructor). The scale of handicap points under which the Competition is run proved a success. It gives competitors in the lower rainfall areas a chance to get within striking distance of the higher rainfall area. Mr. J. O. Bottroff, of Palmer, gained the highest number of points (81), but G. W. Faehrmann, with a handicap of 10 points, eliminated him from first position with 89 points. The order of merit with handicap points are as follows:—1, G. W. Faehrmann, 89; 2, J. O. Bottroff, 84; 3, S. Watchel, 80¾; 4, N. Watchel, 80½; 5, A. F. Watchel, 79½; 5, H. A. Helbig, 79½; 5, H. B. Scheer, 79½; 8, T. O. Peamm, 76½; 9, S. A. Bretag, 74½; 10, L. Watchel, 74; 11, C. M. Hein, 66. Mr. M. Shearer, who was present on behalf of Shearers Limited (the donors of the prize money) then presented the successful competitors with the trophies, at the same time congratulating them on their success.

Crops recommended for seed were:—N. Watchel, Nabawa; T. H. Watchel, Nabawa; J. O. Bottroff, Sword and Nabawa; W. Faehrmann, Nabawa. (Secretary, H. Ramm.)

GOOD THINGS FROM THE OVEN.

[By Grace B. Armstrong, A. Marie Schrieber, and Mary A. McPhee, of the University of Illinois, Urbana, U.S.A.]

(*Continued from page* 428.)

FROSTINGS AND FILLINGS.

The simplest frosting is made by sprinkling sugar over the unbaked cake, While baking, the sugar forms a glaze which serves as a finish.

Frostings which are used to spread over the surface of the cake and as fillings are made of sugar and a liquid. They may be either cooked or uncooked. A frosting should be neither hard enough to crack and crumble nor soft enough to be sticky. It should be well flavoured but not too highly flavoured.

It is a bit difficult to acquire the technique of securing a smooth surface over the whole area of a cake, but skill can be acquired with practice and care. The less the frosting is touched with a knife or spatula, the smoother the surface will be.

UNCOOKED FROSTINGS.

Uncooked frostings may be made of whipped cream, jelly, jam, or confectioner's sugar and a liquid. A confectioner's sugar rather than cane sugar must be used for this purpose, since the frosting must have a smooth, well-blended consistency. Ordinary cane sugar would dissolve so readily that a syrup would be formed. The filler in confectioner's sugar tends to prevent the formation of a syrup.

Confectioner's Frosting.

Equipment.

1 measuring cup	1 tablespoon
1 mixing bowl	1 teaspoon
1 rolling pin	1 spatula or knife
1 sifter	

Materials.

2 Tb. boiling water, cream, or fruit juice	¼ t. flavouring extract
	¾ c. confectioner's sugar

Amount: Enough to cover 1 loaf cake 3in. x 3½in. x 8½in.

Method.

Roll and sift sugar to remove lumps. Gradually add sugar to liquid until mixture is of the right consistency to spread. After each addition of sugar, the mixture should be well stirred. Add flavouring. Spread on cake by using spatula or knife dipped in hot water.

Whipped Cream and Fruit Filling.

Equipment.

1 bowl	1 sharp knife
1 Dover egg beater	

Materials.

2 Tb. sugar	¾ pt. whipping cream
3 oranges or 3 bananas or 1 small can pineapple	½ c. walnuts, pecans, or hickory nuts

Amount: Enough for a 3-layer cake 9in. in diameter.

Method.

How.	*Why.*
Chill bowl, beater, and cream.	Cream that is not chilled may form butter before it can be made stiff.
Beat cream with Dover egg beater. When stiff and of smooth appearance, add sugar.	Cream should not be beaten beyond smooth, stiff stage. If beaten longer it becomes granular; this is condition of the cream just before butter forms.

Spread whipped cream on a layer of cake. Lay slices of fruit on top of cream and sprinkle on some nuts. On top layer put only whipped cream or add some decorations of citron or whole nut meats. This filling makes a very rich cake which should be eaten the same day it is prepared and should be kept in the ice box or other cold place until used. The cream will sour if the cake is not used within a few hours.

COOKED FROSTINGS.

Sugar and a liquid are the ingredients used in cooked frostings. During the process of cooking, the sugar solution is condensed. By beating the cooled product, air is incorporated and any large groups of crystals that may have formed are broken up.

Boiled Frosting.

Equipment.

1 saucepan	1 measuring cup
1 tablespoon	1 Dover egg beater
1 teaspoon	1 large bowl

Materials.

1 c. sugar
½ c. water
1/16 t. cream of tartar

1 egg white
1 t. vanilla or ½ t. lemon juice

Amount: Enough to frost 2 loaf cakes 3in. x 3½in. x 8½in

Method.

How.	*Why.*
Put sugar, cream of tartar, and water in saucepan over heat.	Cream of tartar is an acid. When cane sugar is boiled with an acid a smoother consistency results.
Stir mixture until sugar has dissolved.	Stirring prevents sugar from sticking to saucepan. It also aids in dissolving sugar crystals.
Cover pan for first 3 minutes the solution is boiling.	Steam collects on sides of pan and prevents formation of large crystals, which would fall back into the syrup and make the frosting granular.
Remove cover from saucepan.	Evaporation must take place before the syrup can condense.
Do not stir syrup after it begins boiling.	Stirring beyond this point tends to make frosting granular .because it washes back into the syrup any crystals that may have formed on the sides.
Allow syrup to boil until it forms a thread of "hairs" when dropped from tines of fork. If a thermometer is used, the reading at this stage will be 238°F. On a rainy day the mixture should be cooked longer, or to 244°F.	In rainy weather, moisture in the atmosphere prevents the syrup from hardening unless it is condensed sufficiently to allow for this. It is better to overcook the syrup than not to cook it long enough.
When cooked, remove syrup from fire. While syrup cools, beat egg white until stiff but not dry.	Beating of the egg is left until this time because egg white does not retain its lightness if it stands long after beating. However, the beating cannot be delayed too long, for syrup will require close attention at the very last. If syrup is not cooled slightly, the egg will coagulate too quickly and leave lumps.
Slowly pour syrup on beaten egg white; beat continuously with Dover egg beater while pouring. (If Dover beater is used, the person making the frosting will need assistance.)	A Dover egg beater gives the frosting a fine texture.
Continue beating until mixture is of such consistency that it will spread readily on the cake and yet remain in place. Add flavouring.	If beaten too short a time, the frosting will "run"; if too long a time it will not be smooth. A little experience will make it easy to determine the right consistency.

Put frosting on cake with as few motions as possible. Slowly pour it on centre of cake and allow it to run down sides. Smooth it around sides with a few well-directed strokes of the spatula. Allow frosting to become firm before cutting cake.

Milk Frosting.

Equipment.

1 measuring cup	1 mixing spoon
1 teaspoon	1 saucepan

Materials.

1½ c. sugar	1 t. butter
½ c. milk	½ t. vanilla

Amount: Enough to frost 1 loaf cake 3in. x 3½in. x 8½in.

Method.

Put milk and sugar in saucepan and stir until sugar is dissolved. Boil without stirring for 12 to 15 minutes, or until syrup will form a soft ball when dropped into cold water. Remove from fire. Add butter Allow to cool. (If butter is added at the last it does not lose any of its flavour. It also tends to form an oily film over the top of the syrup, which prevents many crystals from forming.)

Beat until the right consistency to spread. Add flavouring. When beating, do not scrape down any crystals or any syrup that collects on the sides of pan. Pour frosting over cake, spreading evenly with spatula or back of stirring spoon.

Chocolate Frosting.

Follow directions given for milk frosting, but as soon as the boiling point is reached add 1 or 1½ squares of grated chocolate. (If chocolate is added at first, it does not blend well, and is likely to cause the milk to curdle.)

Brown Sugar Frosting.

Equipment.

Same as for milk frosting.

Materials.

1½ c. brown sugar	⅓ to ½ c. cream
1 Tb. butter	

Amount: Enough to frost 1 loaf cake 3in. x 3½in. x 8½in.; use double the recipe for a three-layer cake 9in. in diameter.

Method.

Same as for milk frosting except that it is well to scald the milk before adding the brown sugar. (Brown sugar contains a small amount of acid. Scalding the milk before adding the brown sugar will tend to prevent the acid from curdling the milk.)

PASTRY.

PLAIN PASTRY.

Pastry is a combination of flour, fat, salt, and cold water. The proportion of fat to flour determines the richness of the product and to some extent the method of handling. In plain pastry the usual proportion is ¼ cup of fat to 1 cup of flour.

Equipment.

1 measuring cup	1 tablespoon
1 mixing bowl	1 flour sifter
1 teaspoon	1 rolling pin
1 fork	1 moulding board
2 knives	1 pie pan

Materials.

1½ c. flour	6 Tb. fat
1 t. salt	Cold water

Amount: 2 crusts.

Method.

How.	*Why.*
Have all ingredients cold.	A flakier pie crust results from cold ingredients because more air can be incorporated around stiff pieces of fat around soft ones, and also because the colder the air the greater its expansion during baking.
Sift flour and salt together.	This insures thorough distribution of salt.
Cut cold fat into flour, using two knives, or a fork.	Handling pastry with fingers warms the materials.
Use only enough water to hold ingredients together. Add slowly and toss mixture with a knife or fork. *Do not stir.*	Since any stirring or kneading develops gluten, great care must be exercised in handling pie crust, if it is to be tender and flaky.
Slightly flour board, using as little flour as possible. Toss pastry on to flour. Clean out bowl with a spatula. Using a quick motion, pat rough edges together, at same time forming dough into a circular shape.	The less flour incorporated in pastry, and the less pastry is handled, the more tender it will be.
If 2 crusts are to be made, cut dough into 2 pieces. The one for the lower crust should be slightly larger than the one for the upper.	This avoids having to roll the second crust twice.
Turn over piece of dough so that both sides are floured. Quickly shape it into a round flat surface. Roll with rolling pin from centre to outer edge, using a light, quick motion and pressing on a different part of the dough each time. Occasionally lift crust from board. (When using moulding board, be as neat and economical as possible. Practically no flour should be left on board when the product is finished.)	It may be necessary to lift dough from board or to turn it slightly to prevent it from sticking, but this should be done without stretching dough.
When large enough for the pie, fold crust in half, lift it up, place on pan, and unfold into place.	Crust is more easily handled in this way, and stretching of dough is prevented.
Press out all air bubbles from underneath the crust, beginning to press at centre of pan and working toward edge.	Air bubbles under crust make an uneven surface after baking, as a result of the expansion of air by heat. This is especially true of crust baked before filling is added.
Roll out upper crust and cut small holes in centre. Holes should be larger for a berry pie than for an apple pie.	Holes are to allow for escape of steam and to prevent pie from running over.
When a juicy fruit (berries) or a fruit which darkens easily (apples) is used it is better to make both crusts before filling is added.	If filling is added before upper crust is made, berry juice will soak into lower crust, making it soggy. Apples will become dark.
Fold upper crust in half.	

Method.

How.	*Why.*
With tips of fingers dipped in cold water moisten edges of lower crust. Place upper crust upon pie, unfold, and press edges of upper and lower crusts together. An attractive finish is made by using a fork. Cut around with a knife to make edges even.	The moistened surface causes the 2 crusts to stick together.
Place on lower grate and bake in hot oven (400°F.) about 40 minutes or until light brown.	Pie crusts should be well-baked to make them digestible, but should never be over-browned or burned.

PIE WITH PREVIOUSLY COOKED FILLING.

Method.

Prepare plain pastry, using ½ of the above recipe. Invert pie plate and cover outside with pastry. Press with finger tips, working from centre. Press crust well to plate, making sure that edge of pastry fits edge of plate. A very little air left under the pastry will expand and make a large bubble in baked crust. Trim edges to make them even. Prick crust in several places with a fork to allow steam and air to escape from under the crust. Place on baking sheet or large pan in oven, so that edge of crust will not come in contact with floor of oven. Bake for 15 minutes in hot oven (400°-425°F.) but be careful not to over-brown. Cool and fill with prepared filling.

Lemon Pie.

Equipment.

1 double boiler	1 mixing bowl
1 measuring cup	1 egg beater
1 tablespoon	1 grater
1 teaspoon	1 lemon squeezer

Materials.

¾ c. sugar	2 egg yolks
5 Tb. flour or 3 Tb. cornstarch	1 t. butter
¾ c. boiling water	3 Tb. lemon juice
	Grated rind 1 lemon

Amount: Filling for 1 pie crust.

Method.

How.	*Why.*
Mix cornstarch or flour, and sugar together.	Sugar separates the starch grains and prevents starch from lumping when added to water.
Place top of double boiler directly over heat and allow water to boil rapidly.	Much time will be saved by starting the cooking directly over the heat.
Slowly add the above mixture and continue to boil 3 minutes, stirring constantly.	Adding mixture slowly prevents lumping. Product burns easily and should not be allowed to remain directly over heat for more than 2 or 3 minutes.
Place the 2 parts of double boiler together. Cook for 20 minutes over boiling water. Add butter.	Thorough cooking is necessary to overcome the raw taste of starch.

Method.

How.	*Why.*
Remove from fire and cool slightly; beat egg yolks and add the mixture to them. (The egg whites will be used for the meringue.) Return to fire and heat only until eggs thicken slightly.	If eggs are added to mixture they will be cooked too hard and will form lumps.
Remove from fire. Add lemon juice and grated rind. Stir and beat well.	If acid were added at first, mixture would not thicken well.

Pour filling into prepared pie crust, cover with meringue, and place in slow oven (300°F.). Remove when meringue is a delicate brown.

MERINGUE.

Equipment.

1 platter or large bowl	1 tablespoon
1 egg whip	1 teaspoon

Materials.

2 egg whites	½ Tb. lemon juice or
2 Tb. powdered sugar	¼ t. vanilla

Amount: Enough to cover 1 pie.

Method.

Beat egg whites until stiff. Add sugar gradually and continue beating. Then add flavouring. Pile on the pie lightly, taking care to cover only the filling. The finished product should not look flat and uniform; it is more attractive if uneven. Brown in slow oven (300°F.).

PUMPKIN PIE.

Equipment.

1 mixing bowl	1 egg beater
1 measuring cup	1 stirring spoon
1 teaspoon	1 strainer

Materials.

1½ c. steamed and strained pumpkin	½ t. salt
⅔ c. brown sugar	2 eggs
1 t. cinnamon	1½ c. milk }
½ t. ginger	½ c. cream } or 2 c. milk

Amount: Enough for 1 large pie.

Carefully strain cooked pumpkin. Mix sugar and spices together and add to pumpkin Beat eggs until whites and yolks are thoroughly mixed but not frothy. Add other ingredients and stir until thoroughly blended. Taste the mixture, using a clean teaspoon. Make any necessary additions according to taste.

Prepare a crust of plain pastry, and line a pan with it. The crust may be made deeper by making a fluted edge. Instead of cutting off uneven edges, fold them back and under slightly; pinch dough together by using thumb and forefinger of each hand, pressing hands towards each other. Pour in pumpkin mixture.

Bake at once in hot oven (425°F.) for 20 minutes. Reduce temperature to 25°F. and bake about 30 to 40 minutes more.

BERRY PIE.

Prepare two crusts. Wash and carefuly drain the berries. When filling the pie with berries or any other juicy fruit, it is necessary to mix flour with the sugar before sweetening the pie. Use 1 tablespoon of flour or minute tapioca to ½ cup of sugar. The flour or tapioca thickens the juice and prevents it from soaking into the crust. The amount of sugar needed in a pie will depend upon the tartness of the fruit used.

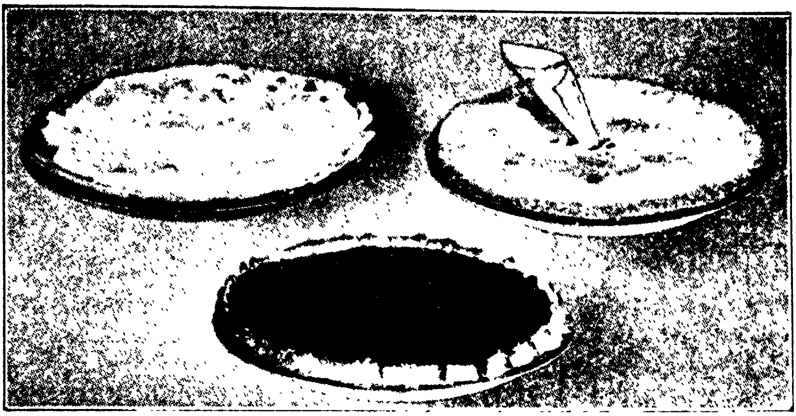

Fig. 18.—Lemon Meringue, Berry, and Pumpkin Pies.

Fig. 19.—Cinnamon Rolls and Yeast Bread.

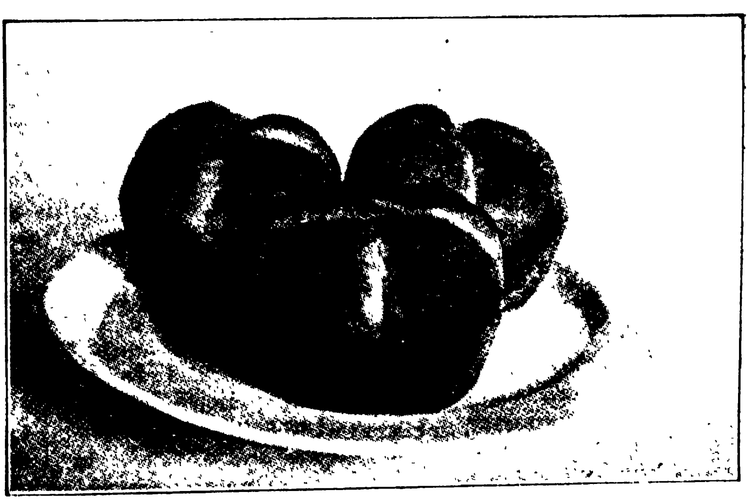

Fig. 20.—4H Clover Leaf Rolls.

Insert a paper funnel in one of the openings in the upper crust. The funnel acts as a chimney, allowing the steam to escape and preventing the pie from running over.

Bake in moderate oven (about 350°F.) until the crust is a light brown and the juice bubbles up in the opening of the top crust.

APPLE PIE.

Materials.

Pastry for 2 crusts	1 t. cinnamon or ½ t. nutmeg
2 or 3 sour apples, or enough to fill the pie	½ to 1 c. sugar

Amount: 1 pie.

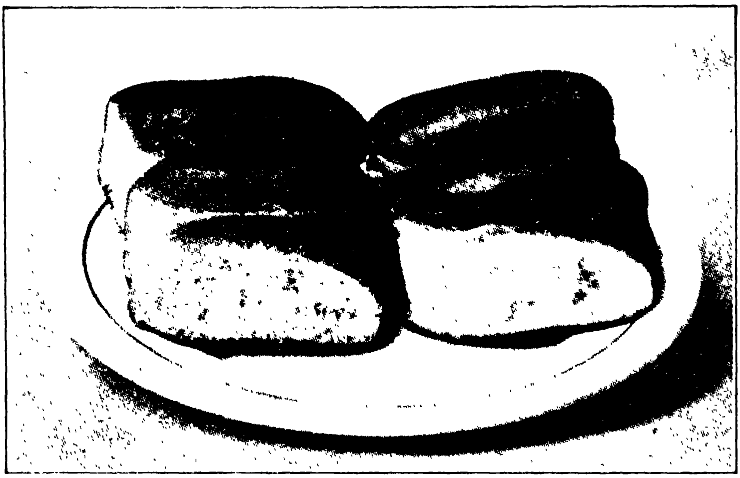

Fig. 21.—Parker House Rolls.

Method.

Prepare the crusts before paring the apples, for apples turn dark very quickly after paring. Pare apples and cut them in small pieces. Put them in the crust, filling it very full. (An apple pie can have more filling than a berry pie or one with much juice.) Mix the spice and sugar together, using ½ to 1 cup of sugar to 1 apple pie, the exact amount depending upon the tartness of the apples, and 1 teaspoon of cinnamon. Sprinkle the sugar and cinnamon evenly over the apples. Put on the upper crust, following general directions for plain pastry (see page 58).

Bake in hot oven (425°F.) for about 10 minutes; reduce temperature to 350°F. and bake until apples are soft. Test with a clean toothpick inserted through one of the holes in the upper crust.

RICH PASTRY.

A rich pastry can be made by using ⅓ cup of fat to 1 cup of flour. Butter makes a tougher but a flakier pastry than does lard and also gives a better flavour. Part butter and part lard is a good combination for a rich pastry. When substituting butter for lard in pastry, remember that butter is not 100 per cent. fat, and so more butter must be used than is stated in the recipe. In general, two tablespoons butter should be added for each cup of pure fat required. Care must be taken to keep the ingredients cold during the mixing process. The baking must be done carefully to prevent scorching the fat.

YEAST BREADS.

PROCESSES OF MAKING.

Bread may be made by either of two processes, depending upon the time allowed. They are commonly called the short process, or straight dough method, and the long process, or overnight sponge.

Short Process, or Straight Dough Method.—All the flour is added at the time of mixing. A stiff dough is kneaded, is permitted to double its size, is made into loaves, and is again permitted to double its size. Either compressed or liquid yeast is used in order to hasten the process, as this yeast is already in an active state. This process may be completed in 3 to 5 hours, depending on the amount of yeast used and the temperature at which it is kept.

Long Process, or Overnight Sponge.—Dried yeast is used for this process As the yeast plants in dried yeast are in less active form, they must be given more time to develop, and their food must be easily available. As the yeast plants do not grow so readily in a stiffer dough, a thinner sponge is made by adding only part of the flour. The sponge usually is allowed to stand overnight. Then the remainder of the flour is added and the rest of the process is the same as for the short method.

INGREDIENTS USED.

Flour, liquid, and yeast are essential ingredients in making yeast breads. Besides these, salt and sugar are usually used. Salt improves the flavour of bread, but if used in larger proportions than 1 teaspoonful to each loaf the action of the yeast is retarded. Sugar hastens the growth of the yeast, but too much sugar toughens both the crust and the crumb. Results show that 2 teaspoonfuls of sugar per loaf is the best amount to use.

KNEADING.

In kneading, use the lower part of the palm near the wrist; curve the fingers to keep the dough from flattening out too much. With every push, turn the dough one-quarter way round and fold over. When bread is kneaded enough, it is quite smooth and elastic, bubbles appear beneath the surface, and it is spongy to the touch. In making the loaf, shape the dough in the hands, working it very lightly and stretching the underside, which will form the top of the leaf. Shape into an oblong piece and place in baking pan. The main point to watch in shaping the loaf is the smoothness of the surface; the corners will fill out in rising.

POINTS IN BAKING YEAST BREADS.

Baking bread in single-loaf pans has been found more satisfactory than baking several loaves in one large pan. Standard size bread pans are 8½in. long, 3½in. wide, and 3in. deep; they hold a 1lb. loaf. This size allows the air to circulate evenly, and insures a well-shaped loaf. If the loaves touch each other, the heat cannot penetrate between the loaves readily, and the side exposed to the heat will rise more rapidly than the unexposed side, resulting in a misshapen loaf. If a large number of loaves are baked at the same time so that the oven is crowded, it is well to change the position of the pans occasionally so that all the loaves may bake evenly. Covering the loaves for the first 10 minutes of the baking period with a bread pan will insure a more uniform shape. The edges of the inverted pan should be greased to avoid sticking.

Loaves of bread made with the proportions given should bake for 45 minutes. The bread should begin to brown in 15 minutes, after which time the temperature should be reduced gradually. Bread should be baked in a hot oven (about 410°F.) for 1 hour. In the absence of a thermometer, one of the following tests may be made:—Place a piece of unglazed white paper of medium weight in the oven; if it becomes golden brown in 5 minutes the oven is about right for the bread. Or,

sprinkle ½ teaspoon of flour on a small tin in a layer ¼in. thick; if it becomes a golden brown in 5 minutes, the temperature is probably about right. These tests are not accurate, but may be of some assistance to the beginner.

Bread is done when it shrinks from the sides of the pan and has a hollow sound when tapped.

The amounts in the recipes given below should be increased in proportion to the number of loaves desired. An exception is yeast, 1 yeast cake being sufficient for 4 loaves of bread. The following proportions are used for 4 loaves:—

4 c. liquid	4 t. shortening
8 t. sugar	1 cake yeast
4 t. salt	3 to 4 qts. flour

SHORT PROCESS YEAST BREAD.

Equipment.

Moulding board	1 flour sifter
1 measuring cup	1 mixing spoon
1 teaspoon	1 mixing bowl
1 saucepan	1 bread pan

Materials.

1 c. liquid (skimmed milk, water and whole milk or water)	1 t. salt
	1 t. shortening
	½ cake compressed yeast
2 t. sugar	3 to 4 c. flour

Amount: 1 loaf.

Method.

How.	*Why.*
Scald milk or boil water.	This kills any bacteria present that might impair flavour or texture of bread.
Put sugar, salt, and shortening in mixing bowl and pour scalded liquid over them.	This is an easy way of melting shortening and dissolving sugar and salt.
Allow mixture to become lukewarm (80°F.).	A boiling temperature would kill yeast plants.
Soften yeast in a little of lukewarm liquid and add to rest of ingredients.	Blending yeast in liquid insures its being more evenly mixed.
Add flour gradually and beat until dough is stiff enough to be handled on a board.	It will probably take some practice to find the exact amount of flour needed. Since different kinds of flour absorb different amounts of liquid, no exact proportions can be stated.
Sift small amount of flour on to dry, clean board.	This prevents sticking, but too much flour will make bread heavy.
Turn dough on to board and knead until it is elastic and does not stick to board or hands. If dough sticks, clean board by scraping with a knife. Grease board slightly, then continue kneading.	At least 10 minutes will be required to knead dough so that all yeast plants may be scattered throughout mixture and all ingredients thoroughly mixed. Proper kneading is necessary if bread is to have a smooth texture with evenly distributed holes throughout. Kneading also makes the gluten more elastic.

Method.

How.	*Why.*
Keep dough soft.	Better bread can be made from too soft rather than from too stiff dough.
Place dough in greased bowl and oil top of dough to prevent formation of crust. Cover with clean towel. Leave in warm place until dough has doubled in bulk.	A temperature of 80°F. is favourable for growth of yeast plants.
Turn on to board, knead lightly, and shape into loaf. Place loaf in greased bread pan and set in warm moist place until it has again doubled in bulk. Moisture may be obtained by placing pan of boiling water near loaves.	A lighter loaf is made by giving yeast plants plenty of chance to develop. A gas (carbon dioxide) is freed as yeast develops. This gas, in trying to force its way to top, causes mixture to rise.
Bake in hot oven (410°F.) from 45 minutes to 1 hour. Remove from pan and place on rack to cool.	Placing loaf on a rack allows air to circulate freely on all sides so that bread will not become steamed.

LONG PROCESS YEAST BREAD.

Same as for short process.

Materials.

1 c. liquid	1 t. salt
¼ cake dry yeast	1 t. shortening
2 t. sugar	3 to 4 c. flour

Amount: 1 loaf.

Method.

How.	*Why.*
Soak yeast for about 20 minutes in ¼ cup warm liquid to which ¼ t. sugar has been added.	Dry yeast is not in an active state and the growth of cells must be started.
Scald rest of liquid and add to sugar, salt, and shortening, and cool until lukewarm. When lukewarm, add softened yeast.	This is an easy way to melt shortening and dissolve salt and sugar. Too great heat destroys yeast cells.
Add about half the flour, or enough to make a batter that can be beaten easily.	Yeast plants grow more readily in a thin than in a stiff dough.
Beat thoroughly for several minutes.	Beating incorporates air, which assists in growth of yeast cells.
Cover well and let stand overnight in warm place. (Temperature should not exceed 75°F.). In morning add rest of flour and knead well.	Standing overnight gives inactive yeast cells time for growth. From here on, method is the same as in short process.
Let rise to double in bulk. Shape into loaves and again allow to double in bulk. Bake in hot oven (410°F.) from 45 minutes to 1 hour. Remove from pan and place on rack to cool.	A lighter loaf is made by giving yeast plants plenty of chance to develop. A gas (carbon dioxide) is freed as yeast develops. This gas, in trying to force its way to top, causes mixture to rise.

VARIATIONS OF YEAST BREAD.

Entire Wheat or Graham Bread.—Equipment is same as for short process except for addition of tablespoon.

Materials.

1 c. liquid	1 t. salt
2 Tb. molasses	2 c. graham flour
¼ to ½ yeast cake	1 c. flour or more

Amount: 1 loaf.

Method.

Either the long or short process may be followed, the smaller amount of yeast being used for the long process and the larger amount for the short process. In the long process the white flour should be used to make the sponge. Graham bread should not be allowed any longer time to rise than white bread, for it will never rise as much as bread made of white flour.

Raisin, Currant, or Nut Bread.—One-half to ¾ cup of raisins, currants, or nuts may be added to the bread just bfeore the first kneading.

Raisin Biscuits.—Part or all the bread dough may be made into biscuits. Proceedceed the same up to time of shaping loaves; then add raisins. Cut or pull small pieces of uniform size from dough and shape in same way as for loaves. Place in baking pan and spread with melted butter. Allow to rise until 3 times the original size, and bake in hot oven (410°F.) 20 to 25 minutes depending on the size of biscuits.

Clover-Leaf Rolls or Biscuits.—Ingredients are used in the same amounts as for bread, except that the amounts of fat and sugar are doubled. Take small portions of dough and roll with hands into balls about ¾in. to 1in. in diameter. Place in well-greased muffin rings, using 3 or 4 pieces to each ring, to make either a 3- or 4-leaf clover. Brush rolls with melted butter and allow to rise until 3 times the original size, or very light. Bake in hot oven (410°F.) about 20 minutes.

Cinnamon Rolls.—Use same dough as for clover-leaf rolls. Roll a portion into an oblong piece about ¼in. to ⅜in. thick. Spread with melted butter and sprinkle with cinnamon and sugar that has been mixed together in the proportion of ½ teaspoon of cinnamon to 2 teaspoons of sugar. Currants or raisins may be added. Roll like a jelly roll and press edges firmly together. Cut in slices 3in. thick and place on greased pan. Let rise until 3 times original size. Bake in hot oven (410°F.) about 25 minutes.

Parker House Rolls.—Use same dough as for clover-leaf rolls. When ready to shape, roll dough about ½in. to ⅜in. thick on lightly floured board and cut with biscuit cutter. Dip handle of case knife in flour, and with it make a crease through middle of each piece. Brush half of each roll with melted butter, fold, and press edges together. Place rolls in greased pan, about 1in. apart. Cover with clean cloth and let rise again. Bake in hot oven (410°F.) about 15 minutes.

HOUSEHOLD HINT COMPETITION.

Conducted by the Belalie Women's Branch and judged by a committee from the Wepowie Women's Branch, who awarded first prize to Mrs. P. Frost, who submitted Hint No. 13. For second place the committee selected Hints Nos. 21 and 30, which were sent in by Mesdames Frost and Haskard:—

1. *Water* is the most useful thing in the house, as it is used for drinking, cooking, cleaning, washing, bathing, watering the garden, and hundreds of other purposes.

2. *To use stale bread and left-over crusts*: Bake crusts in oven until brown and crisp. When cold, put through mincer and store in tin ready for use. These can be used for fish, cutlets, patties, or chops, &c.

3. Place a sheet of paper under the blanket when ironing and the blanket will never slip.

4. *Nutmeg Hint*: Put nutmeg through the mincer, then into pepper shaker to sprinkle over puddings, &c. Saves time and the nutmeg is sprinkled evenly in this way.
5. Sulphur mixed with castor oil is excellent for healing sores, particularly those of chickenpox.
6. A perished hot water bag cut at one side, filled lightly with crumpled newspapers, and sewn up again can be used to kneel on when scrubbing floors.
7. *A beauty hint*: Keep a piece of pumicestone on the bathrack and when taking a hot bath, after soaking it for a few minutes, rub the soles of the feet carefully with the pumicestone, and especially any place where hard skin or corns are at all inclined to form. This remedy will prevent many foot troubles. If the feet and ankles become tired or swollen in warm weather, they will be much benefited by being rubbed at night with pure methylated spirit.
8. When hands are stained through peeling fruit or vegetables, rub them with a mixture of vinegar and salt. It will very quickly remove all stains.
9. The juice of a lemon added to the water in which a lettuce is soaked makes it beautifully crisp.
10. To save in washing up, always grease the bottom of the saucepan before placing on the fire. A piece of flannel attached to a stick and kept in a tin with melted fat is an easy way.
11. Thin raw starch applied to windows, allowed to dry, and wiped off with a soft cloth is an excellent cleanser and polisher.
12. Cloudy ammonia sprinkled on a wad of newspaper and rubbed on window-panes will keep flies off them.
13. *To help croup*: Soak a flannel in 1 dessertspoon each vinegar and methylated spirits, 2 dessertspoons water, and wrap round the throat.
14. 1 teaspoon of cream of tartar in 1lb. of dripping will make the dripping equal to butter for cooking.
15. *To clean aluminium saucepans*: Boil rhubarb for 10 minutes in saucepan and it will clean like new.
16. When arranging flowers in an open bowl or vase, first put in a piece of small-mesh wire netting and the flowers will stay in place much easier than without the wire.
17. When cleaning windows polish with newspaper and it will give a brilliant shine.
18. To get double the quantity of juice from a lemon warm in the oven before squeezing.
19. Orange peel dried in the oven makes excellent kindling.
20. After addressing the label of a bag or trunk and when the ink is quite dry, rub a warm candle all over the label. This will make it rainproof and stop the ink from running.
21 and 30. *To make a lettuce crisp*: Put it in a bowl of water with an ordinary steel knife.
22 and 40. When sealing jam, preserves, &c., with paper, mix Epsom salts with flour paste. This will prevent rats, mice, or cockroaches from interfering with the contents.
23. *A hint for busy times*: Before shearing or harvest begins, when lunches are required for many extra men, make up a large quantity of self-raising flour, have plenty of cleaned currants and sultanas on hand, also a supply of good clarified dripping.
24. A strong and attractive beach or tennis purse can be made from coloured deck chaircanvas. The material can be bought at a reasonable price and will wear for years.
25. A piedish or basin which is difficult to get cleaned, if damped and turned upside down for a few minutes will wash clean quite easily without any scraping.
26. *Floor stain*: To brighten up boards which have previously been stained, ½lb. shellac, ¼lb. resin (rolled), 1½ bottles methylated spirits. Leave for 24 hours and shake occasionally.
27. To remove ink stains from linen, rub with raw tomato juice. If one application is not effective, try again.
28. When making fruit salad, soak the oranges first in boiling water, letting stand for five minutes. The white, pithy part will come off quite easily with the skin, and the orange is left clean for slicing.
29. *Pure grape vinegar*: Procure a large open-mouth earthenware vessel and fill with well-bruised grapes, stems included. Cover with muslin and let stand until all fermentation is completed. This will take perhaps six months. Strain and bottle. This makes very strong vinegar, and good for home use, pickles, &c. Doradilla grapes make good light vinegar and dark grapes the dark vinegar.
31. *To lengthen the life of lustre wear*: Draw lengths of material or pyjama cords through garment before putting on line—pegs always make runs in same.
32. Nothing makes corned beef more tender than a piece of washing soda no bigger than a pea. Put the meat on in cold water and bring to the boil, then drop in the soda and some sugar, and simmer.
33. After singeing a fowl and before opening, wash in warm water with a cloth, using a little common soap; it cleanses the skin and makes it more wholesome for eating.

34. Put all ingredients for making soap into a kerosene tin and stand in water over a brisk fire. This only needs stirring occasionally, which saves time. Time for boiling, 3 hours.

35. *Leaking jug*: A coat of bath enamel inside of a leaking water jug will cure the leak, and if there is a hole, it may first be filled with white sealing wax. This will stand boiling water and last for years.

36. Lemon rinds boiled with tea towels keeps them a good colour.

37. Keep the coffee essence bottle wrapped in a paper bag. This will catch the drops and obviate sticky shelf and fingers.

38. When a tank shows signs of a leakage, clean the part and brush over with paint. Then stick on a new piece of calico. Paint again and stick on another piece of calico. Then brush some more paint over.

39. Empty cotton reels nailed to the kitchen wall make useful pegs on which to hang damp towels and dischcloths, as they do not rust or tear the cloth as easily as nails. They can be enamelled as desired.

41. When jam is boiling, if a teaspoonful of butter is added it will prevent scum from settling on the top, therefore saving the jam.

42. To prevent bananas going black when cut sprinkle with lemon juice.

43. To make a dustless duster, soak in kerosene and dry until rubbed on a white board makes no mark.

44. To repolish furniture, a little olive oil and vinegar rubbed on furniture, and then rub briskly with a dry cloth.

45. When boiling green peas put two or three of the pods in the water to preserve colour of the peas.

46. To remove spots from a woollen skirt, wear the skirt in the house for a few days inside-out. The friction will do the rest.

47. Newspaper screwed up and damped makes splendid fuel for the bath-heater.

48. Boracic acid added to water when washing handkerchiefs whitens them.

49. Add a pinch of sugar to water in rose bowl. This lengthens the life of roses and prevents drooping.

50. Add a pinch of baking powder to mashed potatoes to make light and fluffy.

51. Warm the basin when boiling water before beating eggs for a sponge. Eggs are much lighter and beat more quickly than in the ordinary way.

52. Failing a "mendit," use a patent fastener when the aluminium saucepan leaks.

53. To keep vegetables fresh for several days, keep in an airtight tin.

(Secretary, Mrs. E. Orchard.)

AUBURN (Average annual rainfall, 24in.).

November 30th.—Attedance, 21.

HOME SWEET MAKING.—The following paper was contributed by Mrs. Burfield:—"An aluminium or enamel saucepan to hold more than the amount of the ingredients is the first essential. Any kind of stove can be used although a kerosene one or a primus, the heat of which can be controlled evenly, is preferred. If a wood fire is used it is advisable to have the fire going some little time before ready to start. Be sure that the sugar has thoroughly dissolved before the mixture starts to boil and always boil rapidly. After the mixture boils, put on the lid of the saucepan for two minutes, remove the lid, and wash down the sides of the saucepan with a brush that has been dipped in warm water. Never allow the brush to touch the syrup. To 1lb. of sugar add ¾ cup of water. If more water is added it takes the toffee longer to reach the desired temperature. There are 3 stages in sweet making: 240°, 'caramel stage,' or if the mixture is dropped in cold water it can be rolled in the fingers without adhering to the fingers; 310°, 'toffee stage,' which when dropped in water should snap like glass; 230° is for cocoanut ice and other sweets that have to be beaten. Glucose is often used in the making of sweets, but cream of tartar or tartaric acid can be used as a substitute in many recipes. Never stir toffee after the sugar has boiled, but caramels need stirring all the time." *Toffee Recipe*: 1lb. sugar, ¾ cup water, a little glucose or cream of tartar. Boil to 310°. Add a little butter as the toffee is being taken off the fire, and then pour on to almonds on a buttered dish. *Caramels*: 1 large cup of sugar, 1 level tablespoon flour, stir well together then add piece of butter size of egg, 2 tablespoons golden syrup, ½ cup milk. Boil quickly for ½ hour, stirring all the time. Test by dropping a little into cold water. If there is a soft ball, pour out and leave to set. Before quite cold, cut and shape. Wrap in paper to keep. *Turkish Delight* (Mrs. Jones): 2ozs. gelatine, 2lbs. sugar, ¾ pint boiling water, 1 teaspoon citric acid, essence of lemon, colouring. Soak gelatine in cold water until limp, put into a saucepan with sugar, boil 5 minutes then add citric acid and boil 1 or 2 minutes. Add essence and colouring, pour on to wetted dishes and leave until set. Cut into cubes and roll in icing sugar. (Secretary, Miss L. Dennison.)

PENOLA.

December 5th.—Attendance, 25.

EGGS.—Paper read by Miss L. McKay:—"When we partake of some particularly luscious sweet meat, cake, or other table delicacy, how often do we give a thought to one ingredient without which our bill of fare would be very poor indeed. Can we imagine a kitchen without a supply of eggs in its store? They seem as much an essential as flour or sugar.

Looking back upon the days of the early Britons, you may remember that historians have given us to believe that the table dainties of those far distant days consisted of loaves of sodden dough, but it is not easy to trace first when or where eggs entered upon the list of table luxuries.

Probably some cook (undoubtedly a woman) dabbling in some original ideas in a cave kitchen, produced a remarkable result when experimenting with eggs, a result that was to create most astounding changes in the culinary art, and thus hand down through the ages of what we really owe to this humble agent, as being the principal factor in most branches of modern cookery, and for many other purposes as well. To contemplate a table spread with wonderful examples of the culinary art, must surely cause any of us to realise what a debt we owe to our egg-producing birds. Hens, of course, are the principal egg producers, and quite often ducks supply the necessity and, in some rural districts, swan eggs have been used.

The eggs of the aquatic birds, as a rule are heavier in colour and flavour than those of the ordinary hen, and whilst some people prefer them for eating, yet they are not considered favourably for the baking of light cakes. Turkey eggs may be regarded as something unusual, being somewhat rare, and they have a very pleasing flavour. What may be regarded as a luxury and was at one period regarded as being portion of the royal feasts of the kings of old, are the eggs of the pea-hen. Too heavily flavoured, and extremely rich, one cannot imagine them as being daily fare, but it is easy to imagine them being favoured by the early day royalties, who were noted for their passion for highly seasoned and richly flavoured foods, and their gluttonous feastings.

Eggs vary in size, shape, and colour, and rather strangely the heavier the breed of the hen, the smaller the egg. Light breeds, such as the White and Brown Leghorns, and the Minorcas, produce very attractive eggs, large and white, whilst the eggs of the heavier fowls are usually smaller and of brown shades. Apart from their value as an ingredient in cake and pudding mixtures, eggs are of very special value in so many other branches of housekeeping.

'Necessity is the mother of invention,' so runs the old adage, and in no case is it more truly spoken than of the egg, as it so often has to play a very prominent part in the affairs of life, when more valued articles are unobtainable.

In cases of non-corrosive metallic poisons, such as arsenic, copper, lead or zinc, quantities of egg and milk administered after an emetic are soothing and stimulating. Eggs are of great importance in invalid dishes, and for young children they are invaluable, the yolk containing vitamins which are essential to the growing child. These are but a few of the many uses we may put eggs to, and most people have had, no doubt, occasion to utilise eggs in other directions.

A competition for the best ½doz. eggs was judged by Mrs. Thos. Oswald and Mrs. F. J. Kidman. Points awarded were:—(1) Mrs. A. H. Reschke, 3 points; (2) Mrs. A. J. Ricketts, 2 points; (3) Mrs. R. Lynn, 1 point. (Secretary, Mrs. Edith Kidman.)

SHEOAK LOG.

December 6th.—Attendance, 27.

GARDENING HINTS.—The following points are taken from an address given by Mr. P. Gwynne, of Gawler:—The preparation of soil was most important. Here a gardener could learn a lot from the farmer if he worked his garden the same way as a farmer worked his fallow. One common mistake in gardening was the use of too much manure, especially in the growing of Antirrhiniums and Stocks. Poppies, Sweet Peas, and Dahlias required carefully prepared soil. For seed raising, the soil should not be too rich and well pressed down in boxes. All seeds should only be planted their own depth. Sieved soil and fine manure should be used to cover them. Large seeds such as Zinnias were best sown straight into the flower beds then there was no setback by transplanting. Every gardener was faced with disease. Mealy bug was one of the most common pests found in the fernhouse. Painting everything with methylated spirits would destroy this pest eventually. Slugs and snails were found in every garden in cool weather. Lime sprinkled over the ground was a help, but the best plan was to pick them up." (Secretary, Miss K. Koch.)

TAPLAN.

November 21st.—Attendance, 22.

CULTIVATION OF RHUBARB.—Mrs. Schwerdt read the following paper:—"Rhubarb is a profitable and palatable crop, worthy of a place in every garden. It has decided medicinal properties of no mean consideration; it is easily grown, and with a little attention will last upwards of 20 years. Being a perennial, any extra attention to soil preparation is adequately repaid. Rhubarb requires, for best results, a fairly deeply worked, rich, light, sandy loam, and it should be perfectly drained. Heavy soils are improved by addition of sand, humus, &c., for rhubarb is usually not very profitable on heavy land. The plant is a very gross feeder, so, whilst preparing the soil, work in heavy supplies of manure, and break the soil to a fine tilth. It is better to plant roots, rather than wait for seeds to grow. Plant the roots from early May to late August, in rows 4ft. apart, and leave 4ft. between the plants in the rows. Do not cover the crowns with more than about 2in. of soil. Keep the ground regularly cultivated to destroy weeds and conserve moisture. It will be necessary to continue this treatment regularly until the roots cover the ground. Old established plants should be given a liberal dressing of old manure every autumn to maintain their vitality and ensure a heavy crop for the following season. Some of the best varieties are 'Copp's Winter,' 'Early Albert,' and 'Wilson's Ruby,' also 'Cherry' rhubarb."

INTERESTING AND APPETISING LUNCHES (Mrs. Galley):—"In preparing sandwiches for lunches, bear in mind the fact that they usually are not eaten immediately, and therefore a centre that aids in retaining moisture is always of benefit. In this regard also much may be done by suitable packing of the sandwiches when cut, and in this respect too much emphasis cannot be given to the value of vine leaves whenever procurable as a wrapping. Vine leaves, washed and shaken to take off surplus moisture, combined with the use of grease-proof lunch wraps, will keep a lunch for many hours in the same condition as when it was first packed. The first suggestion is the use of seeded raisins or sultanas with thinly cut brown bread. This is a very simple recipe, but a delightful change from the everlasting meat sandwich. The use of brown bread in itself makes an interesting change in sandwich preparation, and another centre which is particularly suitable for use with it is marmite with chopped pickled shallots or onions. Thin slices of Kraft cheese with slices of onion always make an appetising centre for either brown or white bread, while for use with white bread, finely cut lettuce with egg is a pleasant change from the usual plain egg sandwich. Curried egg is also a good change for those who like curry. Brain and walnut is an extremely tasty and appetising filling for sandwiches. Apart from the sandwich portion of a lunch, there are certain kinds of cakes which definitely pack better than others; and again, raisins can be used in the preparation of raisin loaf, which is very appetising and wonderful for remaining moist over a long period. Nut bread is simply made and a great standby, which is enjoyed by everybody. The firmer types of cakes are most suitable for lunch preparations; sponges and such like cakes have a tendency to crush."

YEAST AND YEAST CAKE (Mrs. Scheadel).—*Yeast*: Boil 1 fair-sized potato with a little hops the size of a 2s. piece with 1½ pints of water for half an hour, strain and cool. Add 1½ cups of sugar and a little stale yeast. Ready to use in the morning. *Yeast Cake*: 4lbs. plain flour, 1½lbs. sugar, 12ozs. butter or lard. Melt the butter, 6 eggs, beat essence of lemon, vanilla, and cinnamon into them. Grate a little nutmeg into the flour, 4 cups sweet milk, about 3 pints of yeast; knead in the morning. It takes six hours to rise. Six or seven cakes can be made from the mixture. *The Top*: 1½ handfuls of sugar, 2 of flour—that means for each cake ¾lb. of butter or lard, melted. Flavour it with essence of lemon, vanilla, and cinnamon; a little nutmeg also. Rub the melted butter into the flour and sugar, then when the cake is ready to put in the oven rub it over with melted butter and put on the top. A few almonds can be chopped and sprinkled on. For an alternative top of cinnamon and sugar, apricots cut in halves and sprinkled with sugar can be used. Plums may be used in place of the apricots, or apples peeled and cut in quarters and sprinkled with cinnamon and sugar add variety." (Secretary, Mrs. Flynn.)

WILMINGTON (Average annual rainfall, 17.43in.).

November 8th,

HINTS ON COOKING FOR SHOW PURPOSES.—Mrs. M. A. Schmidt read the following paper:—"When the exhibitor has decided in which classes to compete, study the show catalogue and follow it closely. Do not deviate in the slightest from what the entry asks for. First prepare the ingredients, and do not put a pinch of anything more or

less than the recipe asks for, especially in the 'rising.' Remember this especially, for very often it is the cause of the entry not being on the prize list. Cakes are spoilt by just that pinch over which makes the cake rise too much, and the small holes in nice cakes evenly cooked are too big. The holes in a good cake should be uniform and small as well as even, and cut lightly and clean from the knife. The show catalogue asks for a collection of biscuits—six of each. On some plates there are five proper biscuits and one odd one is put in to make up the number. This spoils the whole entry and it is disqualified by the judge. Frequently the mixing is wrong—some make one mixing to do the lot or nearly so. This cannot be done and not detected. A couple of plates can be made out of one mixing, but do not make more, unless some spices or chocolate are added to alter the appearance. I advise nicely shaped biscuit-cutters for show purposes. Lightly ice if for fancy biscuits. The arranging often loses points for the exhibitor. Nice clean d'oyleys, linen or lace for preference, on an attractive open tray in small dishes may gain points. If plain goods are catalogued do not ice; if fancy goods, trim with a light hand, the less the better, so long as they are attractive, using for a finish a few silver cachous. Lamingtons are sometimes made from stale cake cut and dipped in chocolate and then the cocoanut is put over. If exhibiting Lamingtons in a show, make them medium size. For example, make a nice coffee cake or orange cake evenly cooked and make the Lamingtons out of that. A cake that crumbles and follows the knife is no good for show purposes. Sponges often appear to be all that can be desired, but when cut they crumble and follow the knife. A pound cake should be of a light amber colour and with a sprinkling of blanched almonds and peel. It should not contain too much fruit. *Coffee Cake.*—The mixture of these cakes is sometimes streaked with long portions of the eggs through their not being beaten properly. This is caused by putting the eggs into too warm a mixture. This spoils a good cake. *Bread.*—Sometimes the bread is so light that it crumbles when cut. This is caused by too much rising. Here again a fine, even texture will be the most successful entry. Often too much salt spoils the exhibit. Scones, like bread, should be a nice light mixture that cuts evenly. A good scone doubles up when cut or broken, and goes back to its original form. *Tomato Sauce.*—Often the catalogue says "best bottle of tomato sauce." There should be two entries in this section, and it is always a difficult class to judge. If not distinctly specified, the light sauce—with most judges—always beats the dark, because of the lighter colour. Competitors do not pay sufficient attention to the classing of their entries and put their exhibits in the wrong sections. Do not seal pickles too tightly. Many good entries are passed over because of this; grease-proof paper or waxed paper is quite sufficient. Do not exhibit four of a kind if three are asked for. Decorate the cakes lightly—a simple design well done is better than a more elaborate one done badly. *Sponge Classes and Butter Sponge.*—Cream the butter and sugar together. Do not melt it on the stove—a basin with warm water is better. Never put eggs into a hot mixture, or the cakes will be spotted with egg running through it. In all cakes texture, flavour, and distribution of fruits, &c., are essential. If a sultana cake, the fruit has a tendency to go to the bottom. There are three causes: too much rising, too loose a mixture, or too slow an oven. Pastry for meat dishes should have a little more salt than others, and be a dark-brown colour for fruit." (Secretary, Mrs. Cole.)

River Murray Swamp Areas, at Wood's Point (Jervois Branch, Thursday, February 21st (F. P. Baily, Woods Point, Secretary).

Yorke Peninsula, at Kadina (Boor's Plains Branch), March 6th, S. G. Chynoweth (Secretary).

Mid-North, at Redhill, Thursday, March 14th (S. A. Pengilly, Secretary).

South-East (Upper), at Mundalla, Wednesday, March 20th (A. Ross, Secretary).

Lower North, at Blyth, Thursday, March 28th (R. H. Eime, Secretary).

South-East (Lower), at Mount Gambier, Wednesday, April 10th (G. T. Gurry), Secretary).

River Murray, at Moorook, Thursday, June 20th (S. Perkins, Secretary).

Each Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda of the Conference in their respective districts.

Artificial Manure Subsidy.

In a recent communication the Officer-in-Charge of the Fertiliser Subsidy Section of the Department of Commerce (G.P.O. Building, Adelaide) points out that the subsidy is payable on artificial manures used in the production of primary products other than wheat during the period 1st July, 1934, to 30th June, 1935. Forms of application are available at all country post offices, and when the particulars required have been filled in and forms duly signed and declared the forms should be forwarded to the supplier of the artificial manure who, after completing the certificate will forward the forms to the address given above. The Officer-in-Charge (Mr. S. Lillywhite) states that he will be pleased to furnish further information to Branches either by correspondence or by personal inquiry.

Cornsacks.

In the December issue we published the specifications of the standard cornsack. The Collector of Customs further states that, in respect to purchased cornsacks which are not of the standard prescribed by proclamation, if the marks and numbers of the bales, a sample of the faulty cornsack, and the name of the Australian supplier (or importer) be furnished to the Collector of Customs, the Department will make further inquiries into the matter.

Controlling Grasshoppers in the River Murray District.

In a report to the Grasshopper Control Committee, Mr. F. R. Arndt (District Horticultural Instructor) states that to deal with grasshoppers in the Renmark district the Irrigation Trust (which acts as a District Council for Renmark) has appointed a Director and ten Zone Supervisors. Each Zone Supervisor has a zone allotted to him, and his duties consist of searching his area for hatching grounds and in seeing that growers obtain their poison bait from him and use it to the best advantage in dealing with the insects. The Trust was practically confining its attention to the use of the poison bran mash, as it was found the most effective method of destroying the young grasshoppers.

The Blocks E and F district was the most badly infested of the Renmark settlement. With the Zone Supervisor (Mr. Petherick) Mr. Arndt inspected a number of hatching grounds. On one semi-neglected lucerne plot the holes made by the insects were very close together, and at one place as many as 640 holes where eggs had been deposited were counted on 1 square foot. On examining a number of holes it was found

that the eggs per hole averaged 40, which made the number of eggs for that square foot slightly over 25,000 All of the eggs were not deposited as closely together as the above but as the lucerne plot was over an acre in extent it must have contained many millions of eggs. Areas on which the hoppers were hatching out in great numbers were being treated with the poison bait twice daily—morning and evening—and were being destroyed in millions. The Wasp Parasite was found at work on many of the egg beds of the Renmark and other areas. On one large egg bed practically all of the eggs examined were found to be parasited with the small black wasp. The work being done by the Renmark Irrigation Trust was well organised and was proving effective in keeping the pest under control.

On 22nd January, together with Mr. N. Fotheringham (Manager of the Berri Experimental Orchard), Mr. Arndt attended a meeting of the Glossop Sub-Branch of the Returned Soldiers' Association and addressed the members on the grasshopper plague.

On the following evening he and Mr. Fotheringham were invited to attend a special meeting of the Berri District Council, and addressed the meeting on the grasshopper plague. The Council decided to appoint an Inspector to report on the presence of hatching areas and to organise methods for the destruction of the insects. On the 24th they delivered similar addresses to a special meeting of the Winkie Progressive Association. The meeting decided to elect a committee to assist and to work with the District Council in helping to eradicate the pest.

Mr. Arndt reports that he has also visited likely areas for the discovery of egg beds, discussed the grasshopper problem with a number of growers, and distributed leaflets on control methods. It appeared that the grasshopper problem was well in hand in the irrigated districts from Kingston to Renmark, and provided present efforts were continued, little damage from the plague should result.

Publications Received.

The Library of the Department of Agriculture acknowledges the receipt of the following publications:—

"Frost Risks and Frost Forecasting." Price 6d. Published by the Bureau of Meteorology, Melbourne.

"Bee Keeping in Victoria." Price 1s. 9d., postage included. Published by the Department of Agriculture, Melbourne.

Rothamsted Experimental Station, Harpenden, England, Annual Report, 1933. Price 2s. 6d.

"Apple Packing," Bulletin No. 84. Price 1s. 3d. net. Published by the Ministry of Agriculture, England.

"General Catalogue Farm Machinery," published by H. V. McKay Massey Harris Pty. Ltd., 95-97, North Terrace, Adelaide. Copies will be sent post free on application.

AGRICULTURAL INQUIRIES.

Replies supplied by MR. R. C. SCOTT, R.D.A. (*Supervisor of Experimental Work*).

Flax Growing.

Strathalbyn Agricultural Bureau. "Contracts have been made with farmers in the Strathalbyn district to sow 700 acres of Flax during the coming season. What are the possibilities of this district for the cultivation of Flax and is the venture likely to prove successful?"

Reply—In a series of experiments conducted some years ago, it was found that fertile soils and good rainfall were necessary for satisfactory returns from Flax. The best returns were secured from the rich lands of the Mount Gambier district and the irrigated reclaimed swamp areas of the lower Murray. However, in these cases there

was no market for the straw and consequently returns were dependent entirely upon the yield of grain. If a mill is erected it would be worth while farmers attempting to produce the crop, but the area from which payable returns are likely to be secured is relatively limited. The most favourable areas appear to be the richer flats and the fertile land of the Ashbourne district, and so far as these are concerned, it is questionable as to whether Flax will be more profitable than the crops at present grown. It is understood that a price of £4 per ton has been mentioned, and consequently Flax is worthy of a trial, but it should be viewed entirely as an experiment. It should also be borne in mind that, unless a mill for the treatment of the fibre is available, the value of the crop is very much reduced.

Crops for Early Green Feed.

"Victor Harbour" asks "What are the best crops to sow to produce early green feed for sheep on sandy land in the Victor Harbour district, and is it advisable to sow with whatever cereal is recommended, Clover and Wimmera Rye Grass?"

Reply—Either Oats or Rye is recommended. For the lighter soils Oats are preferred, since they respond better than Rye when sown on land low in fertility. On the other hand, Rye makes a rapid recovery after grazing and in medium to good soils is a very valuable cereal for planting for this purpose. For the district under discussion, a quick-growing variety of Oats, such as Early Burt, Mulga, or Lachlan is recommended. So far as the inclusion of pasture seeds in the mixture is concerned, it is not wise to attempt the production of Rye Grass until the fertility of the land has been built up by the development of strong crops of Clover. Therefore, the addition of Wimmera Rye Grass to relatively new land is not advised, but there would be an advantage in sowing Subterranean Clover with the Oats. The Clover would have no difficulty in establishing itself in the Oat crop, provided sufficient superphosphate was applied and it would be the means of adding to the grazing later on in the year.

Nitrogenous Fertilizers on Stubble Land.

Cobram. "What is the value of nitrogenous manures for stubble sown crops?"

Reply—Experiments dealing with the value of nitrogenous fertilisers on stubble land have recently been conducted in this State. From the limited amount of work carried out, it appears that under special circumstances Sulphate of Ammonia has a definite place for stubble sown crops. These conditions are when, for some reason or other, the land does not naturally produce a strong growth of leguminous fodder in order to build up a supply of organic nitrogen. It follows, therefore, that on the older farmed land, where the residue from full phosphatic dressings has caused a strong growth of Clovers, Medics, &c., the addition of Sulphate of Ammonia has not proved economic. Where the natural pasture consists principally of non-leguminous species, the response is quite profitable. Consequently, the use of Sulphate of Ammonia depends almost entirely on existing conditions, but if plants of the Clover family are not plentiful in the natural pasture, a trial with this fertiliser on a relatively small scale would be advisable.

VETERINARY INQUIRIES.

[Replies supplied by Veterinary Officers of the Stock and Brands Department.]

"Barmera" has aged gelding that has not shed his coat for the last three years. Other than appearing to be listless the animal is in good health.

Reply—I can suggest no remedy for the thick coat, except to clip him regularly. This can be done in winter as well as in summer. Give a course of Fowler's Solution of Arsenic (1 tablespoon in a small damped feed night and morning for 14 days,

stop for a week, and then continue the Fowler's Solution for another 14 days). Feed chaff damped, and see that bowels are kept regular by giving greenfeed, bran mashes, and small doses of linseed oil in feed, &c.

"Alawoona" has mare with staked hoof and is very lame.

Reply—Make a careful examination of the horse's foot (sole and frog) for any injuries or foreign bodies, and to do this satisfactorily the best way is throw the horse. If foreign body present, remove, and if any wound can be found this should be well opened up and treated with pure lysol. Further, stand the foot for 20 minutes in a tub of hot disinfectant daily. This can be done if you only make it warm for a start, and gradually add hot water. Keep the foot clean by putting in a sack.

"Elbow Hill" reports mare whose udder is swollen and discharging.

Reply—Rub the following liniment into the udder twice daily:—Green extract of belladonna, ½oz.; glycerine, 4ozs.; soap liniment, 6ozs. Keep mare on laxative feed.

"Mannahill" has two aged mares with hard lumps on the ribs. Foals from these mares also have lumps in the same position.

Reply—The trouble appears to be "Osteoporosis," a disease affecting the bones. It is a condition where the lime salts are removed from the bones, and they become enlarged through the deposition in them of increased amounts of organic matter (bone marrow). Any of the bones of the body may be affected with this condition, but those of the head and ribs are the ones most frequently involved. The exact cause of the trouble is still obscure, though it appears to be connected with some dietetic deficiency. The disease is more apt to occur in localities where, owing to the nature of the soil, the feed grown thereon or the stock drinking water is in some way affected. If taken in hand early a cure can often be obtained by simply removing affected animals right away to another district where they can get a complete change of diet.

Where this cannot be done, the animals should be fed as much as possible on food grown in another district, and the drinking water, if possible, changed. The diet should include a liberal allowance of oats, bran, &c. The addition of molasses to the food is also recommended, and a daily allowance of 1oz. common salt and 2ozs. sweet ground bonemeal should be given. If medicinal treatment is given, the animals should receive a mild dose of physic, followed by a course of the following tonic powder:—Ferri. sulph. exsic, 6ozs.; sodi. bicarb,, 1lb.; pulv. nux vom., 3ozs.; pulv. gentianae. 12ozs.; pulv. anisi, 1lb. Dose:—1 heaped dessertspoon to be given twice a day in damped food. If the condition is allowed to become well established before anything is done to check it partial recovery only is more likely to result.

"Gumeracha" reports sheep with a whitish opaque film covering the eye.

Reply—The disease is ophthalmia or "pinkeye." It is very contagious, and is usually introduced on to a farm with bought sheep. Treatment is as follows:—

1. Isolate all affected sheep. Put them in a paddock where water and shelter are available, and hand feed if necessary.
2. Both the *affected and healthy sheep* should be treated as follows:—
   (*a*) Remove all grass seeds from around eyes, and trim well around area.
   (*b*) Put a few drops of following solution in both eyes daily for a few days, and subsequently do affected sheep only till better:—Zinc sulphate, 1 dessert-spoonful; boiled water, ½ pint.

PIG-FEEDING QUERIES.

The following replies to questions submitted by the Secretary of the Blackheath Branch of the Agricultural Bureau have been supplied by Mr. H. B. Barlow, H.D.D. (Chief Dairy Instructor):—

1. *"In feeding pigs from slips to baconers would equal parts Cape Barley and Field Peas crushed be a better ration than Cape Barley alone?"*

A mixture of Cape Barley and Field Peas would be a better feed for pigs than Barley alone, and if the Peas can be obtained or grown cheaply the mixture is excellent.

2. *"When crushing grain for pigs is it best to crush fine or fairly coarse?"*

Grain should be crushed fairly fine, but not necessarily made powdery.

3. *"Is it better to feed crushed grain dry or mixed with their drink?"*

Better results are generally obtained by feeding the grain dry. Feed skim milk in a separate trough, and in addition have plenty of water available.

4. *"Is it known if the roots of bracken fern are of any food value to pigs running in them, as they have a tendency to root after the roots?"*

No analyses are available as to the food value of bracken fern roots, but there is no doubt that they are attractive to pigs and will help to make up a ration if crushed grain and skim milk are also available.

5. *"Would meat meal given to pigs more than repay the cost of same, by them coming to quicker maturity."*

If skim milk is available, meat meal is not necessary, but if no skim milk is available, meat meal fed at the rate of 5lbs. to each 100lbs. of grain is practically essential for quick and economical returns and will easily pay for itself if the pigs are well fed and looked after. Feeding meat meal to semi-starved pigs would not be economical.

. *"If rabbits were fed to pigs, would they take the place of meat meal, and should they be fed raw or cooked?"*

Rabbits can be fed in the place of meat meal. Skin the rabbits and boil with a little wheat and make a watery stew, then feed when cold. It is not necessary to clean the rabbits.

THE CONSERVATION OF FODDER UNDER SOUTH AUSTRALIAN CONDITIONS.

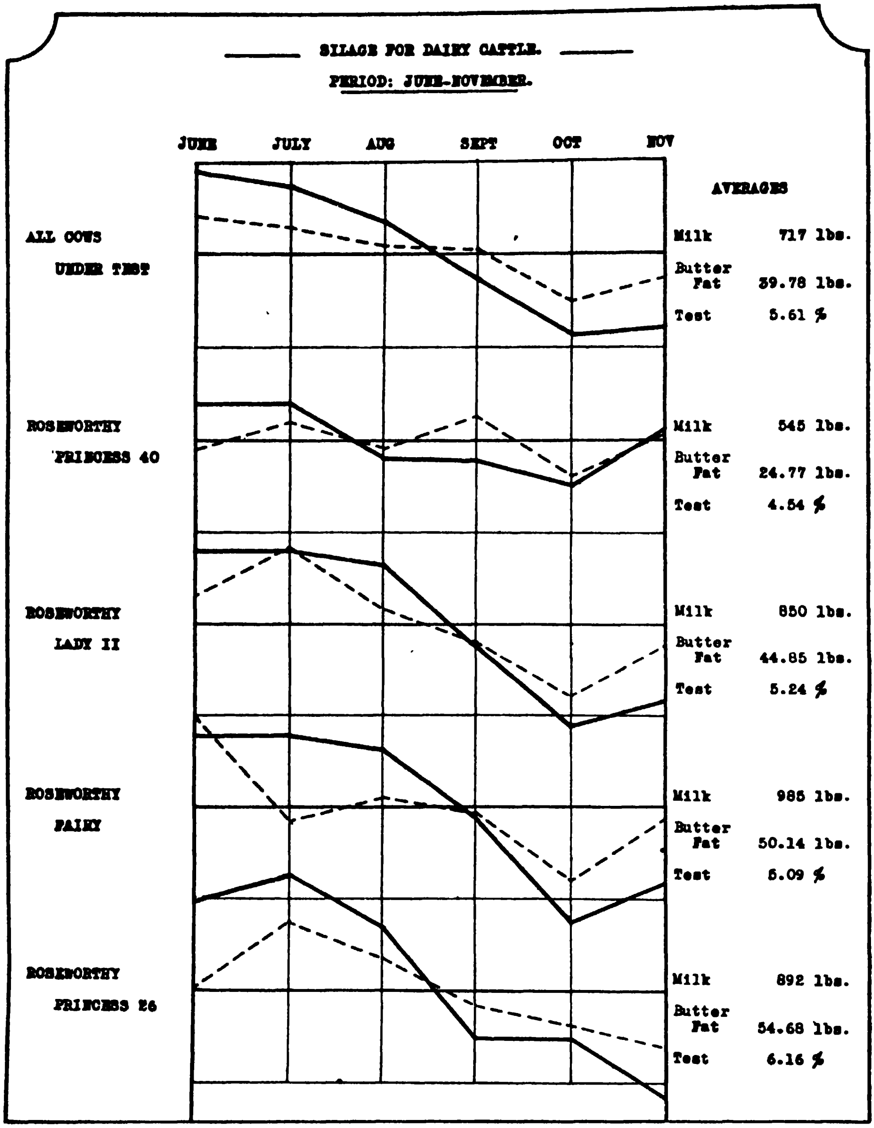
[Being the digest of an address delivered to the Annual Congress of the Agricultural Bureau of South Australia for 1934 by Dr. A. R. CALLAGHAN, Principal Roseworthy Agricultural College.]

On several occasions now I have drawn attention to the trend of agricultural development towards a more diversified system of farming by the tendency to incorporate and make more systematic use of livestock on the farm. Such a change has obvious agricultural advantages. This development is actually under way, and had financial conditions been better in the country during the last three or four years, considerable extension would have taken place. On wheat lands this new development, even though it must come about gradually, involves a re-arrangement of the rotational system in order to carry more stock. This in turn involves the development of a fodder conscientiousness which will have a psychological influence sufficient to compel every good farmer to conserve sufficient fodder to meet the requirements of his livestock over any severe seasonal or drought conditions which may occur. In my opinion there is no more important agricultural consideration in South Australia at the moment than fodder conservation; the lack of it is actually impeding further development, and I give the following reasons, which emphasise the need for more adequate provision in this regard.

THE NEED FOR FODDER CONSERVATION.

There are three basic reasons why conservation of fodder is so important under agricultural and pastoral conditions prevailing in this State, and in fact in Australia in general. *Firstly,* there is the need to preserve food grown at favourable times of the year in order to have a supply available with which to feed stock during the months of the year when very little or no paddock feed is available. To satisfy this need reserves are necessary, which may be termed regular seasonal reserves. *Secondly,* there is need to conserve fodder in order to utilise to the fullest extent the luxuriant vegetative growth, which characterises some seasons, for use as feed for livestock in years of drought, when definite and severe shortage of feed invariably occurs. These are best termed drought reserves, and should be considered apart from the regular seasonal reserves as something additional. One is on current account, the other in the savings account. *Thirdly,* a further object for conserving fodder is to have feed available with which to supplement paddock feed to maintain production or provide extra feed for energy production. These may be called supplementary reserves, and if the regular seasonal reserves are regarded as being on current account, and the drought reserves as a Savings Bank account, then the supplementary reserves can be looked upon as gilt-edged investments. Every successful business man realises the value of these three aspects of finance,, and in the same way every farmer seeking success in livestock pursuits must also pay particular attention to fodder reserves from all three angles.

In discussing these three aspects further, it can be said that for the most part the regular seasonal reserves do receive attention at the moment, but so far fodder conservation has stopped at that. In other words, the general policy of conservation at present is based solely upon the hand to mouth attitude of living. The wheat belt regions of Australia are characterised by winter rainfall and summer drought, with the result that summer feed shortage is a serious proposition. This is especially true under South Australian and Western Australian conditions.



In 1932 the College herd was on ordinary paddock feed until the last week in October, when silage was fed. Although all the above graphs were prepared from cows finishing their lactation period in November, when a normal decline in production is expected, definite increases occurred as a result of the change of feed. The first graph represents the production lines of milk (—) and butter (- - -) of all cows under test and finishing at the end of November. Note the increased production in November, whereas under normal feeding further decline would have been expected.

The others are of individual cows, and the lowest one is included to indicate that just an occasional cow in the herd is liable to decline in production in the first month of silage feed. Following the production of such cows later, however, definite and clear increases in subsequent months are noted after the cows become more accustomed to the silage. This latter type, however, is exceptional, and the general average of cows respond immediately to silage feeding after being on dry rations.

Taking the more favourable districts of the State, where this period of shortage in the summer is not so long and only acute in dry years, it is found that such districts do not have such mild conditions for vegetative growth in the depth of winter, consequently there is a short winter period of shortage to contend with as well. So that from the point of view of regular seasonal reserves alone it is fundamental to the success of livestock management on the farm that fairly extensive provision should be made. No district of this State can boast regular and continuous grazing conditions, and it follows, therefore, that in no district where livestock are a feature can fodder conservation be neglected if the best results are to be obtained.

On the subject of drought reserves, one need only refer to the rainfall records of the State or jog the memory of any experienced farmer to realise how insistently and regularly the need arises for extensive feeding of livestock to carry them over the drought periods which are part and parcel of our climate. Records and experience have warned the producer time and again to be prepared, yet even this year, when a dry spell followed comparatively good years, during which feed was literally wasted, the shortage of reserves in South Australia make one wonder why records are kept or experience is registered. Whenever drought does appear it finds with monotonous certainty the average farmer unprepared. Shortage of vegetative growth coincides with the recurring years of drought, just as luxuriance of vegetative growth greatly in excess of normal requirements coincides with the recurring years of high rainfall. It is during these years of plenty that adequate provision should be made to tide our livestock over the periods of shortage. Just as regular seasonal reserves are necessary to equalise the carrying capacity of the normal year, so drought reserves are necessary to equalise the carrying capacity of the State over good and bad years. It is the only sound commonsense way of preventing excessive fluctuations in livestock numbers and excessive fluctuations in products of all descriptions obtained from livestock.

By adding a little extra to the regular seasonal reserves every good year, or, better still, by making a determined effort to build up adequate reserves in the years of plenty, provision against serious drought losses can be made at comparatively little cost. Merely the cost of handling is involved in most cases, whereas, if unprepared, not only handling and rehandling costs are incurred, but the fodder itself has to be purchased at famine prices. In my opinion it is a very bad business proposition not to have sufficient reserve to carry stock over at least 10 months of the year. Apart from acting as an insurance policy against losses, it offers a sense of security and satisfaction which every farmer should enjoy.

This leads to the next aspect of fodder conservation, and that is the need for supplementary reserves, and, in discussing these, the quality of the fodder conserved is important. To the successful dairy farmer the conservation of fodder in suitable form is perhaps his most important problem; maintenance of production at as high a level as possible can be done most economically if farm-grown fodders possessing desirable qualities have been conserved. There are periods of the year when the feed is scarce or unnutritious, and the dairy farmer is faced with the problem of conserving fodders to answer requirements of succulence, bulk, and a balanced ration. This actually entails provision of succulent reserves of the form of silage, another bulky fodder such as hay, and concentrates in the form of cereal grain, preferably oats, in order to keep his rations balanced.

The same principle underlying the use of supplementary reserves applies to other livestock, especially in the production of fat lambs, and to make provision for extra energy expenditure on the part of horses. Horses in heavy work need extra feeding, and for the most part farmers do provide reserves sufficient

to carry their horses through a normal year's work, but it is appalling to note this year that in many districts fallowing has been considerably curtailed for the rather shameful reason that insufficient horse feed of desirable quality has been conserved on a great many farms to tide them over the present dry season. Thousands of fat lambs have missed the market this year because of the dearth of the right type of fodder reserves. The conclusion is that it is impossible to guarantee any continuity of supply of animal products from season to season and year to year unless fodders of the right type and balance are conserved to tide over seasonal feed shortages and drought shortages. In putting such reserves aside, due regard should be paid to their feeding value and utility; fodders of high feeding value economise space and make feeding thrifty.

Taking the three fundamental reasons for fodder conservation into consideration, it will be apparent that such a practice not only acts as an insurance against loss of stock, but it also operates as an insurance against serious decline in production. Well carried out it would assure a continuity of supply at present undreamt of in many animal products and increase the carrying capacity of most properties. At the same time such carrying capacity would be placed on a true and permanent basis extending over the whole year round, and from year to year, in spite of dry seasons. The average property in South Australia is not stocked to full carrying capacity, and it is therefore not yielding full returns. By conserving fodder the owner can stock up to full capacity and yet feel confident that when the dry spell occurs he will not be forced to sell his stock at starving stock prices or buy fodder well above its actual feeding value.

The Present Position.

The only aspect of the problem which has so far received due attention is that of providing the normally required seasonal reserves. These are chiefly conserved as hay and to a lesser extent as grain. While such a position may seem satisfactory in average years, it is certain that if more suitable and more extensive reserves were made an increase in production of animal products would undoubtedly be possible.

Table showing the Livestock Carried in South Australia, 1931-32, together with the Fodder Conserved in the form of Ensilage and Hay.

District.	Ensilage.	Hay.	Dairy Cattle.	Other Cattle.	Horses.	Sheep.
Central	5,216	250,593	62,995	38,538	55,377	1,332,449
Lower North	230	165,946	17,526	13,282	38,098	954,230
Upper North	15	46,481	8,175	9,131	12,827	720,407
South-East	84	28,829	17,230	19,580	13,042	1,276,646
Western	30	74,073	6,626	5,060	23,724	817,661
Murray Mallee	65	80,956	14,854	11,030	30,490	444,077
Outside Countries	—	180	350	40,947	11,664	1,063,511
	5,640	647,058	127,756	137,568	185,222	6,608,981

It must be admitted that provision of drought reserves is seriously neglected. The above table shows that, apart from thousands of dairy cows and horses, there are millions of sheep in our country, and thousands of other cattle. Thousands of fat lambs are produced annually at certain periods of the year. All these livestock are at the mercy of a dry year as the amount of fodder conserved indicates, and only by a proper systematic and conscientious programme of fodder conservation can their wellbeing remain assured in spite of bad seasons.

So far insufficient attention has been given to the type of fodder to conserve; there is an easy going tendency to trust to luck and depend upon cereal hay. Such apathy towards the problem of fodder conservation means the loss of thousands of pounds annually to the producers. In such a climate as ours dairy farmers can ill afford to neglect to conserve fodder in the form of silage, yet an analysis of the figures given above from the viewpoint of silage reserves in relation to the number of dairy cattle is very illuminating. The second table transcribes the figures and defines the ludicrous position quite clearly.

Ensilage Manufactured in 1931-2 in Relation to the Number of Dairy Cows for the same Period.

District.								
Central	185lbs.	per head	@	40lbs. per day	equal to	4·62	days	ration.
Lower North	29 "	" "	@	" "	"	0·72	"	"
Upper North	4 "	" "	@	" "	"	0·10	"	"
South-East	10 "	" "	@	" "	"	0·25	"	"
Western	10 "	" "	@	" "	"	0·25	"	"
Murray Mallee	9 "	" "	@	" "	"	0·22	"	"
Whole State	98 "	" "	@	" "	"	2·45	"	"
Western Australia	393 "	" "	@	" "	"	9·82	"	"
New South Wales	121 "	" "	@	" "	"	3·02	"	"
Victoria	15 "	" "	@	" "	"	0·37	"	"
Queensland	18 "	" "	@	" "	"	0·45	"	"

Taking the State as a whole, only 98lbs. of ensilage per cow are conserved annually. After allowance for normal manufacturing losses, this would amount to no more than 70lbs. at the very most. Allowing a daily ration of 40lbs. on the basis of fodder ensiled, which is equivalent to no more than 25lbs. to 30lbs. of actual silage, it will be seen that there is only sufficient silage made in this State to give our dairy cows about three good feeds. The data indicate that the position in Western Australia, where they labour under very similar climatic disabilities, is four times better than in this State.

These figures are really startling to anyone who knows the real worth of silage as feed for milking cows. They are more significant when it is recalled that during the early part of this year State production of dairy produce dwindled almost to half the normal production for similar periods of normal years. Adequate reserves of succulent fodder in the form of silage and concentrates in the form of grain would have largely allayed this serious decline in production.

It has been impossible to obtain figures relating to grain stored as fodder reserves. For the most part the storage of grain is based more on hope of a rise in price than on the fear of drought.

By way of summating these remarks on the present position of fodder conservation, it is apparent that, although some attempt is being made to meet regular seasonal feed shortages by the storage of large quantities of hay, only a very feeble attempt to ensile fodder as silage is being made. In fact at present conservation of fodder is based upon haphazard, happy-go-lucky methods, when only careful attention to the requirements of animals and the pursuance of a systematic policy of food storage will suffice.

Methods of Fodder Conservation.

There are three main forms in which fodder may be conserved—(1) as hay, (2) as silage, and (3) as grain. Under the general run of South Australian conditions cereal hay is the chief concern; some grass or meadow hay is made in the more favoured districts, but the chief reliance is placed upon wheaten, oaten, or shandy (wheaten and oaten mixed) hay. Silage, as already shown, is not being made to anything like the extent it should be. Of the cereal grains, wheat, oats, and barley all form very useful reserves, but of the three oats will be found to be of more universal use.

I do not intend to embark upon a detailed account of the ways and means whereby these fodder reserves can be built up, but I will endeavour to draw attention to salient features which I consider may be helpful.

Hay.—Haymaking requires little explanation, but there are one or two points which are not clearly understood, and as a general rule if greater care were taken in making hay, its feeding value would be very greatly increased. The time of cutting is extremely important if the highest nutritive value is to be combined with optimum weight. Nutritive value should not be sacrificed for weight, consequently the grain should not reach the dough stage, for by then the lower portions of the plants will have dried out, become less nutritious, and less digestible. The nutritious elements are evenly distributed throughout the plant at flowering and they are then in very digestible form. No substantial changes in the distribution of nutriment nor in digestibility occur in the plant from flowering until the milky stage of grain development. At this stage the grain has almost taken on its full size, but from this milky stage on a very rapid translocation of food substances takes place from the stems, especially the lower portions, to the grain, and this is accompanied by a similarly rapid decrease in digestibility. Actually, therefore, to combine optimum weight with optimum distribution of food substances and digestibility, cereal hay should be cut after the plants have flowered and the grain is in the early and late milky stages. At this stage, also, good colour, pleasant aroma, and retention of leaf can be expected, all of which contribute largely to the palatability of the hay.

Another point is that once cut hay should be carefully handled so that its natural qualities may be fully and well preserved. The idea is to bring about loss of moisture without loss of nutritive value, colour, or aroma, but if the fodder is allowed to become too dry the actual maturation or finishing touches in its manufacture may not be possible. If it is stacked after completely drying out there is not only serious loss through the bleaching action of the sun, but loss of colour as well. Leaving it so long also leaves it exposed to the chances of rain, which is a very potent agent in reducing the soluble nutrients. It is not commonly realised that rain can remove as much as from 15 per cent. to 20 per cent. of the nutritive value from exposed hay. Actually the hay should be carefully stooked and carted in when it is sufficiently dry to be stacked with safety. This stage is reached when the nodes or knots on the stems have dried and when the stems are sufficiently brittle to break when screwed in the hands. If stacked in this condition there will be sufficient moisture left in the hay to permit of a mild mellowing fermentation in the stack, which is very desirable, without in any way endangering the stack from overheating or the development of moulds.

The careful handling of grass or meadow hay is necessary for the same reason, and the nutritive value of the product can be quite appreciably controlled by care and skill in making. Once in the swath the cut fodder is subject to very rapid drying under our conditions, and if it is allowed to dry this swath, losses of valuable feeding substances are extensive. The idea of making small heaps or "cocks" as soon as wilting of the swath has taken place is to keep the leaves as fresh and moist for as long as possible; in this condition they draw moisture from the thicker stemmy portions of the plant without themselves becoming brittle and fragile. If the leaf is allowed to wither rapidly and become brittle, it will be lost in handling and the most valuable portion of the harvest will be lost. From the cocks, meadow hay should be built into the stack before it has completely dried out, and it should respond as a whole to tramping and give evidence of settling down well. If it is too dry it will not settle compactly or respond to tramping in the same way.

Hay may be considered to be the ideal fodder to conserve for maintenance and dry feed rations to meet the regular seasonal shortages. As a drought reserve it has some serious drawbacks, chief of which are that it is subject to yearly deterioration as a whole, it is generally exposed to the weather, it is open to the ravages of rats and mice, and always in danger of fire. In fact, the annual wastage from conserved hay is enormous, for working in harmony with the influences of weather, rats, mice, and general deterioration, carelessness on the part of the owner also contributes largely to the loss. If hay has to be kept for any length of time more adequate protection is necessary, and the advisability of erecting suitable hay sheds, offering protection from mice by building on guarded straddles or encircling the stack with a low galvanized iron fence, must be given consideration. In addition an insurance policy against fire is necessary.

After having made such provision, only by great care can hay be stored loose in the stack over long periods. Under a shed the hay is given adequate protection from the weather. Elevated straddles protected by inverted plates of galvanized iron are certainly a great protection against mice. Similarly the low galvanized iron fence of from 2ft. to 3ft. high and set in the ground about 6in. offers protection against mice. In spite of such precautions, however, careful vigilance is necessary to prevent the ingress of rodents. Sticks, bags, straws, or any other objects which are permitted to hang over the protections to the ground level give mice every chance of entering the stack. During seasons when mice are bad the iron fence should also be watched to prevent entrance to the stack by burrowing. Haystacks that are intended as drought reserves should be given the attention referred to above. This would prevent much of the enormous hay waste which is such a common sight in the country.

Probably the most economical and faithful method of conserving hay for long periods is to bale it, for in this form it keeps better, occupies far less space, and when the time comes for its use it is easily and quickly transported. It is erroneous to suppose, however, that baled hay is mouseproof; it is the reverse, as the crevices between the bales form very happy hunting grounds for mice, and all baled hay should be given the same protection against mice as outlined above.

The harvesting of hay, especially oaten, before the grain has developed is advocated as a protection against serious mouse trouble, but optimum weight of hay, which is often a consideration, cannot be obtained if the cereal intended for hay is cut too early, and difficulties in curing immediately present themselves. Then, in years of serious mouse plague it is doubtful whether the mice will discriminate between hay of such calibre and that of ordinary composition.

Silage.—Whatever disadvantages the storage of hay as drought reserves may have it is still absolutely necessary as there is no more serviceable way of conserving fodder for horse feed. The placing aside of reserves for sheep or cattle, however, is a different proposition, and in view of the depredations to which hay is subject, the manufacture of more cereal silage is unequivocally advocated.

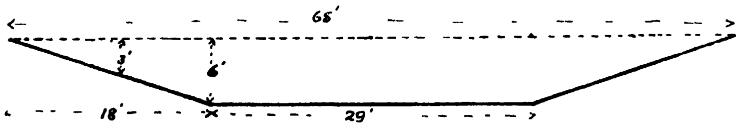
Undoubtedly the most economical and sensible way of ensiling fodder is in the trench silo. The next most serviceable method is the stack. Where loose stacks of grass, clover, or lucerne silage can be made, they can be weighted down and remain sound and undisturbed for many years without depreciating to anything like the extent expected in hay. The building of ordinary cereal stacks of silage I do not advocate, for such stacks have to be built in much the same way as a haystack. Besides being difficult to make and keep standing, it is almost impossible to drive the air out on account of the locking and crossing of sheaved bundles. This involves a heavy manufacturing loss as well as a wide marginal loss; further, such stacks are subject to depreciation and must be used within 12 months to get full benefit from them. Sheaved cereal fodder can be successfully stacked, however,

by means of the pole-guided stack which has been tried very successfully at College and this method is definitely favoured where it is not possible to use trenches as silos. The overhead silo is too expensive to construct merely for conserving drought reserves, but it has its place on dairy farms and stud stock properties where silage should form such an important percentage of the regular seasonal, and supplementary reserves.

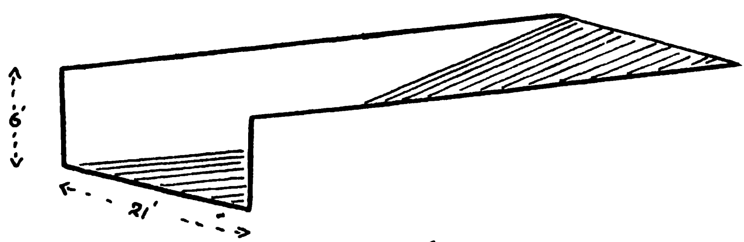
Details of the silage harvest at College last year were published in the September *Journal of Agriculture* and full descriptions of the loose grass silage stack and pole-guided stack have been given, but no trench silage was made so that in the notes to follow special attention will be given to the trench silo.

The Trench Silo.—The site is the first consideration and unless a good sound sub-soil is available on a well-drained spot where there is no danger of seepage into the trench or flooding, then it is preferable to build stacks. In most districts, however, trench silos are possible. The trench should not be made too large or too deep and a pit to hold 100 tons is recommended. If the property is a large one carrying a large number of stock, the size can be increased, but on the average holding it is preferable to have two trenches of 100 tons capacity rather than one of 200 tons.

A trench measuring 65ft. long, 21ft. wide, and 6ft. deep, designed upon the lines illustrated below, will hold 100 tons. Another conveniently dimensioned pit of similar capacity would be 80ft. long, 14ft. wide, and 6ft. deep.



"Side Elevation"



"Half Section"

Scale $\frac{1}{10}$" To 1 Foot

These can be conveniently made with end batters allowing for a rise of about 1ft. in every 3ft. The sides, however, should be as near perpendicular as possible, the width being perhaps 2ft. wider at the top than at the bottom. This can easily be made by using a single-furrowed plough and scoop.

Deeper trenches than 6ft. are more expensive to make and more difficult to empty, so that greater depth is not advocated. The trench type is undoubtedly the most convenient way of handling cereal material.

There are no difficulties in filling such a trench, but the following hints may be useful. The sheaves should be placed lengthways in the pit; the bands need not be removed, but they may be cut to facilitate packing; but this is not necessary for success. After a fair body of material has been unloaded over the sides the wagons can be drawn to the pit with advantage and unloaded. To secure good packing, especially along the margins of the silo, a horse led backwards and forwards over the material between loads has been found very helpful. After the

silo has been filled to a little above ground level, a period of two to three days should be allowed for settling, then resume the filling and stack the material to a height of about 4ft. above ground-level at the centre, and gradually sloping away at both ends. In this process of stacking above ground-level it is a good plan to allow the sheaves to overlap the edges of the trench by about 6ins., then when subsidence takes place the overlap is drawn into the pit along the margins; this acts as a very effective means of obviating shrinkage from the walls of the trench. The material should again be allowed to settle, after which it should be built up to 4ft. in the centre as before. This is a safeguard not to be neglected, as the material settles very appreciably as fermentation proceeds, and if the finishing is not methodically done, a few months after filling and covering the settling may bring about a hollow over the pit which may become a water-hole saturating and spoiling the fodder below. After the final filling further settling should be allowed, preferably with some weight on top to assist, after which it can be covered with a foot or more of soil.

The Pole Guided Stack.—The idea of this type of stack is to build a framework of poles along both sides. The stack frame at College was designed to hold about 90 to 100 tons, and the dimensions were 21ft. by 12ft., and the poles were 22ft. out of the ground. Along the two sides long poles were placed firmly in the ground 3ft. apart. At the moment two frameworks are being constructed at the College to make a permanent demonstration of this type of stack, and for the purpose railway irons 27ft. long are being used. These will be set in concrete 5ft. and will be 22ft. out of the ground. The base measurements will be 27ft. by 14ft. 6ins., and the railway irons taking the place of poles will be placed 3ft. apart on both sides.

For a stack to take 100 tons a farmer who is able to get long poles conveniently, the dimensions 21ft. by 14ft. 6ins. are very convenient, and if raised to a height of 20ft. and filled to that height, say, three times after allowing for settling, 100 tons of green stuff would be required.

The secret of this type of stack is that it enables the stack to be built with sheaves in parallel fashion, and not with the butts to the outside of the stack, except at each end. It is advisable when building to lay one layer with the heads all one direction, the next layer with the heads the other way, and so on, so that at each end the heads protrude over the edge of the stack in alternate layers. These are then trimmed level with the butts of the alternating layers, and thrown back into the stack. This parallel stacking of the sheaves is made possible by the poles, and it is the most important attribute to the method, for the parallel stacking enables much better compaction and general packing of the fodder, and it guarantees the exclusion of air quicker and far more effectively than if the stack were built on the haystack principle, where sheaves are criss-crossed to bind them together. Further, the poles facilitate building and make the chances of serious slipping of the stack during building and settling very remote. It is a method than can be recommended with assurance, and, in fact, is the soundest method available for the stacking of sheaved wheat, oats, or barley.

The Loose Stack.—For handling pasture, clovers, or lucerne as loose material an ordinary round stack is the most desirable. The base for a stack to take 100 tons of green fodder should be 24ft. in diameter and no more. This means building to a height of 18ft. to 20ft., and allowing to settle and rebuilding say three or four times according to subsidence of the fodder. To handle the fodder at College an attachment was made to the mower, which rolled the fodder into light windrows. The fodder was then taken by sweep rakes to the site of the stack, tipped, and later elevated on to the stack by means of grab and tackle. This handling is quick, economical, and easy.

The weighting of these stacks is not so essential after each day's work as in handling sheaved fodder, as it settles down readily, and provided a fair quantity is added each day, it will make excellently in normal spring weather which is not too drying.

The advantages of silage are many, but to enumerate them at length would be mere repetition of long standing advice. Suffice it to say that silage is vermin, fire, and weather proof and, well made, can be preserved in succulent nutritious condition for much longer periods than hay. Its succulence places it in an unchallenged position as bulky fodder for dairy cows or ewes suckling lambs.

The Storage of Grain.—Most farmers are inclined to talk bulk-handling at the slightest provocation, but very few attempt to practise the bulking of grain in large bins, or silos, in order to store it effectively. Grain cannot be stored for any length of time in bags. There it is subject to vermin of all descriptions and enormous waste and the eventual rejection of much grain is inevitable. Some kind of galvanised iron container is necessary and in this regard galvanised iron tanks serve the purpose well. At College we have recently divided one side of an old barn which has mouseproof walls and flooring into four bins each of 600 bag capacity. The divisions and inside walls are of galvanised iron supported on a timber framework. All our grain reserves are bulked into these bins from which grain can be gravitated out for crushing or direct feeding.

In New South Wales the storage of oats in special galvanised iron silos has become very popular and as a rule these silos are designed to hold about 600 bags of grain. Such silos can be constructed of 22 gauge iron but if silos to hold greater quantities are desired, the lower layers should be of 20 gauge with the upper iron 22 gauge. It is preferable to have all joints both riveted and soldered; in any case the lower junctions must be riveted and soldered, even though the upper junctions may be only rivetted or securely joined by screw bolts and made watertight by reasonably waterproof packing. Angle iron may also be used to support the sides with advantage.

These silos are filled through a chute near the top, and in some of the larger ones another door halfway down allows filling at lower levels to be done manually. Normally the grain has to be elevated to the top of the silo by means of a hoist, or another method is to have a stand from which the grain can be tipped in. A small doorway at the bottom allows for emptying; in this regard two doors, one on either side, are of great help and facilitate the emptying when the grain is at a low level in the silo. The use of the sliding door from the grain box of any old harvester serves the purpose admirably.

Grain placed in such silos must be perfectly dry; it will then keep in sound condition, free from vermin, for indefinite periods. If fouled at all by rain, or if placed in the silo other than perfectly dry some sweating and the ingress of weevil will result. With the sign of any vermin the following fumigation, using carbon bisulphide, will be found effective. Pour the carbon bisulphide into shallow flat containers or on to bags on top of the grain. Where the silo is reasonably airtight, four pints of the chemical to every 1,000 bushels of grain-holding capacity is sufficient. Even though the silo be only half full the same amount would be necessary as for a full silo. If the silo is not airtight increase the quantity up to 4 times the amount and if possible cover the grain with a tarpaulin after adding the fumigant. It should then be left for about 48 hours. Carbon bisulphide is highly inflammable, but is not over-poisonous to humans and it is possible to work in the silo for about 10 minutes without danger. For convenience of measurement the following relationships are worth remembering; 1,000bush. are the equivalent of 8,025galls., occupying 1,284 cub. ft.

In this somewhat rambling discourse I have endeavoured to emphasise the absolute necessity which exists for more general and serious fodder conservation and at the same time have offered a few practical suggestions which, it is hoped, will be of assistance. The inauguration of fodder conservation competitions throughout the State would draw attention to the need as well as encourage further development and I would commend to this Conference the idea of placing on record their desire to see such competitions begun. Following an expression of desire for these competitions from this meeting I feel sure that support from the Department of Agriculture, livestock organisations, and the Royal Agricultural and Horticultural Society would be forthcoming.

THE REMOVAL OF SPRAY RESIDUE FROM APPLES AND PEARS.

[By A. G. STRICKLAND, M.Agr. Sc., Deputy Chief Horticultural Instructor.]

The necessity for using sprays of various kinds in order to protect ripening fruit from insects and diseases is universally recognised.

Such sprays are customarily applied at certain intervals during the growing season, and often up to a few weeks before the fruit is harvested, and despite natural weathering, some of the applied spray must be present in greater or less amount on the harvested fruit. In a wet summer, spray residue is removed at a relatively rapid rate, and it is, therefore, in dry seasons that spray deposits are most conspicuous and persistent.

The presence of spray residue on marketed fruit may be objected to on two grounds:—

Firstly: The arsenic content of the fruit may exceed the legal maximum prescribed by Health Authorities; and

Secondly: Spray residue, dust and other deposits may be present in such amount as to detract considerably from the appearance of the fruit. Bright, clean apples and pears are far more appetising than fruits which are spotted or smeared with foreign substances, and it is always the grower's endeavour, or it should be, to market his fruit in the most attractive condition possible.

Prevention is ever better than cure, and before discussing methods of cleaning fruit, I will make short reference to possible methods of avoiding excessive residue. The tendency for lead arsenate sprays to leave an objectionable residue has prompted extensive trials of other spraying materials for codlin moth control, but although in some instances over 100 possible substitutes have been tested, no spray has yet been devised that will universally replace arsenate of lead. One of the most promising of these substitutes, namely, Barium fluosilicate, was tested recently, but it gave such poor results that ultimately arsenical and oil sprays had to be brought to the rescue in order to save the fruit. White oil emulsion, as an adjunct to earlier calyx sprays with arsenate of lead, has given better results in moth control and reduction of residue than any other substitute for arsenicals. Experiments in various States have shown that two sprayings of lead arsenate, followed by subsequent sprayings of White Oil emulsion, give efficient control of codlin moth, and at the same time arsenical residue is kept practically within legal limits. The efficacy of this and similar programmes is still being investigated.

Where harvested fruit still bears excessive residue in spite of the use of oil sprays in substitution for some of the arsenical applications, the fact that oil has been applied greatly complicates the problem of removing the residue. A residue of arsenate of lead is removed with little difficulty, but if such a residue has been coated with a film of oil it is not so easily got rid of. Pending the results of various spraying and washing experiments, it is urged that if the inclusion of White Oil in the schedule does not satisfactorily avoid residue, then in the interests of removing the spray marks, it would be far better to omit the oil altogether. Most trouble in this respect is experienced, when, after putting on several sprays of lead arsenate and achieving a fairly heavy residue, the orchardist closes his spraying season with oil. This practice seldom has the effect of dispersing the spray deposit, and serves merely to render the fruit unhappily resistant to any cleaning process which may be employed.

Generally speaking, a complete schedule of lead arsenate sprays will leave more or less residue, depending on weather conditions and methods of spraying. The subsequent removal of this residue is greatly facilitated by the addition of 1lb. to 2lbs. of hydrated lime per 100galls. of lead arsenate spray, when making the final

applications. Growers are advised to add this lime to the last spray of lead, when it seems likely that they will have to take steps to remove the residue after the fruit is picked.

We now come to the question of removing spray deposits, which are sometimes unavoidably present when the fruit is picked. Recently there has been a tendency on the part of Health Authorities, both in Australia and Overseas, to enforce the regulations regarding spray residue more stringently, and to protect themselves, growers must avoid marketing fruit with excessive residue.

In the past, hand wiping has been employed, to remove excess spray, but during the last year or so, many growers have taken advantage of the less expensive, and more efficient method of washing the fruit in a weak solution of hydrochloric acid. Nevertheless, a large number of growers still have the idea that washing apples and pears is an expensive and complicated procedure. This is, definitely, not so. The labour costs for washing are far cheaper than for hand wiping; the residue is more thoroughly removed, and the process itself is very simple to carry out. If large quantities of fruit had to be treated, as in a central packing shed, the use of a machine would become necessary, but the average grower requires no further equipment than two moderate-sized wooden troughs or tubs, and some sort of a water supply.

Hydrochloric acid may be purchased from chemical or fertiliser companies in a concentrated form, containing about 33 per cent. actual acid. It is supplied usually in 35lb. jars (containing about 3galls.), and the price varies from 2½d. to 3d. per pound according to the quantity purchased. On these prices the concentrated acid costs approximately 2s. 6d. to 3s. per gallon. In this form, the acid is very corrosive, and should be handled with the greatest of care. Splashing should be avoided when pouring it, and a supply of hydrated lime or common baking soda should always be handy for the purpose of neutralising the acid should it be accidentally spilt.

Proper washing of apples or pears only requires 1gall. to 3galls. of this commercial acid per 100galls. of water. Light residues will be removed with the minimum

strength of 1gall. per hundred, but for heavier or more difficult deposits the strength will need to be raised to 2galls. or 3galls. per hundred of water. When preparing quantities of solution less than 100 gallons, correspondingly smaller quantities of commercial acid are used.

The essential equipment for treating fruit with this solution consists of two wooden troughs or tubs—one to hold the acid solution, and the other to contain fresh water for rinsing the fruit after treatment in the acid.

All decayed and bruised fruits are sorted out prior to packing the fruit in boxes for dipping. Any convenient box is suitable for holding the fruit while dipping, provided that it has slatted sides and bottom, which will enable rapid drainage when the box is removed from the bath. Kerosene boxes are unsuitable, because of their poor drainage facilities. Apples should not be submerged deeply in the solution, and shallow trays or long bushel cases on their side, constitute containers which will prevent too deep immersion in the bath. A loose fitting cover to the box or tray is also necessary when dipping apples, in order to prevent fruit from floating out of the box.

For pears, the boxes need not be shallow—they may be submerged deeply in the solution—and as pears do not float, no lids are required for the dipping boxes.

The box of fruit is placed in the acid trough, and plunged up and down for a period of two minutes in the case of 1 per cent. acid and 1 minute in the case of 3 per cent. acid. It is then transferred to a draining board, which slopes back into the acid trough; here the box is allowed to drain for one to two minutes. When draining is complete, the case is moved into the rinsing trough, which should contain circulating fresh water. Here it is plunged up and down again for a further one or two minutes, and finally placed on a second draining board, sloping, this time, into the rinsing bath.

Whilst on this last draining board, it is desirable to give the fruit a final rinse by thoroughly sousing it with a hose. This hose may be left running into the rinsing bath, and with provision for an overflow outlet to the trough, a constant change of the rinsing water takes place. This is highly desirable in order to ensure absolutely thorough rinsing of the fruit. Failure to rinse the fruit properly after it has been through the acid may cause subsequent injury during storage, and the necessity of adequate rinsing cannot be stressed too strongly. No injury to fruit will occur with proper rinsing, and a very simple test is available for determining whether rinsing has been complete. The tip of the tongue will detect very minute traces of acid, and if applied to the calyx end of a rinsed apple or pear will give a good indication of the efficiency of the rinsing treatment. A sharp stinging sensation on the tongue is evidence that all traces of acid have not been removed.

The use of running water is not always possible, and in such cases the water in the rinsing bath must be changed frequently. It is not impossible to rinse in still water, provided that the water is changed after the equivalent of 50 cases of fruit per 200 gallons of rinse water has passed through the bath. If lime be added to the rinse water, the quantity required may be halved. It will be readily understood that without adequate water, the washing treatment cannot be used.

Although the rinse water requires frequent renewal, the acid solution does not lose strength very rapidly, and 50galls. of the weak solution will treat about three or four hundred cases of fruit before the necessity for renewal occurs. If dirty or decayed fruit is passed through the bath, however, it may be necessary to change the solution more frequently. Between renewals of solution, both troughs should be thoroughly disinfected with a weak solution of formalin, in order to prevent the accumulation of mould spores.

Removal of residue by the process which has been briefly described should be carried out soon after picking—especially in the case of apples; otherwise the fruit will, in the course of time, develop a protective coating of wax, which impedes the action of the acid, and makes cleaning very difficult.

FARM SHEEP AND WOOL.

[By C. A. GODDARD, R.D.A. (Asst. Wool Instructor, School of Mines).]

The farm flock has rapidly increased in importance, and has now a definite economic bearing on general farming. It can no longer be looked upon as a sideline, because it ranks among the major farm operations. By the judicious management of sheep the rotation may be widened, fertility increased, and the cost of production reduced.

The farm flock has not received the attention from farmers that it deserves, either from a breeding or a managerial point of view. Sheep are too often looked upon as fallow scavengers, and the quality is frequently so low that profitable production is impossible. It is not economic to keep poor producers, nor, as often happens on farms, to neglect the flock. Sheep of a reasonably high standard and well cared for are excellent producers. There is probably more scope for development along breeding and managerial lines with the farm flock, than in any other form of agriculture.

In this article it is proposed to deal with the subject in three sections:—

i. The Establishment of the Flock, and General Breeding Principles.
ii. Management.
iii. Shearing, Grading of Wool, Marketing of Wool.

THE ESTABLISHMENT OF THE FLOCK, AND GENERAL BREEDING PRINCIPLES.

It is necessary to subdivide this section as follows:—

i. When lamb for export is the first consideration.
ii. When the flock is maintained for the dual purpose of "Lambs" and "Wool."
iii. When wool is the chief object.

These subsections must be studied from a strictly economic aspect, and this brings forth the main issue, viz., climatic and pastoral conditions and situation to markets and transport. When establishing a farm flock, the breed or cross decided upon will depend on these factors. There is a very old and true saying, "Sheep for Districts," and unless this is strictly observed, sheep keeping on the farm cannot be conducted on truly economic lines. When considering the establishment of a flock, the State may be divided as follows:—

i. Good rainfall, heavy carrying pastures within reasonable distance of markets, and good transport. Cross-bred ewes to mate with British rams for fat lamb production.
ii. Moderate rainfall, good average pastures, within reasonable distance of markets and good transport. Merino ewes, to mate with British rams.
iii. Light rainfall, light pastures, long distances from market, and indifferent transport. Merino ewes, mated with Merino rams.

Cross-Breds.

It must be pointed out that sheep husbandry is to some extent influenced by personal inclination. For example, some men appear unable to interest themselves in cross-breds, while others prefer them, and although the division of the State as shown above is made on sound economic lines, some farmers may possibly obtain better results by modifying it to suit their "likes" and "dislikes."

This type of sheep is recommended for the good rainfall districts with heavy carrying pastures. First because these districts are particularly suited for fat lamb production, and cross-bred ewes are best for the purpose, being better mothers,

producing better percentages both in numbers and first grade lambs. Secondly because heavily grassed pastures are subject to internal parasites, foot-rot and other diseases, and while cross-breds are not immune to these troubles, they have a greater resistance than Merinos.

When establishing a cross-bred flock of ewes, there are two methods of procedure—

i. To breed them.

ii. To buy them.

The first essential is to decide on the cross which will be the most profitable. Climatic conditions have a bearing on this, because under very hot, dry conditions, some breeds are inclined to lose fertility, while others do not appear to suffer. Another point which must also be considered is "wool." In spite of the fact that the lamb is of the first importance, wool cannot altogether be disregarded. When all factors are considered, the choice must be for one of the long-woolled British breeds, and one has the Lincoln, English Leicester, Border Leicester, and Romney Marsh to choose from. The English Leicester is the best wool cutter when quality and fleece weight are considered. The Lincoln is very coarse, and the other two are not heavy wool producers.

The English Leicester cross-bred ewes are therefore recommended for Southern districts. In the hotter Northern districts, however, they appear to lose fertility, and the Border Leicester, which does not appear to suffer in this way, is recommended for Northern districts. The Border Leicester, although a lighter cutter than the English, has many excellent points, such as very early maturity, and can be used in any district suitable for cross-breds. Where the pastures are marshy and particularly subject to internal parasites, such as lung worm and fluke, then the Romney Marsh cross is the most resistant and consequently the best.

In a general way, it may be said, "English Leicester or Romney Marsh for the wet Southern districts and the Border Leicester for the drier ones."

When cross-breds are recommended for these districts, it should be clearly understood that reference is made to well bred, first cross ewes, and not the mongrel lines of so-called cross-breds, so often seen on Southern farms.

When establishing a flock of cross-breds by breeding, the first essential is to secure a straight line of well bred station ewes, culled for age. These are joined with a British long woolled ram, the ewe lambs kept for breeding, and the wether lambs sent to market. It is also advisable to cull the worst of the ewe lambs and send them to market. When the ewe lambs are old enough for breeding, they should be joined with a ram of one of the Down breeds, such as Southdown. There is one objection to establishing cross-bred ewes by breeding, and that is it means keeping two different breeds of rams on the farm, and there is always the danger that the Down ram may get with the Merino ewes. Should this happen, the ewe lambs of this cross should not be kept for breeding purposes.

Establishment by Purchase.

There are two serious objections to this method. First, really good first cross ewes are very expensive to buy, and secondly, independent of price, they are often unprocurable. A few breeders are now adopting the practice of breeding half-bred long wools, marketing the wether lambs and keeping the ewe lambs to sell as hoggets for breeding purposes. This is proving quite profitable, and no doubt, the practice will extend, and the objections cited will disappear.

Merino Ewes Mated with British Rams.

The moderate rainfall districts which constitute the best wheat growing areas of the State, are particularly suitable for wool growing, and the maintenance of the Merino. Therefore, the ewe flock should be Merino. There are different types of Merino, however, and it is of the utmost importance that the best or most suitable

type should be established, and this is the large plain-bodied, medium to strong woolled type. The chief points in favour of a Merino flock for these districts are:—

i. The climatic and pastoral conditions favour wool growing and are suitable for the Merino, and as they are the best wool cutters, they are the most economic proposition.

ii. This type of ewe may be bought in any numbers, at about a third of the cost of cross-breds.

iii. They cost less to keep than cross-breds, therefore more may be kept on a given area, and in this way the smaller lambing percentage that may be expected is to some extent compensated.

iv. The wool clip is even and can be easily graded for market, while the clip from cross-breds is always difficult to class.

v. The stations are to some extent dependent on the agricultural districts, as a market for their surplus stock. If farmers universally kept cross-breds, this market would be denied them, which would be a national loss.

Generally speaking, it is not an economic proposition for the farmer to breed his own ewes, because farm conditions are not altogether suitable for breeding the best type of Merinos. Further, the station manager is expert at breeding to type, and the farmer is not. When aged ewes are bought, they are proved breeders, and there is less risk of loss when mating them with British rams, than there is with young farm bred ewes. As the farm flock in these districts should be kept for the dual purpose of wool and lambs, it is practically impossible to breed both cross-bred and Merino lambs on the average sized farm.

Merino Ewes Mated with Merino Rams.

Light rainfall districts such as the outer wheat belt make cross-bred lamb raising out of the question. Yet these districts can and do maintain sheep profitably, in fact, the flock of sheep is perhaps of greater economic importance to farmers in these than in districts of surer rainfall. The first consideration must be wool, and it is imperative that the flock should be good wool producers, and their productivity maintained by careful management and breeding.

When establishing a Merino flock, a straight line of cull for age station ewes should be obtained when possible; failing this, and if the flock is below standard, it may be soon improved by culling and by the introduction of good flock rams.

Frequently in the outer wheat belt the holdings are only partly cleared, and the sheep are expected to live a part of the time in the scrub, and quite often the only fencing is a ring fence. Breeding cannot be successful under such conditions, and so a flock of Merino wethers would be best. When purchasing a flock, every effort should be made to secure a straight line, and an important factor is, do not keep a flock of wethers too long. Old wethers are difficult to fatten, and after a few years their wool production deteriorates.

Breeding.

For those who can finance it, it is a comparatively simple matter to establish a good flock, but to maintain a high standard is more difficult, chiefly because sheep are very prone to degenerate to original type. And if the ordinary every day principles of breeding are not observed, the standard of the flock will soon slip back.

Like Begets Like.

This principle means that in a general way it may be expected that the progeny will resemble their parents, allowing for a percentage of freaks and throwbacks which must always be anticipated. The principle has an important bearing on breeding, because it demonstrates how important it is to breed from high class animals. Misshapen rams and ewes may be expected to produce lambs of their own kind.

Blood Line Breeding.

The farmer breeder cannot go into line breeding to the extent of keeping family records, but he can practise it to the extent of buying his rams always from the same stud breeder, who breeds strictly on blood lines. This is a very important breeding principle, because it is the only way that a definite type can be established, and adhered to. The wide variation in type is one of the greatest disabilities of farm flocks.

Pedigree.

Pedigree is a record of ancestry, and it is especially important when breeding cross-bred lambs for export, because pedigreed animals will throw truer to type than mongrels. This means that a larger percentage of lambs will favour the pedigreed male parent in conformation, which is the type desired, and so a larger percentage of first class lambs may be expected when pedigreed rams are used. Stud rams cost more to begin with, but the extra money received for their progeny more than compensates for this.

Culling.

The almost total lack of culling by farmers is chiefly responsible for the low standard of quality in farm flocks. Sheep are particularly prone to revert to original type, and unless the degenerates are culled, even a good flock will soon become poor producers. This, of course, does not apply when the farmer buys cull for age Merino ewes, but those who breed to maintain a flock—and there are many such—culling is of paramount importance. It is absolutely essential when culling to work on definite lines or culling points and adhere to them. The chief culling points are:—

i. SIZE.—For farm purposes it is most important to have big sheep, because size denotes constitution, which is of primary importance in a farm flock. Size also gives a large area for wool. Large sheep in a general way are the heaviest wool cutters, and also mature earliest. Therefore, when culling, undersized animals should be rejected.

ii. CONFORMATION.—The Merino sheep are not symmetrical like the Southdown, but by judicious culling a reasonably square sheep may be produced. Therefore when culling, reject narrow chested, goose rumped, slab sided specimens. Conformation, like size, is also an indication of sound constitution.

Wrinkles.

Avoid body wrinkles in the farm flock, as they indicate sheep of poor constitution; and are particularly susceptible to fly attack. They do not fatten readily, and the wool on the wrinkles is uneven in length and quality. Practically every station breeder avoids them as unthrifty and poor type of sheep, and farmers should do likewise.

Wool.

It is important that the sheep should be well and evenly covered, with a profitable type of wool for farm purposes. A medium to strong type will be found the most profitable because it will stand severe farm conditions by retaining its character and fleece weight. An important point is character. By this is meant the natural crimp peculiar to Merino wool. Character is a sign of good breeding. Plainness and and hairiness are signs of degeneration. Another important point when culling for wool is to take particular note of the breech, because on this point the wool is very much inclined to become hairy or doggy, which is a serious fault, causing a great deal of comment from buyers, and means a reduction in values. Woolly heads are also undesirable. They are usually described as muffled.

When culling for wool, reject extra fine woolled sheep, also coarse straight fibred ones, and any that show hairiness of the breech, and also muffled headed sheep.

Time to Cull.

The best time to cull is when the young ewes are brought in for shearing, as they are then from 16 to 18 months old, and have a full fleece of wool, and if they have been well cared for, they will be well developed. The degenerates will stand out clearly, and culling will not be difficult. The best method is to run a few at a time into a small yard or pen, catch each sheep and examine it. Mark the culls on the nose with raddle, and when culling is finished, the flock may be shorn as one. A cull mark is any figure 2 to 9 put on the culls as well as the ordinary brand. The culls should then be put into a good paddock, fattened for sale or for ration sheep.

(To be continued.)

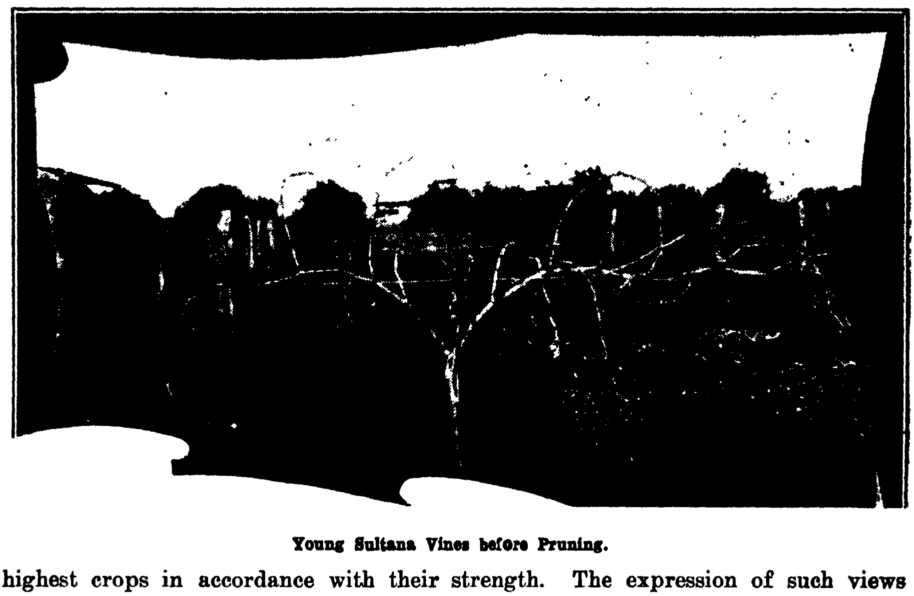
EXPERIMENTS IN THE PRUNING OF SULTANA VINES IN RELATION TO CROP RETURNS—RESULT OF SIX YEARS TRIALS AT BERRI.

[By N. S. FOTHERINGHAM, W. R. LEWIS, and F. R. ARNDT.]

[*A paper read at the Conference of River Murray Branches of the Agricultural Bureau held at Barmera on June* 22*nd,* 1934.]

The idea that in Pruning Competitions the crop as well as the actual pruning of the vines should be taken into consideration has for some time been the opinion of a number of sultana growers, who hold to the belief that the pruning of this vine has been based too much on theoretical standards without sufficient regard being paid as to how the methods used by pruners affect crop returns.

The statement has also been made at times that neatness and symmetry often appear to be the chief objective of many pruners at Pruning Competitions, and that the vines are not always pruned in a manner to enable them to produce the



Young Sultana Vines before Pruning.

highest crops in accordance with their strength. The expression of such views during recent years has led to some extent to greater uncertainty among sultana growers as to pruning methods, and has made it desirable that such ideas should be tested, so that the effect that pruning methods have on crop returns should be more clearly understood.

THE WILKSCH CUP.

The present pruning trials owe their inception to the initiative of Mr. P. M. Wilksch, of Berri, who offered portion of his vineyard for the purpose of holding a pruning competition under the auspices of the Berri Branch of the Agricultural Bureau, in which the pruners would be judged according to the total weight of fresh fruit produced during the three consecutive seasons of 1928-29, 1929-30, and 1930-31, but that the shape and general wellbeing of the vines at the end

of that period should also be taken into consideration by the judges in giving their award. The Berri Branch agreed to take charge of the competition, and appointed Messrs. N. S. Fotheringham, W. R. Lewis, and F. R. Arndt to act as judges.

It will be noticed that the original period laid down for the competition was three years. At the end of that period there was a dead-heat for first place, and on the recommendation of the judges the question of extending the competitions for another three years was agreed to by Mr. Wilksch, the donor of the cup and owner of the property, provided that the competitors were agreeable. With two exceptions the competitors agreed to the suggestion, and in consequence the trials were conducted for another three years, making six years in all.

Site of the Experiment.

The land chosen for the site of the experiment consisted of good, fertile, deep, sandy, red loam. The vines were in good heart—strong and vigorous—and had been well pruned and cared for. Each competitor was given a row of 46 vines to prune, and he pruned the same row every year. The nature of the soil and general condition of the vines was practically the same for each row. The vines all received the same treatment in regard to fertilisation, irrigation, and tillage operations, all of which work was performed by Mr. Wilksch.

Pruned Sultana Vine.

The Competitors.

The competitors who took part in the pruning trials for the first three years were:—Messrs. B. H. Jungfer, G. H. Bottrill, E. R. Moss, A. G. Jarvis, J. R. Johnson, W. N. Ellis, A. W. Magarey, and L. A. Chapple, but during the second three years Messrs. G. H. Bottrill and W. N. Ellis dropped out. The vineyard numbers of the rows selected for the pruning trials ranged from 11 to 18, and in this respect the competitors are referred to by the number of the vine rows they pruned.

Observations on Pruning Methods.

The judges attended the pruning trials each year and observed the methods used by the various pruners. The chief points upon which information was obtained included:—

1. The number of fruiting canes left by each pruner per vine per year.
2. The number of spurs left by each pruner per vine per year.
3. The system of pruning adopted by the various competitors.

4. The approximate average number of fruiting buds left by each competitor per vine from the 1930 pruning trials onwards. This was arrived at by counting the buds on 12 typically pruned vines in each competitor's row and averaged per vine, and the number so obtained was in each case used as the average number of buds per vine for each competitor.

WEIGHING THE FRUIT.

The fruit was weighed by Mr. Wilksch, who took every precaution to ensure that the weights were correctly taken. The following is the record of the weight of fresh fruit produced during the course of the experiments:—

TABLE I.—*Showing Weight in Pounds Yearly, Three-yearly, and Six-yearly for Each Competitor.*

No. of Competitor.	1929.	1930.	1931.	1929-1931.	1932.	1933.	1934.	1932-1934.	1929-1934.
	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.
14	2,133	1,949	856	4,938	1,317	2,615	1,924	5,856	10,794
18	2,083	1,799	723	4,605	1,872	2,457	1,843	6,172	10,777
11	2,178	1,957	803	4,938	1,419	2,355	1,672	5,446	10,384
15	1,995	1,756	685	4,436	1,380	2,766	1,615	5,761	10,197
13	1,839	1,773	772	4,384	1,482	2,482	1,703	5,667	10,051
17	1,703	1,532	668	3,903	1,504	2,114	1,612	5,230	9,133
12	1,683	1,823	643	4,149	Withdrawn				
16	2,215	1,804	782	4,801	Withdrawn				

From the above table it will be observed that Competitor No. 14 (Mr. A. G. Jarvis) headed the list, with No. 18 (Mr. L. A. Chapple) next. The difference between these two competitors was 17lbs. of fresh fruit in six years.

EQUIVALENT ANNUAL AVERAGE WEIGHT OF DRIED FRUIT PER ACRE.

Worked out on an acreage basis, the average annual crop of dried fruit for each competitor for the six years, if calculated at the ratio of 3⅝lbs. of fresh fruit to 1lb. of dried, would represent the following weight in pounds for each of the three-year periods as well as for the full term of the experiment.

TABLE II.—*Showing Equivalent Average Annual Weight of Dried Fruit Per Acre in Pounds.*

Competitors—	11.	13.	14.	15.	17.	18.
Years.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.
1929-31	4,831	4,289	4,831	4,339	3,868	4,505
1932-34	5,328	5,544	5,729	5,636	5,116	6,038
1929 34	5,079	4,916	5,280	4,987	4,492	5,271

From this table it will be seen that the lowest average yield of dried fruit per acre for the six-year period was 2 tons and 12lbs. per acre, and the highest 2 tons 5cwts. and 40lbs. per acre. This shows that the pruning was good commercial pruning, as all growers would like to average a 2-ton crop for six years.

The relation of the number of fruiting canes left on the vines to the total weight of fresh fruit obtained by each competitor is shown in the following table.

TABLE III.—*Relation of Number of Fruiting Canes to Yield.*

No. of Competitor.	Total Fruiting Canes.			Total Weight Fresh Fruit.			Order of Competitor in Relation to Crop Yields.			Order of Competitor in Relation to No. of Fruiting Canes.		
	1929-31.	1932-34.	1929-34.	1929-31.	1932-34.	1929-34.	1929-31.	1932-34.	1929-34.	1929-31.	1932-34.	1929-34.
				lbs.	lbs.	lbs.						
14	991	1,229	2,220	4,938	5,856	10,794	1	2	1	2	1	1
18	844	858	1,702	4,605	6,172	10,777	3	1	2	3	5	4
11	1,007	911	1,918	4,938	5,446	10,384	1	5	3	1	3	2
15	785	918	1,703	4,436	5,761	10,197	4	3	4	4	2	3
13	695	770	1,465	4,384	5,667	10,051	5	4	5	6	6	6
17	774	888	1,662	3,903	5,230	9,133	6	6	6	5	4	5

A record of the number of fruiting canes left by each competitor at each pruning was taken in order to ascertain if any definite relationship could be established between the number of canes and the crops secured. At the end of the six-year trials, however, very little information that could serve as a guide to pruning practice was obtained from these records, for although the competitor who secured the greatest weight of fresh fruit (No. 14) also left the greatest number of canes on his vines; the competitor second on the list in regard to weight of fruit (No. 18), who was only 17lbs. behind the first competitor in respect to fruit returns, was fourth on the list so far as the number of canes left on the vines was concerned, while the results obtained by the other competitors showed but little connection between the ratio of canes to fruit for the six-year period of the experiment.

RELATION OF NUMBER OF BUDS ON CANES TO FRUIT YIELD.

As it was realised that the relationship between the number of fruiting canes and vine yields could be approximate only—as the fruiting rods, being of various lengths, could not all be of equal value for fruiting purposes—it was considered that the number of buds left on the fruiting canes would probably give a more accurate ratio to crop returns than that given by the number of fruiting rods only.

Accordingly, as previously stated, from the 1930-31 season onwards, the buds on a number of typically pruned vines of each competitor were counted and averaged per vine, and the numbers so obtained were used as the average number of buds per vine for each competitor. The relation of buds to fruit yields is shown in the following table for the four years during which these records were taken.

TABLE IV.—*Relation of Number of Buds on Canes to Fruit Yields.*

No. of Competitor.	App. Average Buds per Vine.			Total Wt. Fresh Fruit, 46 Vines.			Average Wt. Fresh Fruit per Bud in lbs.			Order of Comp. in relation to Yields.			Order of Competitor in relation to No. of Buds.		
	31	32–34	31–34	31	32-34	31-34	31	32-34	29-34	31	32–34	29–34	31	32–34	29–34
				lbs.	lbs.	lbs.	lbs.	lbs.	lbs.						
18	63	73	72	723	6,172	6,895	·2494	·6127	·5205	4	1	1	4	4	5
14	90	101	99	856	5,856	6,712	·2067	·4202	·3685	1	2	2	1	1	1
15	58	78	75	685	5,761	6,446	·2567	·5352	·4671	5	3	3	5	3	3
13	64	73	72	772	5,667	6,439	·2622	·5625	·4860	3	4	4	3	5	4
11	81	79	80	803	5,446	6,249	·2155	·4995	·4245	2	5	5	2	2	2
17	53	72	69	668	5,230	5 898	·2739	·5264	·4646	6	6	6	6	6	6

During the 1930-31 season, which was the first year that the relationship of buds to yield was investigated, the results showed that the six highest competitors of the eight pruners then in the competition obtained fruit yields in the same order as the number of fruiting buds left on the vines. During the following

C

three years, however, this [illegible]irely changed, and for the four-year period during which these records were taken the results showed no definite relationship between the number of buds and fruit yields:—Thus, Competitor No. 18, who secured the largest crop returns for this period was fifth in order of the number of buds left on the vines, while No. 14, who was second in order of fruit yield left more buds on his vines than any of the other competitors.

It would appear, therefore, that the buds left on the vines by the various competitors were not all of equal value for fruiting purposes, and that it is the quality of the buds rather than their number that is the chief factor in fruit production.

Comparison of Yields Between First and Second Three-year Periods.

The following table which shows the comparison between the yields of the first and second three-year periods is of interest as showing the difference of yield obtained by the various competitors during these periods:—

Table V.—*Comparison Between Yields in Pounds During First and Second Three-year Periods.*

Competitor No.	14.	11.	18.	15.	13.	17.
	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.
1932-34	5,856	5,446	6,172	5,761	5,667	5,230
1929-31	4,938	4,938	4,605	4,436	4,384	3,903
Increase. 1932-34	918	508	1,567	1,325	1,283	1,327

The chief feature to be noted from the above table is that Competitors Nos. 14 and 11, who tied for first place in the first three-year period, have had during the second three years much less gain in fruit than any of the other competitors. Both these latter competitors had left considerably more rods and spurs on their vines than any of the other pruners for the first three years. It would appear, therefore, that their vines were more overtaxed during that period than those of the other competitors.

Referring back to Table III.—Showing the Number of Fruiting Canes in Relation to Yield—it is seen that Competitors Nos. 15, 13, and 17 considerably increased their canes during the second three-year period, whereas No. 18 increased his by only 14 canes. This would lead one to believe that the three above-mentioned competitors had given their vines too little to do in the first three-year period, and knowing the results of the first three years' trials had increased the number of canes and spurs per vine during the second three years of the competition. No. 18, however, although increasing the number of his canes only slightly, increased the average number of buds per vine from 63 to 73, which is almost equivalent to another cane.

From this it would appear that the vines of Competitors Nos. 13, 15, 17, and 18, on account of lighter fruiting, were in first-class condition at the beginning of the second three-year period, which enabled them to respond with larger yields when given more to do, whereas the vines of Competitors Nos. 11 and 14, having been more heavily taxed during the first three years, were not sufficiently strong to give the same increase during the second three years as the other vines.

The Present Condition of the Vines.

On examining the vines this winter after the leaves had fallen the first thing noticed was that the vines that had produced the greatest yield during the first

three years of the trials, that is, those pruned ...rs Nos. 11 and 14, were weak in places, and were not in so good a c..dition in re. lation to shape and position of fruiting wood as were the others.

Thus No. 11 had a considerable proportion of the fruiting w ood of the vines pruned by him well out from the centre of the vines, while s everal vines were in weak condition, probably on account of having been given too much to do.

No. 14 secured the greatest weight of fruit for the term of the competition, although in most cases having good fruiting wood, much of this was well away from the centre of the vines. This competitor pr ned on the system of depressing the fruiting canes, but the trellis was not ver y suitable for this class of pruning. On a number of vines there were as many as five to six secondary arms, and in most cases there was very little new growt h near the centres of the vines, so that to get suitable fruiting wood at present it would often be necessary to go out several feet from the crown of the vine. A s the fruiting wood was getting farther out every year it would be necessary to re move much of the surplus outer growth to get the vines into good shape again.

Competitors Nos. 13, 15, and 17.—The vines prune d by these competitors were generally of fairly good shape, with fruiting wood reasonably close to the centres of the vines, making them comparatively easy to prune during the present

Vineyard of Trellised Sultana Vines after winter pruning.

winter. These vines generally did not appear to have been depleted in strength on account of excessive fruiting, and should be capable of continuing to bear good average crops.

Competitor No. 18.—The vines pruned by this competitor were in good heart and of good shape, there being an abundance of good, bold fruiting canes on the vines in good positions, with sufficient new growth near the centres of the vines to which to prune back to if necessary. These vines generally were in a better state than those of any of the other competitors, and owing to their good shape would present no difficulties in pruning this winter. By the appearance of these vines there was no suggestion that their strength had been overtaxed during the period covered by the competition, and as there was an ample supply of good fruiting wood to select from situated in good positions on the vines, there was every indication to suggest that they were capable of continuing to produce heavy crops during the coming years.

Conclusions Reached as Result of Competition.

The final conclusions that may be deducted from these competitions are not of the same nature as would have been the case had these trials been discontinued after three years. At the end of that period the records showed that the crop

returns were in propo... work that the vines had been given to do, and that the order of crop produ...n during the third year was in six cases out of eight in proportion to the number of buds left on the fruiting canes of the vines.

During the following three years this ratio of fruiting wood to crop production was not maintained, for although four of the competitors increased their crops by giving their vines more to do, their yields were neither in proportion to the buds nor to the fruiting canes left on the vines. The records of the whole six-year series of experiments gave similar results to those obtained during the second three-year period, and showed that no definite rule could be laid down as to the exact number of buds or fruiting canes that should be left on the vines to secure the best crop returns over a number of years.

What conclusions, then, may be reached from the results of these experiments that would serve as a guide to pruning practice? Although these records show that no hard and fast rule can be deducted for the pruner's guidance, there are, nevertheless, certain aspects of good pruning practice that these trials have

Well-grown Sulta... Vine with Fruit.

emphasised, and which have to be intelligently applied if satisfactory results are to be obtained over a number of years. The chief of these pruning essentials may be briefly summed up as follows:—

1. In the first place it should be realised that the vine is a living thing that must not be abused if it is to produce its best. It must not be given too much fruiting wood to carry, and at pruning time must be carefully treated and not injured by making big saw cuts on the main arms of the vines, as is often done, which restricts the sap flow and weakens the vitality of the vine.

2. That the fruiting wood left on the vine should be proportionate to its strength. From this it follows that as no two vines are exactly of the same strength the pruning treatment must vary with each vine.

3. That the object of good pruning practice should be to strike the correct balance between growth and fruit; too drastic pruning will give growth at the expense of fruit, while the leaving of too much fruiting wood gives fruit at the expense of growth, and so weakens the vine for future production.

4. That a smaller number of good strong fruiting canes with well-developed buds should be left in preference to a greater number of weaker canes with smaller buds. The results of the pruning trials showed that the buds and canes left by the various pruners were not all of equal value for fruiting purposes, and that it was the quality of the fruiting wood rather than its quantity that gave the best results.

5. That on well-developed vines that have been well cared for, as those utilised in these pruning trials, six good strong fruiting canes carrying, about 72 well-developed buds, are sufficient to enable the vines to carry a 2-ton crop of dried fruit for a six-year period without depleting their vitality, and that on such vines the laying down of more fruiting wood was not desirable, either in regard to crop production or in respect to the vigour of the vines. This relationship of fruiting wood to yield and vine vigour was probably the most important feature brought out by this series of experiments, a knowledge of which should be of value as an aid to future pruning practice.

The Winner of the Wilksch Cup.

As previously mentioned, this cup was offered by Mr. P. M. Wilksch as a prize for the winner of the pruning competition in which the pruners were to be judged according to the total weight of fresh fruit produced by their vines during the term of the trials, but that at the end of that period the shape and general well being of the vines should also be taken into consideration by the judges in giving their award.

The general condition of the vines pruned by the various competitors at the end of the trials has already been described. Of the various competitors there were practically only two in the running at the end of the six-year period, namely, Nos. 14 and 18, and of these the former had secured 17lbs. more of fresh fruit than the latter.

On examining the condition of the vines, however, it was at once apparent that those pruned by No. 18 were in far the better condition, both in regard to shape and position of fruiting wood, while those of No. 14 were in a much less satisfactory state, having fruiting canes in many cases far from the centres of the vines.

Therefore, as there was only a difference of 17lbs. of fresh fruit in six years between the two competitors, and as the vines pruned by No. 18 were in much better condition than those of No. 14, thereby making them much less costly to prune, which would much more than compensate for their slightly lighter yield, the judges decided to award the cup to Competitor No. 18, Mr. L. A. Chapple.

VETERINARY INSTRUCTORS.

In July, 1934, a deputation consisting of members of the Advisory Board of Agriculture, supplementing a deputation of the same Board in May, 1933, waited on the Hon. Minister of Agriculture with reference to the requests of Branches of the Agricultural Bureau seeking the appointment of Veterinary Instructors in country districts. The deputation made the following statement:—

During the past two years, resolutions have been carried at nine Conferences of the Agricultural Bureau in various parts of the State, asking for Veterinary assistance for country districts. These resolutions, together with numerous inquiries for Veterinary lectures and demonstrations, are regarded by the Advisory Board of Agriculture as definite indications that farmers of South Australia feel the need of adequate instruction in the principles of stock management in health and disease.

A committee appointed by the Board gave careful consideration to the persistent requests of Conferences and Branches, and after looking into the matter from the point of view of practices adopted elsewhere and of the value and the mortality of livestock in this State, made the following recommendation:—

"That your Committee, having carefully considered the question of Veterinary Services for country districts, recommends that in view of the importance of the livestock industry to this State, and on account of the yearly mortality among livestock, the Veterinary staff be strengthened, and a Veterinary officer be stationed at each of the following districts:—

1. Central (Adelaide).
2. South-East (say, at Naracoorte).
3. Murray Mallee (Loxton or Lameroo).
4. Eyre's Peninsula (Yaninee or Minnipa).
5. Northern (Port Augusta or Wilmington).

The staff would be under the control of the Chief Inspector of Stock in Adelaide.

The Committee believes that the duties of the country Veterinary Surgeons should be to supervise the livestock of their districts, and to that end they should travel about their districts over a defined itinerary. They should give advice and, if possible, practise as Veterinary Surgeons when required. For such Veterinary work they should make a revenue charge on the basis of a fixed scale, it being understood that no charge for mileage shall be imposed upon those requiring their services."

The Committee attached to its recommendation a statement showing the value of the livestock industry and the yearly mortality of stock in this State.

The Advisory Board endorsed the recommendation of the Committee, and appointed a deputation to wait on the Hon. Minister with the hope that action would be taken to give effect to the proposal.

The matter was referred to the Chief Inspector of Stock, who reported as follows:—

The Committee appointed by the Advisory Board refers to the fact that at nine Agricultural Bureau Conferences resolutions have been carried asking for veterinary assistance in country districts. These requests are obviously due to the fact that there are no qualified Veterinary Surgeons in private practice in the country districts of this State. This Department has, wherever possible, made its professional staff available to assist country stockowners, and it would appear that this has given rise to the impression that it is one of the functions of the Stock and Brands Department to provide veterinary attendance for all cases of sickness and injury in farm animals.

The absence of qualified Veterinary Surgeons in country districts is due to a number of causes, among which may be stated the inability of South Australian students to qualify in Veterinary Science within the State, and that in South Aus-

tralia there is no legislation for the registration of Veterinary Surgeons and for the control of the practice of veterinary surgery. It is nevertheless the fact, however, that notwithstanding these disabilities, there are few country districts within the State in which a qualified Veterinary Surgeon could not be induced to practise his profession if an organised effort was made by the stockowners themselves by means of a guarantee, by the establishment of a veterinary lodge, or by other means.

I am of the opinion that the provision of veterinary services by the Government should be for the control of contagious stock diseases, the investigation of serious outbreaks of disease in animals, and for veterinary research. It would be of more value to the State if the Department could be extended for these purposes than for the practice of Veterinary Surgery, which is the province of the private practitioner.

I am of the opinion, therefore, that the requirements of the State in the above respects should be fully supplied before any consideration is given to an extension of the activities of the Department in the manner suggested.

It is strongly recommended, however, that any steps which can be taken for the encouragement of private practice should be adopted, and legislation for the registration of Veterinary Surgeons and the establishment of veterinary scholarships by the Government will materially assist in this direction."

The Minister has informed the Board that he agrees with the opinion expressed by the Chief Inspector of Stock.

THE EFFECT OF ARSENIC—AS USED IN POISONING GRASSHOPPERS—UPON BIRDS.

[Review of Bulletin No. 218, published by the Oklahoma, U.S.A., Agricultural Experimental Station.]

The author reviews the literature dealing with the possibility of domestic and wild birds being poisoned by feeding on bran baits used in control of grasshoppers or on the poisoned grasshoppers themselves. In Oklahoma, domestic fowls and quail confined without food for 24 hours and then supplied with bran poisoned with 4 per cent. white arsenic (As_2O_3), which was scattered about the pens at the rate of 100lbs. per acre, showed no indications of poisoning after 24 hours. When poisoned bran was forcibly administered, 74 mg. As_2O_3 proved slightly toxic to a 22oz. fowl (*i.e.*, 3.363 mg. per oz. of bird weight).

When individual grasshoppers were caged with bran flakes of selected standard size, each weighing approximately 2.337 mg. and containing 0.0935 mg. As_2O_3, the number eaten by one adult of three species averaged 8.05, 3.02, and 3.2 respectively. The reliability of these tests in indicating the arensic content of poisoned grasshoppers was confirmed by analysis of 72 poisoned adults of *M. bivittatus*, which were found to contain an average of 0.75mg. As_2O_3.

From a series of experiments in which 144 birds of various species were fed on grasshoppers, the following conclusions were drawn:—Fowls discriminate between poisoned and unpoisoned grasshoppers, and eat less than half as many of the former; the amount of arsenic consumed by them in eating only poisoned grasshoppers averages less than half the toxic dose, and their weight and growth after 66 days is not materially affected; quail eating a normal number of grasshoppers would, if the latter were poisoned, receive only from 1 to 7 per cent. of a toxic dose of arsenic; there is practically no danger to adult wild birds from eating poisoned grasshoppers, though there may be slight danger to nestlings. Chemical analysis of the bodies of fowls that had eaten many poisoned grasshoppers showed that they could safely be used for human consumption.

COKE POT AND FAN METHOD OF DRYING CURRANTS.

[By H. H. ORCHARD, R.D.A., Horticultural Instructor.]

Some four years ago, Mr. A. H. Howard, of Langhorne's Creek, experienced damp weather conditions soon after spreading his currants on the racks. The grapes quickly reached a state that, under ordinary conditions, there was no chance of obtaining a satisfactory dried article, and unless something was done, and at once, a dead loss of anything up to £300 confronted him.

From this forced situation, he evolved the coke pot and fan method of finishing off his currants, a method which was originally tried out by Mr. W. Cooper, sen., of McLaren Flat, some twelve years ago, but not persevered with. The idea is very simple, and, briefly, consists of enclosing the drying shed with galvanised iron along sides and ends, and then circulating hot air through the racks by means of coke fires and fans.

Naturally, methods were crude at first, but on the basis of experience gained during the intervening seasons, improvements have been made; it is not claimed, however, that perfection has yet been attained. The method is still in the experimental stage, and success largely rests with the grower himself, and his ability to apply common sense. The only claim made is that it is a simple and cheap method of dehydrating currants in a minimum of time. Whilst admittedly mistakes have been made in the past, no fruit has been spoilt under this system, and last season approximately 46 tons were dried.

Mr. W. C. Cooper, of McLaren Flat, is another grower who favours the system after three years' trial.

The main essential is a suitable drying shed, and without this a grower may easily be disappointed with the result. The galvanized iron roof should be curved; the hip roof is not satisfactory. The sheds used comprise double sets of racks, each set 6ft. wide and 56ft. long, divided into bays of 7ft., and with a 7ft. race. Each set of racks contains 14, placed about 6in. apart. The sheds hold 7 to 8 tons of fruit.

Galvanized iron is used to enclose the shed, and should be fastened so that it will withstand the rapid circulation of air created by the fans; clamping, for instance. Hessian is not at all suitable for this purpose. The ingress of cool air must be prevented as much as possible, but at the same time, the shed must not be absolutely air-tight, and therefore should operate in calm weather, if possible. The floor of the shed requires attention to minimise dust, and whilst straw can be used immediately under the racks if reasonable care is exercised, it will possibly be found necessary to brick or cement the centre.

One-inch water piping is used to carry the fans; if of smaller diameter the threads will gradually become stripped. This piping runs down the centre the full length of the shed, overlapping at each end, and is placed not higher than 6ft. from the floor. To carry this piping, 3in. x 2in. timbers 7ft. 6in. long are placed at intervals, and fastened to the shed or rack uprights. In the centre of these cross pieces are two smaller pieces of timber, the lower one attached, and the higher one clamped, and each grooved, so that when clamped tightly together a circle sufficient to take the piping is formed.

Double fans, that is, one either side of the shafting or piping, are fixed, generally one for each bay or not more than 7ft. apart. The fans vary in construction amongst the growers, but due regard must be given to stability, area in which they are to operate, and that they work reasonably close to the coke

pots. One type was made of 24-gauge iron, 18in. square, rivetted to 1¼in. by ⅛in. iron, which was in turn clamped by means of a collar to the piping. The overall length of this fan from centre of piping to edge of fan was about 24in. Directly under each fan is placed a coke pot. These pots are 40gall. petrol or bitumen drums cut in halves; the former are preferred because of their greater strength. Holes are made in the bottom and side near the bottom, and to each are attached two wire handles for carrying. A pulley is placed towards the end of the piping, and by means of a belt operating from an engine the fans are revolved, and it is estimated that upwards of 150 revolutions per minute should be sufficient. Mr. Howard uses his Fordson tractor for the purpose, but a 3h.p. engine should be quite suitable for a shed of the dimensions stated. The advantage of a tractor is that it can readily be shifted to the other end of the shed if required, and so reverse the movements of the fans. Naturally, both movements cannot be obtained from the one end, as the pipe length will unthread, and a pin through the thread is not permanently effective.

The coke pots must be started outside; and the whole of the kindling wood thoroughly burnt out before being placed in the shed. This point must be closely observed, as otherwise fruit will be affected. Wood must not be used in the pots in the shed. For the first three hours the temperature should be kept down, and after that never at any time allowed to get over 130° F. Should the temperature become too high, place the covers ready for the purpose on the pots. In handling the coke, a good plan is to have a large case (an old piano crate will do) filled with coke and wetted down, and then add this as required to pots. The damp coke when added to the fire appears to form a crust on the surface, obviating the risk of coke dust which otherwise would settle on the top trays.

It is not possible to estimate actual costs, as no definite figures have been kept. The city price of coke is 38s. per ton, and there are about 33 bags to the ton. Mr. Cooper last year used 10 to 12 bags a day, and approximately 3 tons for the season. He finished off one lot of 7 tons of currants in 60 hours, which he estimated a portable dehydrator would have taken seven days to do.

Currants should be a little on the dry side when the heat is removed, as they invariably come back a little. Thorough mixing is also necessary when removing from the racks.

The whole of the equipment required need only be of a temporary nature, and could, if necessary, be used for other purposes during the rest of the year.

Apart from the simplicity and economy in working, probably the greatest claim for the coke pot and fan system of dehydrating currants is that fruit once on the racks is not again handled—as in the case with dehydrators—until ready to come off.

Rough handling at any stage of drying can very easily reduce the fruit one crown, and this loss would be additional to the charge of £3 per ton for dehydrating.

It is again stated, in conclusion, that the method is still in the experimental stage, and at present success largely rests on the ability of the grower to recognise and correct faults. The growers mentioned, who have profited from their experiences, are of the opinion that the method is advantageous, it is simple to construct, economical to run, saves considerable time, and correctly handled no damage to the fruit results either in appearance or keeping qualities.

There seems, however, one factor that requires further consideration, and that is the movement of the fan—whether the present rotating method is superior to a pendulum motion or to the horizontal position.

PURE CULTURED YEASTS.

[By A. R. BECKWITH, R.D.A. (Oenology Cadet, Roseworthy Agricultural College), now employed by Penfolds Wines Ltd.]

[This paper outlines the results of an investigation conducted at the Roseworthy Agricultural College, South Australia, to determine the advantages or otherwise of using pure cultures for the manufacture of Australian wines.]

The importance of pure cultured yeasts in the manufacture of wine has long been recognised, and it is a known fact that large variations in the quality of the finished wine can be brought about by the use of different yeasts, at vintage. This is due to variations in the amounts of by-products formed during fermentation.

Apart from differences in the quality of the wine produced by various yeasts, another factor to be considered is the quality of the must. A poor must could not be turned into a high-class wine by use of one special yeast, but a high-class must could be made into a high-class wine with a suitable yeast, or only an average wine by one of inferior fermenting powers.

It is the general practice of many of the larger wineries to import fresh cultures of yeast from the Continent every year or two. There is some difference of opinion as to whether a local yeast should be selected and cultivated, or whether an imported yeast known to give good results should be used. It is quite probable that the local yeasts may prove unsuitable for fermentation when vines are introduced into a new district, and in this instance it would be of advantage to introduce a yeast which has proved itself. Even now, the importance of the yeast supply is not fully appreciated, and with the use of tested and selected strains, improvements in the fermentation and the finished product would be brought about.

In many cases, the natural yeasts which adhere to the skins of the grapes are allowed to ferment the must, sometimes with good results, but more often with results which do not compare favourably with those obtained from a known yeast. The habits of a pure, selected yeast become known to the wine maker, and to some extent the type of fermentation can be anticipated; this knowledge is very useful in a winery at the rush period of vintage. Besides, with normal vintage practices and precautions, a clean fermentation is assured.

The variations in the amount of alcohol produced by different yeasts from a given amount of sugar are also of practical interest, especially in the manufacture of fortified wines. This has a bearing on the amount of fortifying spirit to be added, and, incidentally, the cost of the wine.

To demonstrate the influence of different yeasts, eight types were collected from various wineries in South Australia. The yeasts originally came from some of the main wine-producing countries of the world, and include types from France, Germany, Portugal and Algeria, and four Australian types (Magill, Barossa and Roseworthy).

The yeasts, when received, were immediately cultured on a solid medium until required. They can be so stored on such medium for a long time, and culturing them in this way is a suitable means of carrying them over from one vintage to another. In one case, a local yeast was stored on an agar slope in a dry place for nearly 12 months. The agar dried out hard, but the yeast was still alive, and conducted a normal fermentation when placed in a flask of sterile must.

METHOD OF CULTURING.

For culturing the yeasts, solid agar nutrient medium (modified Lorenz standard) was used. This contained ammonium sulphate, magnesium sulphate potassium phosphate, tartaric acid, glucose, agar and water, thus supplying the necessary food requirements and at the same time being sufficiently acid to suit the yeast. To prepare the mixture it is melted and dissolved in the autoclave, which, incidentally, affects sterilisation. After filtering through cotton wool, it is kept in a flask plugged with cotton wool. When required, it is melted in the Koch steamer, and about 10 ccs. of the hot liquid poured into petri dishes (previously sterilised), and allowed to set.

When the agar is inoculated with the yeast, giant colonies appear on the surface after a day or two; and the object is to assure that each colony arises from a single yeast cell. When "seeding" the plates it is necessary to dilute the fermenting must, so that a drop in a platinum loop contains about 10 cells (otherwise the concentration of cells will be too great). This is accomplished by making several dilutions with sterile distilled water as follows:—

(*a*) Three drops of must in full fermentation are added to 15 cc. of sterile distilled water, in a sterile test tube and thoroughly shaken.

(*b*) Three drops of (*a*) are added to 15 cc. of sterile distilled water and shaken.

(*c*) Three drops of (*b*) are added to 15 cc. of sterile distilled water and shaken.

A drop of the liquid from tube (*c*) normally will contain approximately the right concentration of cells for inoculating the agar plate with the platinum loop.

To guard against mould infection, a metal hood was used to cover the plates while operating. This was easily sterilised by heat.

The yeast was grown on the agar in the form of stripe surface cultures. The platinum loop was sterilised by heat, and dipped into tube (*c*) of the yeast solution, and drawn over the surface of the agar. About five stripes were made on each plate, and these were placed in the incubator at 25° C. (77° F.). This temperature is suitable for the growth of yeast, and the first signs of growth on the agar were apparent after 20 to 24 hours.

The next process consists of subculturing to be certain that the culture is absolutely pure. This is carried out as follows:—One colony, typical of the type under examination, is selected, and transferred to a test tube of sterile distilled water by means of the platinum loop. Dilutions are made as above, and another plate inoculated with the cells from the single colony. These cells again produce colonies on the agar, and when fully grown are stored in a cool place or transferred to sterile must for fermentation. These colonies should therefore represent a pure culture, as they have been derived from a single yeast cell.

THE YEASTS.

1. *Local Muscat.*—From 1932 Muscat, Roseworthy College.
2. *Local Shiraz.*—From 1933 Shiraz, Roseworthy College.
3. *Rioja Tempranillo.*—From Geisenheim University, Germany.
4. *Vezenay.*—From the Institute Zymotechnique, France. Suitable for light and delicate types of wine.
5. *Port Type.*—From Portugal, through the Institute Zymotechnique. Suitable for sweet wines; vigorous fermentation and rapid rise in temperature.
6. *Dorrien High Strength.*—From a vat of wine, 33 per cent. P.S., which showed active yeast and which had no difficulty in fermenting sterile grape juice. 1933 vintage.
7. *Magill.*
8. *Algerian.*—The optimum temperature of fermentation with this yeast is said to be about 40° C.

GENERAL OUTLINE OF METHOD.

Duplicate flasks of sterile must were fermented by each yeast, and the following determinations were made, in duplicate, on the wine obtained in each flask:—Alcohol, glycerine, unfermented sugar, total and volatile acids.

THE MUST.

Muscat juice which had been pasteurised and stored in bottles. Sulphur dioxide was not used in its preparation.

TREATMENT.

About 10 litres of must were blended in a stone jar, and sterilised by steaming in the autoclave at 100° C., with two heatings, totalling six hours. Ammonium phosphate was added at the rate of 4ozs. per 100galls., and tartaric acid, 1 gram per litre. This must was then siphoned while hot into sterile flasks and plugged.

The yeasts were transferred from the agar plates to small flasks of similar must and allowed to ferment vigorously. When in full fermentation, 10 cc. of must were added to each of the test flasks.

THE FERMENTATION.

Vigorous fermentations were in progress at the end of 21 hours, and observations were taken on them as they proceeded, but nothing outstanding was noticed.

At no time did the temperature of the fermenting must exceed the room temperature by more than 1° C. The temperature was ideal for fermentation, and was maintained between 20° and 25° C. for most of the time, but at the end of the fermentation the temperature exceeded this by a few degrees.

SYSTEM OF TESTING.

Eight yeasts were employed, and for each yeast there were two separate fermentations, which were carried out in 1 litre Erlenmeyer flasks plugged with cotton wool. Upon each flask duplicate chemical tests were conducted, thus making four separate analyses for each type of yeast. In the case of alcohol, duplicate distillations were carried out for each flask, with at least two weighings for the specific gravity of each distillate.

By using the duplicate system a check was kept on all analyses.

THE ANALYSES.

After fermentation was complete, and the lees had settled, all samples were filtered brilliant with the aid of a small gauze-plup filter.

For each wine the following tests were conducted:—Alcohol, glycerine, unfermented sugar, total and volatile acids.

The alcohol was determined from the specific gravity of the distillate at 20° C./4° C. in vacuo, by weighing in a Sprengel tube, and adopting the method of the Association of Official Agricultural Chemists.

Unfermented sugar was determined gravimetrically by reducing the copper sulphate of Fehling's solution to cuprous oxide and igniting this and weighing as cupric oxide. (Leach, "Food Inspection and Analysis.")

Glycerine was extracted with alcohol and ether then weighed (A.O.A.C. method.)

Total acids were titrated with 0.13 N. sodium hydroxide, using phenolphthalein as an indicator.

Volatile acids were determined with the Sellier distillation tube, and titration with 0.1 N. sodium hydroxide, using phenolphthalein as the indicator (A.O.A.C. method). There were no corrections for sulphur dioxide, as none was added to the must.

ALCOHOL.

Ethyl alcohol, the most important product of fermentation, is the one of greatest interest to wine makers. Its formation from grape sugar is represented simply by the equation

$$C_6H_{12}O_6 - 2C_2H_5OH + 2CO_2$$

Grape sugar — Ethyl alcohol + Carbon dioxide.
but in reality it is not as simple as this.

It is a complex action, brought about by the enzyme, zymase, and closely associated with phosphates. With reference to the part played by phosphates in the fermentation process, there is considerable difference of opinion.

If the action were as simple as the above equation indicates we could expect to obtain a theoretical maximum of 51.10 grammes of alcohol for every 100 grammes of sugar present in the must.

In practice the yield falls far below this, and in attempting to ascertain greater details of the process, the following observations require consideration:—

1. Consumption of sugar by yeast.
2. Some sugar remains unfermented.
3. Besides ethyl alcohol, other by-products are formed from the sugar.

These factors will be dealt with individually. The large number of by-products formed, and the large variation in the quantities produced, particularly ethyl alcohol, make it easy to understand why one yeast should be superior to another from the wine maker's point of view.

The following figures show the variations in alcohol produced by the eight yeasts, from a must containing 22.26 grammes of dextrose per 100 cc., about 12.5 degrees B.—

	Alcohol.	
	% Vol.	% Proof.
Magill	12.79	22.38
Algerian	12.74	22.29
Dorrien H. S.	12.68	22.19
Port type	12.64	22.12
Vezenay	12.58	22.02
Rioja Tempranillo	12.56	21.98
Local Muscat	12.30	21.53
Local Shiraz	12.18	21.32

The two latter yeasts, viz., local Muscat and local Shiraz, may be considered as natural yeasts derived from the skins of the grapes, while the other six have been selected and used by various wine makers of this State to conduct their fermentations. Taking these figures into account, it will be seen that the selected yeasts are definitely superior as far as alcohol production is concerned.

The following table is prepared from the above figures. This shows the amount of sugar necessary in the must to produce 1% of alcohol by volume:—

Grammes of Sugar Necessary to Produce 1% Alcohol (Vol.)

Magill	1.74
Algerian	1.75
Dorrien H.S.	1.76
Port type	1.76
Vezenay	1.77
Rioja Tempranillo	1.77
Local Muscat	1.81
Local Shiraz	1.83

The advantage of the Magill yeast over the local Shiraz yeast is obvious from these figures.

To the practical wine maker, the above results put in terms of pounds, shillings, and pence would be of greater interest. For this reason, comparison has been made along these lines, taking the Magill yeast, which gave the highest percentage of alcohol, in contrast to the local Shiraz yeast, which produced the least amount.

The figures for each yeast are:—

Magill	22.38% P.S.
Local Shiraz	21.32% P.S.
Difference	1.06% P.S.

Example.—Fortify 1,000galls. of must, similar to that used in the test fermented with each yeast, to 34 per cent. P.S., using spirit at 64 O.P.

1. Magill Yeast $$\frac{1{,}000 \times 11.62 \times 164}{130 \times 100} = 146.6 \text{ pf. galls.}$$

2. Local Shiraz Yeast $$\frac{1{,}000 \times 12.68 \times 164}{130 \times 100} = 160.0 \text{ pf. galls.}$$

Difference is 13.4 proof gallons.

The difference of 13.4 proof gallons of spirit, at 4s. 3d. plus 6s. 6d. Excise = 10s. 9d. proof gallon, is £7 4s. in favour of the Magill yeast, and shows the value of using a selected, cultured yeast in the production of fortified wine.

The above examples cannot be taken as final, as the number of fermentations was limited, viz., two in each case, but these results open up a field for investigation. To confirm these results it would be necessary to determine the standard variation over a large range of samples, perhaps 20, but the large difference in yield of alcohol offers a very good reason for further work.

GLYCERINE.

During fermentation a relatively large amount of glycerine is formed, dihydroxyacetone and glyceraldehyde acting as contributory compounds in its production.

For the purpose of this test it has been found necessary to determine the amount of sugar which went into the formation of glycerine, and the calculation was based on the following equation:—

$$\underset{180}{C_6H_{12}O_6} + 2H_2 - \underset{184.}{2C_3H_5(OH)_3}$$

Thus 184 grammes of glycerine are derived from 180 grammes of sugar, and 1 gramme of glycerine is derived from $\frac{180}{184}$ grammes of sugar, or 0.98 grammes.

Thus the amount of glycerine formed, multiplied by 0.98, represents the quantity of sugar from which it was derived.

The glycerine produced by each yeast is given in the table below:—

Glycerine, Grammes per 100 cc.

Vezenay	0.54
Dorrien H.S.	0.58
Local Shiraz	0.66
Port type	0.66
Algerian	0.69
Local Muscat	0.69
Rioja Tempranillo	0.70
Magill	0.71

There is considerable variation, 0.54 grammes per 100 cc. being the lowest, and 0.71 grammes per 100 cc. being the highest amount formed, a variation of nearly 24 per cent. The yeasts were consistent in the glycerine formed in the duplicate fermentations. The Magill yeast, which produced the most alcohol, also produced the most glycerine, showing its ability to consume the greater part of the sugar present.

Pasteur's estimate for a normal fermentation is that 3.2 parts of glycerine are formed to 100 parts of sugar fermented. The figure obtained in this test with the Magill yeast supports this estimate, and is almost 3.2.

UNFERMENTED SUGAR.

The whole of the sugar is not consumed by the yeast, and the residual sugar unfermented showed wide variations with the types employed. Some sugar is necessary in any wine, otherwise it would be very harsh on the palate. It assumes the role of protector, and is not likely to be deficient. With maturation this residual sugar enters into various chemical combinations, in the formation of organic compounds.

The unfermented sugar in the wine gives some indication of the amount of sugar consumed, and the Magill yeast, which produced the most alcohol, left only 0.28 grammes of reducing sugar per 100 cc. The must, before fermentation, contained 22.26 grammes of reducing sugar per 100 cc. The local Shiraz yeast left a greater quantity, viz., 0.70 grammes per 100 cc.

By deducting the amount of unfermented sugar from the total sugar before fermentation commenced, the amount of sugar transformed by the yeast can be determined, and with reference to the alcohol table, the percentage of alcohol to sugar transformed, is also assessed as follows:—

$$\frac{\text{Alcohol, grammes per 100 cc.} \times 100.}{\text{Sugar of must—unfermented sugar, grammes per 100 cc.}}$$

The following table gives the percentage for each yeast:—

Per Cent. of Alcohol to Sugar Transformed.

Port type	46.26
Dorrien H.S.	46.01
Magill	45.95
Vezenay	45.93
Algerian	45.65
Rioja Tempranillo	45.42
Local Shiraz	44.62
Local Muscat	44.42

Put in another way, these figures represent grammes of alcohol which are produced from the actual fermentation of 100 grammes of sugar.

The amount of sugar which was left unfermented in the various wines is given below, as dextrose—

Residual Sugar, as Grammes Dextrose per 100 cc.

Algerian	0.22
Magill	0.28
Local Muscat	0.40
Rioja Tempranillo	0.42
Port type	0.44
Dorrien H.S.	0.48
Vezenay	0.62
Local Shiraz	0.70

This table represents the amount of sugar remaining after the first fermentation had been completed. It is more than likely that this figure would be further reduced in the following spring, with the rise in temperature, when a secondary fermentation of unfortified wines generally takes place. Considered in the light of fortified wines, this is of no importance, as the yeast is killed on the addition of fortifying spirit.

TOTAL ACIDS.

The chief consideration here is non-volatile acids, which form the greater part of the total acids. Tartaric and malic acids are present in the must, and appear to some extent in the wine. A considerable portion of the tartaric acid is precipitated, because of the formation of potassium hydrogen tartrate, which is sparingly soluble in water, and even less soluble in dilute alcohol. Certain acids are readily attacked during fermentation, while a small amount of tartaric acid is produced by different yeasts.

In the experiment there was quite a definite range in the acidity, and this may be attributed to the formation chiefly of succinic acid. There may also have been differences in the amounts of tartaric acid deposited. The following table shows the final acidity, both total and fixed, of the various wines:—

Total and Fixed Acids, as Grammes Tartaric Acid per 100 cc.

	Total.	Fixed.
Local Muscat	0.74	0.70
Algerian	0.76	0.69
Magill	0.80	0.76
Local Shiraz	0.80	0.74
Dorrien H.S.	0.81	0.75
Vezenay	0.82	0.77
Port type	0.82	0.77
Rioja Tempranillo	0.84	0.78

The initial total acidity of the must was 0.68, and fixed acid 0.61.

The figures of the above table show a considerable increase over the original acidity of the must. As some acids are consumed during fermentation, necessarily a greater quantity must be produced in order to explain this increase. Succinic acid is probably the acid produced in greatest quantity, and is derived from the amino acids of the must.

VOLATILE ACIDS.

Here again differences are observed, and the figures given below show the production of volatile acid by the various yeasts:—

Volatile Acid, as Grammes Acetic Acid per 100 cc.

Magill	0.030
Local Muscat	0.034
Port type	0.038
Vezenay	0.041
Local Shiraz	0.045
Dorrien H.S.	0.049
Rioja Tempranillo	0.050
Algerian	0.057

The volatile acidity of the must was 0.021 grammes per 100 cc.

These volatile acids affect the bouquet and flavour of the wine by partial esterification, and are known to consist of acetic, formic, propionic and valeric acids.

SUGAR USED BY THE YEAST.

This figure was obtained by calculating the amount of sugar which was necessary to form the alcohol and glycerine, and including the unfermented sugar. This sum, deducted from the sugar present in the must before fermentation, was regarded as being sugar used by the yeast.

The amount of sugar used in this manner varied widely, and to some extent, gives an idea of the economy of the yeast. Thus the two local yeasts, which were the poorest, consumed 2.15 and 2.05 grammes of sugar respectively, while the Magill and Dorrien High Strength yeasts, which were among the best, consumed only 1.11 and 1.22 grammes respectively, in this manner.

This figure is important, as naturally the wine maker does not want to use a yeast which consumes a large portion of the sugar at the expense of alcohol. The figures for each yeast are given below:—

Grammes of Dextrose per 100 cc. Consumed by the Yeast.

Magill	1.11
Dorrien H.S.	1.22
Algerian	1.29
Port type	1.61
Vezenay	1.63
Rioja Tempranillo	1.71
Local Shiraz	2.05
Local Muscat	2.15

A considerable portion of the sugar which is used by the yeast is consumed in the first part of the fermentation, when it lives aerobically, and multiplies very rapidly, using sugar for the formation of yeast tissue.

DISCUSSION OF RESULTS.

This paper has been designed to show the advantage, if any, of using a selected, pure cultured yeast (see 1), and to demonstrate the variation in the production of the by-products of fermentation.

The analyses leave no doubt as to the advisability of using a selected, cultured yeast, in the production of wine, and the difference in yield of alcohol between the types is conclusive evidence in itself.

This interests the distiller and the maker of fortified wines more than the maker of dry wines, as the amount of alcohol produced is an economic factor in production. (See 2.)

Some specific examples of the value of several yeasts may be taken from the foregoing figures. Firstly, in the manufacture of sweet fortified wine. In this case we would choose the port type, or the Dorrien High Strength yeasts. The amount of unfermented sugar is unimportant in this case, as the fermentation is stopped while a large percentage of sugar remains, by the addition of fortifying spirit. The point of particular interest is the percentage of alcohol produced, to the sugar transformed, and these two yeasts gave the best figures in producing the most alcohol from the sugar actually transformed.

For a sherry type, a yeast is required which will ferment out practically the whole of the sugar, and produce a high percentage of alcohol. In this case the Magill yeast comes first, followed by the Algerian, and the chief consideration here is the percentage of sugar necessary in the must to produce 1 per cent. of alcohol by volume. The Magill yeast required the least sugar of any to produce 1 per cent. of alcohol, and consequently is the most economical. Reference to the case quoted under "Alcohol" emphasises the value of this yeast in comparison with others. The same yeast would also be the best for fermenting the juice for distillation purposes, as here again, a high percentage of alcohol is required.

---

(1) The majority of Australian wine makers use cultivated yeasts, without knowing definitely whether or not they are gaining any advantage from the practice.

Many assume that they are obtaining better results than they were when wine was made through the agency of the yeasts occurring naturally on the skins of the grapes. Modifications must of necessity be adopted in ordinary wine making practice in order to secure results, shown to be attainable by the use of selected yeasts.

(2) To say with absolute certainty, however, that the Magill yeast will produce 1 per cent. more of proof spirit than the local Shiraz yeast, from a must of about 12.5° B., is somewhat premature, as this difference would have to be proved conclusively over a large range of samples, and the results submitted to biometric analysis. To be quite emphatic and leave no doubts about the matter, further investigation is necessary, using the differences shown in the tables accompanying this article as the basis for more detailed work.

Possibly the Algerian yeast would be very suitable for fermenting must intended for brandy making, because it produces a large amount of volatile acid, which is an important flavouring constituent, more so in brandy than in wine, where conditions are more favourable to ester formation because of the greater proportion of alcohol. Further, the Algerian yeast can be depended upon to ferment the sugar economically.

The analytical data may not be of such practical interest to the maker of dry wines, as the amount of alcohol produced in dry wines, excepting those used for distillation purposes, is of no very great importance.

The yeast required for dry wines is one which will give a cool, steady fermentation rather than a very vigorous one.

The Vezenay yeast, in practice, is used in making light and delicate types of wine, and gives a steady and cool fermentation. According to report, the Rioja Tempranillo yeast is also used with success for the fermentation of dry wines. This latter yeast was used in the course of these investigations to ferment a tank of Cabernet Sauvignon in 1933, and the fermentation was steady, with a very quick finish, taking much less time to finish the fermentation from 1° B. to 0° B. than the local yeast.

The two yeasts, local Shiraz and local Muscat, would be discarded before any of the other types, as they proved by comparison to be uneconomical in fermentation.

One aspect of the work not taken into consideration was the effect of the different types on the flavour and bouquet. The volatile constituents play a part in the bouquet of the wine, and the fixed substances affect the palate. Muscat juice, when fermented out dry, is hardly a suitable wine for assessing values of this nature. Mr. C. P. Haselgrove, who has had some experience with the Magill and Vezenay yeasts, says there is a marked difference in the flavour and bouquet of the wines fermented with them. The wine from the Vezenay yeast is fine and delicate, while the other, in contrast, is flat.

When the complex nature of fermentation is considered, together with the many by-products formed by the proces, it is only to be expected that there should be considerable variation in the quantity of the various constituents, and the quality of the wine produced. The analyses have shown this to be the case, and clearly illustrate differences between the types.

In conclusion, it may be stated with assurance, that variations do occur in fermentations conducted by different types of yeast, and more important still, that it is an advantage to use a selected, pure cultured yeast in the production of wine, as opposed to allowing the yeast cells adhering to the skins of the grapes to conduct the fermentation.

ACKNOWLEDGMENTS.

For their interest, generous help and suggestions in compiling this work, I desire to thank Dr. A. R. Callaghan (Principal) and Messrs. J. L. Williams, R.D.A., and A. R. Hickinbotham, B.Sc., A.A.C.I., of the staff of Roseworthy College, and also Messrs. C. P. Haselgrove, R.D.A., K. Weidenhofer, R.D.A., and W. G. Geiger.

SHOW WHEATS OF 1934.

[By C. E. CHAPMAN, F.I.C., F.A.C.I., Deputy Government Analyst, and A. J. FARQUHAR, A.A.C.I., Chemist, Department of Chemistry.]

Further comparative tests have been made on the 31 Competition Wheats exhibited at the Royal Agricultural and Horticultural Society's Show, 1934, including wholemeal fermentation tests and baking tests. The tests were conducted on exactly similar lines to those conducted on the previous year's competition samples, the results of which were published in this *Journal* (August, 1934). In order that farmers may be able to recognise the wheats which they exhibited, the class number and exhibit number are given.

MOISTURE CONTENT OF WHEATS.

The moisture content of the wheats when received in the laboratory varied from 11.4 to 13.3 per cent., the average being 12.5 per cent. The previous year's samples varied from 12.2 to 14.2 per cent., the average being 13.1 per cent. The lower moisture content of last year's show wheats was probably due to the dry winter experienced.

WHOLEMEAL FERMENTATION TESTS.

These tests were made on the wheat as received, and also on the samples conditioned for milling purposes to 14 per cent. moisture. It was found that it was not practicable to obtain a constant moisture content of 14 per cent. on the wheat ground to the fineness necessary to make the dough test. The first sample that was passed through the mill lost practically no moisture, but subsequent samples, owing to the metal grinding plates of the mill becoming heated in consequence of the work done, lost varying amounts of water. In every instance it was found that the wholemeal contained less moisture than the original wheat. An attempt was made to adjust the moisture of the wholemeal to 14 per cent. moisture by commencing with the moisture of the wheat in excess of 14 per cent. before grinding, but it will be seen on referring to the table below that the wholemeals only roughly approximated to 14 per cent. The moisture of the wheat has a marked influence on the wholemeal fermentation dough test, and unless the moisture is known, the times obtained by the test are of very limited value. The time of the test in every instance increases as the moisture increases.

There is no definite ratio between the percentage increase of moisture of the sample and the percentage increase in the time of the test.

Some of the varieties gave the following results:—

Variety.	Per Cent. Increase of Moisture.	Per Cent. Increase of Time.
Ford	4	21
Ford	7	37
Ford	9	55
Waratah	13	40
Waratah	14	40

Quality	13	80
Quality	15	97
Comeback	8	39
Comeback	9	48

It is probable that the moisture has some action on the gluten, and probably combines with it to form an hydrated compound. The hydration or hydrolysis apparently takes place slowly, as when varying amounts of water are added to the wholemeal to form the dough the time of the test does not appear to be affected by increasing the quantity of water. In testing freshly harvested wheat in the summer, when the moisture of the grain is usually below 11 per cent., the figures obtained by the test should not be very seriously affected by slight variations of moisture.

The moisture of stored wheat in the winter often rises as high as 14 per cent. and if fermentation dough tests were made on wheat of this moisture content, high test figures would be obtained, which would give rise to an over-estimation of the quality of the wheat. The test is by no means satisfactory when done on high moisture samples, as agreeing results on the same wheat are difficult to obtain. At times the results are erratic and must be repeated many times.

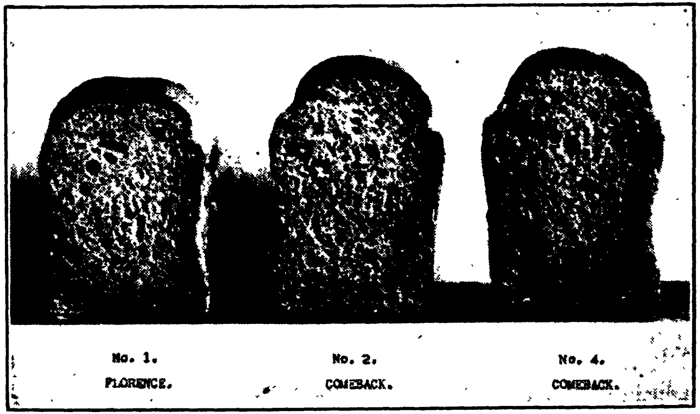
BAKING TESTS.



In determining the baking score, marks are awarded for general appearance, colour of crumb, flavour, texture, and pile, giving 10 points for each characteristic, making a total of 50 points.

If a baking score of 40 points or more is obtained by a flour it will make a bread of very good quality; a score of below 35 represents poor quality flour.

As the test loaves are made from a weight of flour equivalent to 100 grams of flour of 14 per cent. moisture, *i.e.*, 86 grams of dry flour, the weight of the test loaves multiplied by ten equals the number of two pound loaves which will be obtained from a ton of flour containing 14 per cent. of moisture.

The analyses of the flours and baking tests are given below.

No.	Class.	Entry No.	Variety.	Wholemeal Fermentation Test Number, as Received.	Baking Score.	Volume of Loaf.	Weight of Loaf.	Flour Dry Gluten.	Flour Protein. (N x 5·7.)	Flour Water Absorption.	Flour Yield.	Ease of Milling.

A review of the results of the baking tests shows that the samples of Comeback were not up to the usual high standard of this variety. This also applies to the two Quality wheats, both being of poor flavour, and evidently not true to type. The sample of Florence was characterised by the exceptionally good flavour it gave to the loaf. The S.H.J. wheats differed, No. 7 being the better sample.

The three samples of Ford were similar. No. 14 was low in quantity of gluten, which was partly compensated for by its good physical qualities. It also had a pale crust colour. No. 11 had a rich brown crust, and No. 18 a pale brown crust.

In considering the Nabawas, it was found that No. 10 had rather a high water absorption capacity for this variety, and baked into a good loaf of bread. No. 15 was not so good, whilst the other two can be classed as only medium. These four samples showed plainly the variations which occur on growing the same variety of wheat. Whether it is due to soil and climatic conditions, *i.e.*, environment, or to poorer quality of seed, is not known. It can be said that Nos. 17 and 19 are of too low a grade, and the elimination of these and similar quality wheats would materially improve our f.a.q. standard.

The only sample of Gresley, a new variety being grown in this State, appears to be very promising, and is similar in many respects to the best samples of Ford, from a baking point of view. White Tuscan and Croston are other varieties of which only one has been baked.

The flour obtained from Ghurka showed no improvement on last year's sample, giving a loaf of very poor quality. As regards the Waratah samples, the results obtained in this State agree with those obtained by the Department of Agriculture, New South Wales. They state that "it produced a small, light-brown coloured loaf, with a coarse crumb texture, of light-yellow colour."

Ranee is one of the most widely grown wheats in this State, but all four samples are only of medium quality. The sample of Sword is an improvement compared with last year's samples.

The growing of low grade wheats has been an economic loss to the country. These wheats do not make the palatable bread of former years, the texture is poorer; in some flours the crumb colour is much more yellow, and the bread appears to go stale more quickly. Bleaching and the use of improvers are the means adopted to rectify these faults.

The deficiency and low quality of the gluten have also brought into practice new commercial baking processes whereby portion of the flour is washed away as starch, with the result that those of the public who can afford it, pay roughly 50 per cent. more for the better article.

These samples were made available to the Department of Chemistry by Mr. H. J. Finniss, the Secretary of the Royal Agricultural and Horticultural Society.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on 30th January, 1935, there being present Messrs. H. N. Wicks (Acting Chairman), P. J. Baily, F. Coleman, S. Shepherd, A. M. Dawkins, A. J. A. Koch, Hon. A. L. McEwin, M.L.C., Professor A. J. Perkins (Director of Agriculture), and H. C. Pritchard (Secretary), Apologies were received from Messrs. A. J. Cooke, R. H. Martin, G. Jeffrey, J. W. Sandford, and Dr. A. E. V. Richardson.

Leave of Absence.—The Secretary was instructed to apply for 5 months leave of absence for Mr. Jeffrey, who was on a visit to America.

Change of Place of Upper North Conference.—On the motion of Mr. Dawkins, seconded by Mr. McEwin, the Board agreed to the request of the Wepowie Branch to change the place of the 1935 Upper North Conference from Pekina to Booleroo Centre.

River Murray Swamp Conference.—At the request of the Jervois Branch it was decided that this year's River Murray Swamp Conference should take the form of a Field Day.

Branches to be Closed.—The Board decided to close the Koonibba and Tulkineara Branches.

Life Members.—The honour of Life Membership of the Agricultural Bureau was conferred on the following members:—Messrs. A. M. Fuller (Inman Valey), E. P. Filsell (Lyndoch), J. P. Bagley and D. J. Turvey (Milang), F. W. Lehmann (Murray Bridge).

New Members.—The following names were added to the rolls of existing Branches:—Adelaide—L. G. Ayton, K. O. Ayton, A. R. Ninnes, H. R. Walsh; Balhannah Women's—Miss N. Pitt, Miss J. Kelsey, Miss D. Carr, Mrs. W. W. James, Mrs. A. S. Kelsey, Mrs. H. Nolan, Mrs. F. T. Norsworthy, Mrs. A. Bottroff, Mrs. H. Boehme, Mrs. E. W. Mattner, Mrs. H. A. Spoehr, Mrs. Cooney, Mrs. C. Cox, Mrs. L. Spoehr; Balumba—C. H. Jericho, J. A. Callis; Barmera—W. G. Richards; Blackwood—W. J. Hargreaves; Buchanan—W. G. Marschall; Chandada—J. V. Evans; Gladstone Women's—Mrs. R. Turley, Miss R. Flavel; Hanson—C. Bailey, T. Williams, G. R. Finch, A. T. McWater, M. Humphrys; Inman Valley—T. G. Hodgson, C. Westlake; Koonunga—Walter Hampel; Kybybolite Women's—Miss W. G. Miles; Laura Bay—Wm. McGee; Laura Bay Women's—Miss G. F. W. Lowe—Lone Gum and Monash—F. D. Kuss; Lone Pine—A. Liebich, B. Liebich, E. Pfeiffer, Les. Hoffman, V. Nendner, H. Grossman, H. Kiel; Longwood—A. W. Cameron; Maltee—Owen Peters; McLaren Flat Women's—Miss Hazel Ward, Miss Elsa Foggo; Monarto South Women's—Miss E. Thiele, Miss G. Stevens; Mount Barker—J. Walsh; Mount Compass—H. J. Meyer, A. V. Smith; Mount Gambier—C. R. Kilsby, Wm. B. Johnson; Murray Bridge—F. Douglas, H. S. Kentish, R. Kuchel, A. C. K. Beviss; Mypolonga—J. Hourahan, A. H. Burrett, J. Burrett, D. Haynes, V. Wright; Nantawarra—G. Henderson; O'Loughlin—J. I. Ellis, A. R. Schulz; Owen—Rex Moeller; Paruna—Jas. Petch; Pinbong—J. Coffee; Roberts and Verran—J. W. R. Walton; Sheoak Log Women's—Miss Freda Mattiske, Miss Linda Mattiske, Mrs. W. Nuemann, Mrs. R. Cliff; Tantanoola—F. Seller; Tatiara—V. Killmier; Williamstown Women's—Mrs. D. Coleman; Willowie—G. T. Wood, R. I. Bartlett, M. M. Bartlett; Wirrabara Women's—Mrs. C A. Kranz, Mrs C. M. Kranz, Mrs J. Porter; Yeelanna—Ray Proctor, J. H. Lloyd, K. N. Brinkworth, T. Drummond, H. O. Clements, V. Modra; Monarto South Women's—Mrs. J. Hartmann, Mrs. E. A. Thomas; Wirrabara Women's—Mrs. L. G. Grant, Miss M. L. Jettner, Mrs H. L. Cugley. Miss E. Hicks, Mrs. B. Holland, Mrs. Ray Banfield, Mrs. A. G. Banfield; Hope Forest Women's—Mrs. P. Hailstone; Auburn Women's—Mrs. Linke.

Present number of of members, 7,527; present number of Branches, 340.

Several items were taken in committee.

EXPERIMENTAL FEEDING TESTS CONDUCTED AT PARAFIELD POULTRY STATION.

[By C. F. ANDERSON, Poultry Expert.]

A series of feeding tests are being conducted at Parafield Poultry Station with a view to ascertaining if suitable foods which are obtainable on the majority of our farms can be satisfactorily fed to poultry. The tests are each of 50 White Leghorn pullets, and commenced on April 1st, 1933.

The feeding is as follows:—

No. 1 *Test.*—Morning—Wet mash composed of 1 part crushed barley, 2 parts wholemeal (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 2 *Test.*—Dry mash composed of same proportions as No. 1 Test.
Midday—Greenfeed. Evening—Wheat.

No. 3 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts pollard (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 4 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts wholemeal (by weight), ½ lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 5 *Test.*—Morning—1½ozs. wheat per bird.
Evening—1½ozs. wheat per bird. Greenfeed in season.

The following are the numbers of eggs laid by each pen from April 1st, 1933, to January 31st, 1935.

Definite conclusions, however, cannot be given at this juncture with regard to the various methods of feeding. It is necessary for the tests to complete the 24 months before any satisfactory opinions can be formed.

	No. Eggs Laid April 1st, 1933, to Dec. 31st, 1935.	No. Eggs Laid Month of Jan., 1935.	Total Eggs Laid April 1st, 1933, to Jan. 31st, 1935.
No. 1 test	12,777	596	13,373
No. 2 test	11,925	483	12,408
No. 3 test	11,551	508	12,059
No. 4 test	12,771	487	13,258
No. 5 test	6,711	279	6,990

DAIRY AND FARM PRODUCE MARKETS.

MESSRS. A. W. SANDFORD & Co., LIMITED, reported on 1st February, 1935:—

BUTTER.—Trade in produce during January was more or less spasmodic, for at the beginning of the month traders had hardly got into stride after the holidays and in some instances were carrying stocks. In butter, however, there was a steady demand, and a greater quantity of factory butter was sold because of the lessened supplies of dairy butter available. Under the new Government plan of equalisation the local rates were unaltered, but it is pleasing to report that London values have shown a firming and the outlook is more promising than has been the case for many months past. Production is steadily declining in this State, and importations of choicest butter are now necessary from Victoria. Local values at present are:—Choicest creamery fresh butter, in bulk, 1s. 3¼d. per lb.; prints and delivery extra; store butter, 6d. to 8d. per lb., according to quality; separator lines, from 9d. to 1s. 1d. per lb. for choicest. These prices are subject to equalisation levies.

CHEESE.—The South-Eastern factories kept the markets nicely supplied and a steady trade was carried on with Western Australia. An improved demand was experienced for matured cheese and stocks are now considerably reduced. Present rates are:—Large and medium, from 8d. per lb.; loaf, from 8½d. per lb. at store door, delivery extra; semi-matured and matured, 8½d. to 9d. per lb.

EGGS.—As is usual at this time of the year production is declining, but the falling away is greater than was expected. However, there are more than sufficient for local needs, and until better outlets are obtainable in the eastern States rates will remain steady and at present are:—Ordinary country eggs, fair average quality, 4d. per dozen net; long distance rail or shipping eggs, lower; selected new laid clean eggs, 1⅞ozs. and over, 6d. to 6½d. per dozen net.

BACON.—Average sales were made from week to week and values continued on an even keel at:—Best quality sides, 9½d. to 9¾d. per lb.; middles, 10½d. to 11d.; heavy middles, 9d. to 9½d.; rolls, 8½d. to 9d.; hams, 1s. 1d. to 1s. 2d.; cooked, 1s. 3d. to 1s. 4d. per lb.

ALMONDS.—Only limited supplies were marketed throughout the month under review and were satisfactorily cleared. Merchants are now awaiting consignments of the new crop, which is reported to be only a moderate one, and, in the meantime, values are without change, being:—Softshells and Brandis, 9d. to 9½d. per lb.; hardshells, 5d. to 5½d. per lb.; kernels, 1s. 11½d. to 2s. 0½d. per lb.

HONEY.—Sales are still dull and there was no alteration in quotations, although concessions were given by some sellers to effect quittance. Rates are:—Prime quality clear extracted, 2½d. to 3d. per lb.; lower grades, 1d. to 2d. per lb.

BEESWAX.—Continued in good request, and all consignments met with ready sale at 1s. 4d. to 1s. 4½d., according to quality.

LIVE POULTRY.—Sales are held every Tuesday, Thursday, and Friday and our salerooms are the best equipped in the State. As is usual after the Christmas markets supplies were somewhat short, more especially of heavyweight table birds, although there were considerable quantities of White Leghorn hens marketed each week. As poulterers are now short of stocks, the demand is likely to remain strong. We advise consigning. Crates loaned free on application. The following are prices realised:—Prime roosters, 4s. 6d. to 5s. 6d.; nice conditioned cockerels, 3s. 6d. to 4s. 3d.; fair conditioned cockerels, 2s. 3d. to 3s. 4d.; chickens, lower; heavyweight hens, 2s. to 2s. 10d.; medium hens, 1s. 5d. to 1s. 9d.; light hens, 1s. to 1s. 4d.; couple of pens of weedy sorts, lower; prime young Muscovy drakes, 4s. to 5s.; young Muscovy ducks, 2s. 3d. to 3s.; ordinary ducks, 1s. 3d. to 2s.; ducklings, lower; geese, 2s. 6d. to 3s. 6d.; goslings, lower; turkeys, good to prime condition, 8½d. to 11d. per lb. live weight; turkeys, fair condition, 6d. to 8d. per lb. live weight; turkeys, poor and crooked breasted, lower; pigeons, 4½d. to 5d. each.

POTATOES.—New season's, 10s. 6d. per cwt.

ONIONS.—New season's, 9s. 6d. per cwt.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall at the subjoined stations for the month of January, 1935, for the year 1935, also the average precipitation for January, and the average annual rainfall.

Station.	For Jan. 1935.	Av'ge. for Jan.	Total Rain for 1934.	Av'ge. Annual Rainfall.

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SOUTH-EASTERN DISTRICT.

PENOLA (Average annual rainfall, 26.01in.).
December 14th.—Attendance, 27.

The meeting took the form of a debate on the subject "Horses *verses* Power Farming" between members from the Coonawarra and Penola Branches. The Coonawarra team which consisted of Messrs. E. Gaffney (leader), J. Kain, and W. L. Redman, debated in favour of horses. The claims of power farming were supported by Messrs. S. Ockley (leader), W. Clifford, and C. Provis of the Penola Branch. The Reverend A. McNaughton, who adjudicated, gave his decision in favour of the Penola team. (Secretary, F. Hinze.)

UPPER NORTH DISTRICT.
(PETERBOROUGH AND NORTHWARD.)

APPILA (Average annual rainfall, 14.65in.).
1st February.—Attendance: 12.

HARVEST REPORTS.—Despite a rather trying year for all cereal crops, returns in the Appila district have been generally satisfactory. Members reported the following yields:—Nabawa, 24bush.; Sultan, 24bush.; Currawa, 24bush.; German Wonder, 24bush.; Sword, Waratah, and Aussie, 17bush.; Ranee, 18bush.; Crostan and Canaan, 15bush.; Early African, 20bush.; Minister, 12bush.; Free Gallipoli, 17bush.; Noongar, 14bush.; Fondling, 11bush.; Sepoy, 14bush.; Ghurka, 16bush.; Turvey, 15bush.; Daphne, 13bush. Oats, 18bush., and barley, 30bush. (Secretary, E. H. Wurst.)

MIDDLE NORTH DISTRICT.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

KOONUNGA.

January 16th.—Attendance: 16.

In the course of an address, "Fruit Drying," Mr. B. Boehm, of the Light's Pass Branch, said that in order to obtain a good sample of dried fruit the fruit should be picked whilst it was firm. It should then be left in the case for at least one day, or until it had become ripe. Fruit treated in that manner was not likely to become squashy, such fruit having a tendency to dry out into "slabs." Other subjects dealt with by Mr. Boehm included sulphuring and dipping operations. Concluding his address, Mr. Boehm stressed the fact that as the bulk of the State's dried fruit had to be sent overseas it was most important that every fruitgrower should aim at marketing a product of the highest quality. (Secretary, H. Mibus.)

LAURA BAY.

November 13th.—Attendance, 19.

HOBBIES.—Under the title "Hobbies for Winter Evenings and Wet Days on the Farm," the following paper was read by Mr. W. Bowell:—"Perhaps one of the best is carpentry, it is interesting and profitable, and many useful articles can be made. Petrol cases can be made into settees, bottle drainers, cupboards, and shelves for the pantry. Leather work is another good hobby. Perhaps the hobby that can be turned to best use is that of blacksmithing, because so much can be done to keep down repair bills. If it becomes necessary to do repairs that one does not feel capable of doing satisfactorily, the best plan is to take the job to the local tradesman and watch him do the work. Next time it can be done at home. If a lathe is included in the equipment it can be turned to profitable account. Chip carving and fret work will also help to while away many hours during long evenings in winter." (Secretary, P. Morrison.)

WOMEN'S BRANCHES.

LAURA BAY,—January 8th.

HOUSEHOLD HINTS.—Paper read by Mrs. R. W. Burke, Hon. Secretary:—When making starch, try whisking a candle in the liquid for a few seconds while the starch is very hot. When the articles are ironed after being starched in this manner, they should have a nice glossy finish. Do not destroy old gramophone discs, use them in place of beeswax to keep the iron smooth and clean. Cover the disc with a cloth before using. Fine wire, rolled into a ball makes a good pot-cleaner. To keep pots and pans from getting black when used over an open fire, rub them over with a greasy cloth before use. When they are washed the black comes off easily. A lemon heated in the oven or before the fire, will yield twice as much juice as when cold. An orange is also improved if treated in the same manner. When making fruit or meat pies, place two or more wooden skewers across the pie-dish. They will keep the pastry from falling into the dish. If changing the covers of pillows, mattresses, etc., open the case containing the feathers or kapoc about 9in., have the new cover sewn with a 9in. opening left to correspond, then tack the two openings together and gently work the filling into the new case.

MANGALO (Average annual rainfall, 14in. to 15in.).
November 21st.—Attendance: 11.

HOME DRESSMAKING.—Mrs. J. Hissey read the following paper:—"In addition to being an interesting and pleasing pastime, dressmaking can be the means of saving many pounds, especially if there is a young family to provide with clothes. Many garments can be made for a few pence each, and clothes that have been used by the adults can be unpicked and re-made for the children. Knickers can be made for small boys from the bottoms of men's flannel trousers, and singlets and shirts can also be refashioned for the children. Before cutting out a garment always place the pattern against the figure; measure the hips, bust and length, and leave ½in. to allow for turnings all round, except the hem, which is cut to the required length. Be careful to place the pattern centre front, straight down the fold of the material, and when making up a figured design, see that the design runs the same way. Do not cut 2 pieces for one side, nor 2 sleeves for one arm; cut one, and then lay it on the material with the two right sides together, thus making a pair. Never tack a garment without first pinning it and fitting it on. The pins can be easily removed to take up a seam, and any alterations can be made by moving the pins. If turnings are first pressed with a warm iron they lie flat, and are easier to handle. When making up a dress, first sew the shoulder dart and then shoulder seams, measure the waist and join the skirt. Then do the side seams from armhole to hem, measure length all round, and bind hem. See that the sleeves are exact, and place at the required notch, then the collar, overcasting, and press well. Trimming and buttons can be put on where desired." Reports of the Annual Congress were given by Mesdames Hannemann and Turner. (Secretary, Mrs. B. Coles.)

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences—1935.

South-East (Lower), at Mount Gambier, Wednesday, April 10th (G. T. Gurry), Secretary).

River Murray, at Moorook, Thursday, June 20th (S Perkins, Secretary).

Each Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda of the Conference in their respective districts.

Argentine Wheat Position.

An outline of the operations of the Argentine Grain Control Board, which was established by the Government in November, 1933, appeared in our April, 1934, issue. The object of this Board was to extend assistance to wheatgrowers. Under the plan the Government would, in short, establish basic prices from time to time for produce dealt with (wheat, linseed, and maize), and would purchase at those prices all produce submitted to it, afterwards reselling it for export only, in accordance with the prices prevailing on the world's markets. The Exchange Control Commission would establish the rate at which the banks should purchase exporters' bills. The exchange made available in this way would be sold daily to the highest bidders, and any resulting difference would meet losses incurred in the grain operations of the Control Board, and also expenses.

Up to 28th November, writes Mr. W. J. Jackman, of Buenos Aires and quoting from an official statement, the Board has sold 3,776,329 metric tons, having still on hand a remnant of 167,153 tons. Below is a statement of the handlings and stocks month by month:—

Months.	Purchases. Tons.	Sales. Tons.	Cancellations. Tons.	Stocks, End of Month. Tons.
December . ..	571,450	28,171	3,039	540,240
January	1,512,653	477,153	7,437	1,568,303
February	927,356	295,802	2,505	2,195,352
March	423,577	475,039	2,927	2,140,963
April	392,578	159,712	4,252	2,369,577
May	174,253	1,154,796	5,785	1,383,249
June	10,112	140,154	19,504	1,233,703
July	635	355,722	13,604	865,012
August	146	103,765	7,961	753,431
September . ..	20	191,647	1,518	560,286
October	—	181,117	115	379,054
November	1,350	213,251	—	167,153

The total expenses of the Board amounted to $8,814,942 paper pesos, of which $2,455,000 was interest on money borrowed for the purpose of its operations, and $714,000 general expenses. These costs and expenses are, of course, more than covered by the profits on the purchase and sale of exchange bills received in payment for the exported grain, and there still remains on hand a balance of $43,000,000 pesos, which it is announced will be used by the Board for its operations with the new crop.

The report mentions that it had been originally estimated that there would be a loss of 50 millions on the operations of the Board, but the situation was completely changed by the rise in prices following the drought in the United States.

The Minister of Agriculture announces that the Grain Control Board will continue its functions, and will buy grain of the new crop at the same basic rates as last year, viz., $5.75 for wheat, $4.40 for maize, and $11.50 for linseed.

Enforcement of Stock Brands Act.

A resolution of the Kyancutta Conference requesting a more stringent enforcement of the provisions of the Brands Act was placed before the Registrar of Brands, who has supplied the following information:—

"Should any person illegally or wrongfully brand sheep or earmark same contrary to the Brands Act, it should be at once reported to the nearest police officer, who, in turn, will advise this department, and the necessary action will be taken.

"Before a person can rebrand his sheep, it is necessary for him first to obtain permission from this department. Where brands are placed on the wrong position, or are indistinct, blotched, or smudged, if information is given to this department in this connection, steps will be at once taken to investigate.

"Sheep earmarks can now be registered, the near ear being reserved for ewes and the off ear for wethers or rams. The opposite ear, *i.e.*, off ear of ewes and near ear of wethers, is reserved, so that the owner of a sheep brand may use any private earmark he desires, provided he does not exceed the size ½in. by ¾in.

"All marks, with the exception of a slit, must be made with a pair of pliers.

"Inspectors of stock and temporary Inspectors appointed under the Stock Diseases Act, 1888, are Inspectors of Brands, also all Inspectors of Police."

Blackberry Control.

Replying to an inquiry from Longwood, Mr. A. G. Strickland (Deputy Chief Horticultural Instructor) states that for successful control of blackberries it would seem that either grubbing or slashing is an indispensable preliminary operation, except perhaps in the case of isolated infestations.

After slashing or grubbing, other plant species, such as subterranean clover, may be sown (together with super), in order to provide a measure of plant competition. The patches should be heavily grazed by goats, cattle, or sheep, in such a manner as to ensure damage by grazing and trampling of new blackberry shoots. This method constitutes a long range project, but has given fairly successful results in certain parts of Victoria.

Where infestations are small and scattered, chemical sprays may be used—such as arsenite of soda or chlorates. After the first spraying, new growth may be resprayed at the required intervals, or, if preferred, the dead material resulting from the first spraying may be piled on the new blackberry growth and burned. Less spray will be required if the patches are all given a preliminary slashing, the crowns swabbed or sprayed, and all new growth similarly treated at intervals as required.

In the case of widespread blackberry invasion, the use of chemical sprays would be expensive and difficult, and in all probability the slower method of slashing and heavy grazing, combined with efforts to establish other plants, such as subterranean clover, would be preferable.

This summary is based on information supplied by the Weeds Research Officer of the Victorian Department of Agriculture.

VETERINARY INQUIRIES.

[Replies supplied by Veterinary Officers of the Stock and Brands Department.]

"Aldinga" asks for a drench for control of parasitism in sheep.

Reply—The following drench has given very good results, but it is suggested that it be given a trial on a few sheep in order to see the effects:—

Drench for Sheep.—Copper sulphate, 1lb.; "Black Leaf 40," 13½ fluid ounces; water, 1gall.

Doses.—Lambs, 3 to 6 months, ½oz.; lambs, 6 to 12 months, 1oz.; sheep, 2-tooth, 1½ozs.; sheep (over these ages), 2ozs. Repeat doses in 3 weeks.

In drenching sheep, it is not necessary to starve them either before or after giving the drench. No drench is 100 per cent. effective against parasitism in sheep and it is very necessary where symptoms of the disease are present that better nourishment be provided.

"Sutherlands" reports mares off feed, legs wide apart, head hanging down and turned towards the belly.

Reply—The symptoms described are those of impaction of the bowels due either to accumulation of food or sand. The treatment indicated is:—

Give the following drench:—Raw linseed oil, 1·1½ pints; oil of turpentine, 4 tablespoonfuls. Mix and shake well before administration. Four hours after the above drench has been given administer the following medicine:—Take aromatic spirits of ammonia, spirits of nitrous aether, of each 3ozs.

Directions.—Give 2 to 4 tablespoonfuls mixed in one pint of cold water and a cup of treacle. This should be repeated every four hours, and every two hours enemas of warm water should be injected into the top back passage taking care that the bowel is not injured by the syringe or piece of rubber. If possible inject 3 or 4galls. If no improvement the following morning, repeat the oil drench and follow by the spirits drench. It is most important to administer the drenches and enemas until normal bowel action is established. Signs of recovery are return of appetite for food and water.

"Andrews" asks cure for 2 mares with split hooves.

Reply—A horizontal groove about 1in. long (deep, but not so deep as to draw blood) should be cut and burned in the hoof just at the upper extremity of the crack, so as to prevent any further extension of it in an upward direction. The crack itself should be thoroughly cleaned out and its bearing on the shoe "eased." The hoof should be dressed all over daily with a little of the following dressing:—Oil of tar, 1 part; oil of turpentine, 1 part; fish oil, 4 parts.

THE CHAMPIONSHIP WHEAT CROP COMPETITION.

(Won by Mr. P. McD. Smyth, Salter's Springs.)

In his report on the Championship Wheat Crop Competition for the 1934-35 season, Mr. R. C. Scott (Supervisor of Experimental Work), who judged the entries, states that Wheat Crop Competitions supervised by the Department of Agriculture have been conducted in South Australia during the past 10 years.

For the first six seasons financial assistance was given by the Government, but unfortunately in 1931 and 1932 it was found necessary to discontinue the granting of this subsidy. However, in the following year a generous donation by the South Australian Farmers' Co-operative Union Limited materially assisted in the success of these competitions, whilst in the present season the Government subsidy was renewed. The help thus given has been a very big factor in maintaining interest in the crop competitions during the period of depression and the low price of wheat.

The past season has been most abnormal so far as the development of wheat crops is concerned. Until the end of July the rain registered in practically all districts was very much below the average. From August onwards the weather conditions improved, and satisfactory falls were recorded, with the result that many crops were permitted to make full recovery.

However, in the lower rainfall areas the winter check was too severe to permit this, and crop competitions in the Murray Mallee and Eyre's Peninsula districts suffered accordingly.

Over the balance of the State really good crops matured, whilst an excellent sample of grain developed, but unfortunately before harvest was complete this good quality was militated against by unseasonable weather, which delayed reaping, and ultimately an average grain sample much inferior to that originally anticipated was secured. However, throughout the State the crops were particularly free from disease, and only in exceptional cases could any appreciable reduction in yield be attributed to this cause.

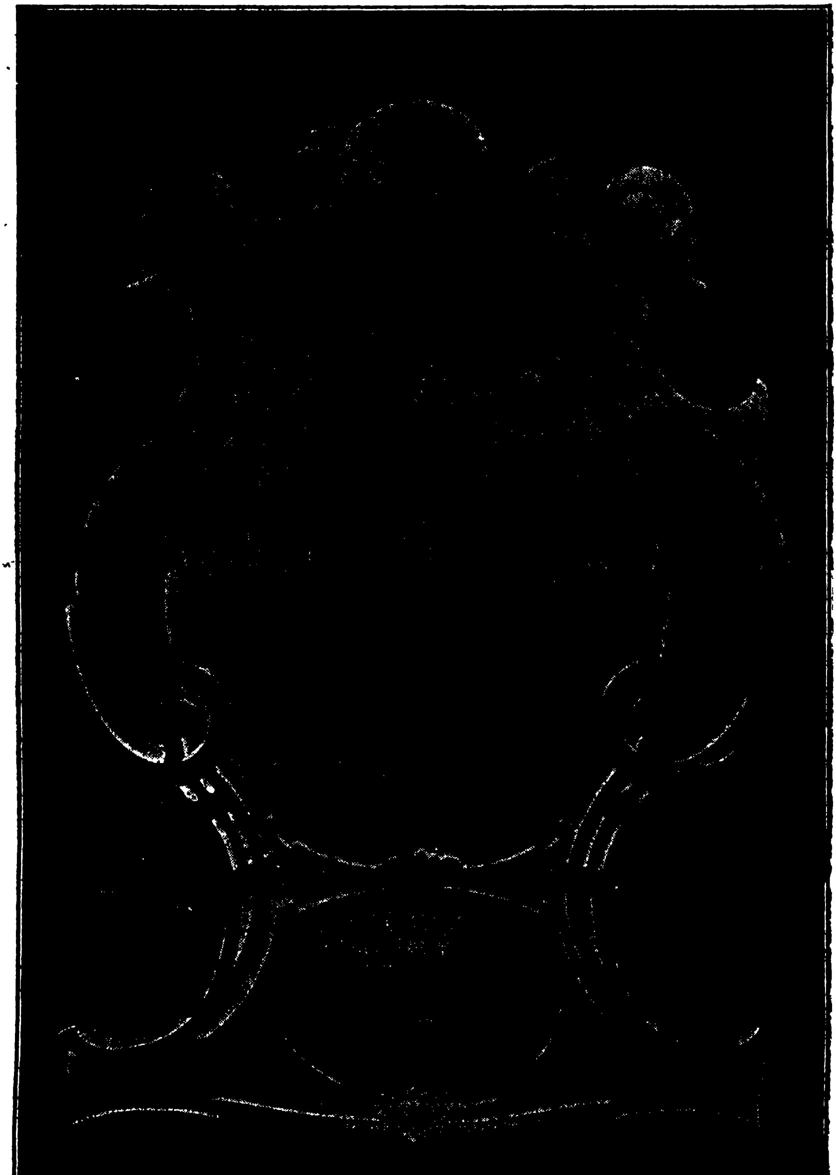
In all, 18 districts conducted competitions, and the number of crops exhibited totalled 328. The Department of Agriculture appointed the judges, who made the awards and issued reports on all crops entered. In four of the districts the judges decided that the winning crop was not sufficiently good to leave in the Championship, and therefore only 14 crops took part in this competition.

Table Showing Progress of Wheat Crop Competitions.

Year.	Districts Conducting Competitions.	Number of Crops Exhibited.
1924	12	290
1925	13	248
1926	17	444
1927	19	525
1928	22	634
1929	21	520
1930	19	473
1931	16	352
1932	20	385
1933	19	351
1934	18	328

In 1927 the Royal Agricultural and Horticultural Society offered as a prize in connection with Wheat Crop Competitions conducted under the auspices of the Department of Agriculture a silver challenge shield of the value of 50 guineas, and annually a small replica of the shield valued at 5 guineas.

The Royal Society desired specially to encourage the Wheat Crop Competitions, and in accepting the generous offer the Government agreed to the conditions laid down by the Society, which were as follows:—



1. The prizes go to the person exhibiting the best crop in the Competitions supervised by the Department of Agriculture, the silver challenge shield to be held for a period of 12 months immediately succeeding the award, and the silver replica to become the absolute property of the winner.

2. The challenge shield, with the name of each year's winner engraved thereon, to be exhibited in the town hall or institute nearest the farm on which the winning crop was grown.

3. The crop awarded first prize in each supervised district competition to be taken as an entry for the Championship Competition, except in any case in which it is thought by the judge of the district competition that the winning crop is not of sufficient merit to warrant inspection for the championship trophy.

4. All entries for the championship to be inspected by one judge. Such inspection to be undertaken in each district soon after the district judge has made his awards, but not before the crop has ripened.

5. Each competitor for the Championship to be required to stage one bag of grain and one sheaf (about 1ft. in diameter) of grain in the straw at the Royal Spring Show following the competition.

WINNERS OF THE CHAMPIONSHIP WHEAT CROP.

1927. F. V. Trenorden, Bordertown. (Federation wheat.)
1928. F. Coleman, Saddleworth. (Leak's Rustproof and Fondling wheats.)
1929. F. V. Trenorden, Bordertown. (Bena wheat.)
1930. H. C. M. Pilgrim, Wolseley. (Gallipoli wheat.)
1931. A. M. Dawkins, Gawler River. (Ford wheat.)
1932. J. P. Carrigg, Hamley Bridge. (Sword wheat.)
1933. H. Michael, Hilltown. (Dan wheat.)
1934. P. McD. Smyth, Salter's Springs. (Sword wheat.)

THE ENTRIES.

Of the 14 crops included in the Championship Crop Competition, 9 were of the Sword variety, and 1 each of Ford, Gallipoli, Gluyas, Nabawa, and Pine Head wheats. They were all well grown and of high competition standard, well worthy of exhibition in such a competition. However, the crops submitted from the lower rainfall districts showed evidence of the difficult winter conditions experienced, and the apparent yield was not as great as that from those in the more favoured areas.

In all cases, the filling of the ears and the quality of the grain was really good, but in some of the Sword crops quite an appreciable quantity of grain had shaken out.

The standard of farming set by the men responsible for the planting of these crops was excellent, and worthy of general adoption throughout the districts concerned.

THE AWARDS.

In reporting on the entries, it has been decided to follow the practice of other years of indicating the crops which have been placed second and third to the winner of the championship trophy, but with other crops the exhibitors' names are placed in alphabetical order, and not according to points awarded.

The awards and a brief description of the crops submitted in the competition are set out below:—

THE CHAMPIONSHIP WHEAT CROP (SWORD WHEAT).

P. McD. Smyth, Salter's Springs.

The crop which was successful in gaining the championship was that grown by Mr. P. McD. Smyth, at Salter's Springs, a good wheat-growing area, about 7 miles in a westerly direction from Riverton.

This was an excellent crop of Sword wheat, and had been awarded first prize in the Midlands District Competition.

It was wonderfully dense, regular, and well headed, and despite the fact that the rough weather of 17th December had led to the loss of several bushels of wheat to the acre, the grain yield promised to be particularly heavy.

Very few weeds were present, only an occasional plant of charlock, nancy, and slender thistle being seen, whilst, except for a little take-all on the rising ground near the south-western corner, the crop was practically free from disease.

So far as purity is concerned, it was the best crop of Sword judged, there being very few brown chaffed plants in evidence, although the variations of type common to all except the latest selections of this variety were present.

The field had been carefully seeded, and very little land missed.

The crop was sown on an area which in the past had been worked on a three-course rotation, namely, pasture, bare fallow, wheat.

The block was ploughed in March, 1933, harrowed in July, cultivated in August, followed by a good tillage throughout, and finally sown in the first week of June with 80lbs. of Sword wheat, together with 150lbs. of 45-grade superphosphate to the acre.

It was obvious that the whole of the operations associated with the preparation of the land and the seeding of the field were most efficiently carried out, and the crop which resulted not only reflected considerable credit on Mr. Smyth as an agriculturist, but also created very favourable comment from all who had the pleasure of inspecting it.

THE OTHER PLACED CROPS.

A. H. Wolf, Rosedale (Pine Head).

The crop placed second in the Championship was that grown by Mr. A. H. Wolf, at Rosedale, about 10 miles to the north-east of Gawler. This magnificent crop gained first position in the Central Competition, and promised to be the highest yielder of all those entered in the major competition.

The plants were exceptionally well headed, and the crop was very thick, whilst an excellent sample of grain had developd. Weeds were not plentiful, isolated plants of slender thistle, geranium and narrow-leafed clover being the only ones present.

A little disease in the way of take-all, flag smut, and rust was found, but the latter was not sufficiently plentiful to affect the filling of the grain.

The variety, Pine Head, is a selection made by Mr. Wolf. Its parents are not known, but the wheat possesses some Gluyas characteristics, and probably originated from that variety. At present it is somewhat unfixed in type, varying considerably in rate of maturity, colour of straw, and class of ear, but is a prolific wheat, well worthy of further selection.

On account of the hilly nature of the field, there were a few drill misses. The land was farmed on an oats, fallow, wheat rotation. The fallow was broken in July, cultivated in October, and after the usual tillage sown in the middle of May with 85lbs. of 45-grade super, together with 75lbs. of graded and dry-pickled seed wheat.

This was an excellent commercial crop, but from a competition point of view was affected by the unfixed nature of the wheat variety utilised.

W. H. Watkins, Yeelana (Gluyas).

The County Flinders Crop Competition was won by Mr. W. H. Watkins, at Yeelanna, and this crop of Gluyas wheat was awarded third position in the Championship.

It was well grown and well headed, but had lodged a little, and some damage had been caused by grasshoppers.

The crop was particularly free from weeds, only a few plants of Cape weed being present. Except for a little rust on some later maturing plants, no disease was found.

The variety was not quite pure, containing a sprinkling of plants carrying white chaffed ears, whilst bearded plants were also present.

Only one fairly large patch had been missed by the drill, and, generally speaking, the evenness of the crop was satisfactory. The cropping rotation of the field since 1929 had been fallow, wheat, barley, pasture, fallow. The land was ploughed in July, harrowed, and cultivated four times, including the tillage given at seeding, and drilled with 70lbs. of Gluyas wheat, together with 120lbs. of superphosphate per acre. This was an excellent competition crop, practically free from weeds, and showing evidence of sound farming methods.

OTHER ENTRIES (IN ALPHABETICAL ORDER).

L. S. & R. J. BEINKE, Kimba (Sword).

The crop submitted by Messrs. L. S. & R. J. Beinke was successful in winning the County Buxton Competition, and when the seasonal conditions are taken into consideration, the entry must be regarded as very creditable to the men concerned.

Sword wheat was planted on somewhat variable land, and on the lighter soil the yield was lower than on the better type country, whilst grasshoppers had caused appreciable damage on the later ripening patches. The chief weeds were charlock, slender thistle, brome grass, and wild oats, whilst there was a fair amount of take-all. There was a considerable admixture of brown-eared wheat, resembling Waratah, together with the usual variation in ear characteristics associated with the Sword variety. Prior to being fallowed in 1933, the land had lain out as pasture for two seasons. It was ploughed in July with a mouldboard plough, cultivated in September, February, and March, and 70lbs. of Sword wheat and 45lbs. of superphosphate combined in during the second week in June.

JAS. CAMPBELL, Barabba (Sword).

This crop was awarded the premier position in the Balaklava Crop Competition. It was an excellent competition crop, except for the fact that the character of the season had caused a reduction in the average yield comparatively with that which would have been harvested had normal weather conditions prevailed.

It was difficult to find any weeds, the crop being particularly clean in this respect, and the only disease present was a few isolated plants affected with hay die. A few brown chaffed wheat plants showed up, but practically no land was missed in the seeding operations, and everything pointed to the fact that very efficient farming methods had been adopted by Mr. Campbell.

The cropping rotation practised on the competition field was pasture, bare fallow, wheat, and after the land had been ploughed in July it was harrowed three times, then cultivated in September, October, and March before 104lbs. of 45-grade super and 63lbs. of Sword wheat were combined in to the acre early in June.

L. Y. LANGDON, Kongal, Bordertown (Gallipoli).

This crop was placed first in the Tatiara Crop Competition, and consisted of 50 acres of Gallipoli wheat, which had made good, dense growth and headed well. It was fairly clean, the weeds present being scattered plants of slender thistle, nancy, silver grass, sheepweed, and horehound. On the other hand, there was a good deal of take-all throughout the crop, together with a fair amount of rust, but the latter disease had not had a serious effect upon the filling of the grain.

The variety was very clean and true to type, only a few white chaffed plants and an occasional bearded wheat being present. Care had been taken in the seeding operations, but a few strips had been missed by the drill. Before being prepared

for this crop, the land had been under grass for four years. It was ploughed in August, harrowed four times, and cultivated twice, prior to the combining in of 114lbs. of superphosphate and 79lbs. of Gallipoli wheat in early July.

G. E. & H. M. Meier, Paskeville (Sword).

This entry of Sword wheat had won the Northern Yorke Peninsula Competition. It was a well-headed, even crop, which was tending to lodge and shake a little grain. The latter was very well filled, and of high weight per bushel.

Weeds were not plentiful, consisting chiefly of isolated charlock, sheep weed, wild oat, and poppy plants.

The crop was relatively free from disease, a little take-all and a light infection of red rust being the only ones present, although grasshoppers had stripped much of the flag and a few ears from the plants. The usual impurities and strain variations found in the majority of crops of Sword wheat were in evidence. The crop was even, and very little land had been missed in the seeding operations. It was planted on fallow land, which had been preceded by a fallow-wheat-barley rotation.

The first tillage took place early in April, 1933, when the soil was worked over the combine. It was ploughed in August, cultivated in September, and harrowed three times during the course of the season, whilst 90lbs. of 45-grade superphosphate and 65lbs. of Sword wheat were planted to the acre by means of a combine in June.

J. L. Noonan, Abbeville (Sword).

This was a really good and attractive crop, which had been awarded first prize against keen opposition in the Mid-Northern Competition. It was a wonderfully dense and even field of wheat, with the plants carrying well-developed ears, each of which held full plump grain.

In places, weeds were rather plentiful, particularly patches of mustard, with a little nancy and wild oats.

In connection with disease, there was a little ball smut, with an odd spot of red rust, and a few plants affected with flag smut. There was a fair amount of land missed at seeding, particularly at the corners, thus affecting the evenness.

Throughout the crop there was a sprinkling of brown chaffed wheat plants and the type variations of Sword wheat.

The land had been worked on a bare fallow-wheat rotation. It was fallowed in July, cultivated in September, and after preparatory tillage, seeded with 75lbs. of Sword wheat, together with 75lbs. of 45-grade superphosphate per acre.

A. Piggott, Morchard (Ford).

This crop of Ford wheat, which won the Far Northern Crop Competition, was particularly clean, and, except for an odd plant of charlock and Salvation Jane, was free from weeds.

An excellent sample of grain had developed on well-headed, disease-free plants. There was a light sprinkling of brown chaffed wheat, but the variety was really good for trueness to type. There were no drill misses, and the crop was quite satisfactory as regards evenness. This was an excellent competition crop, and, despite the unfavourable winter weather, promised to yield well.

The land had been worked on a wheat, fallow, wheat, pasture, fallow rotation, and in preparation for this crop the field was ploughed in July, cultivated twice during the season, and, together with the usual seeding tillage, planted with 60lbs. of Ford wheat and 62lbs. of 45-grade superphosphate to the acre.

H. POLKINGHORNE, Minlaton (Sword).

Although this crop of Sword had been damaged by hail, it was still a good field of wheat, and had won first prize in the Southern Yorke Peninsula Competition. It was fairly clean, except for patches of wild oats, with scattered plants of hog weed, charlock, poppy and sand rocket.

The only disease doing damage was a little take-all, whilst the purple-strawed strain of Sword was affected with rust. The crop was only fair regarding trueness to type, containing some bearded wheat and a little Pryor barley.

Except for a few strips missed at seeding, the crop was regular.

The field had been farmed on a barley, bare fallow, wheat rotation, and for the competition crop had been fallowed in July, 1933, and after thorough tillage throughout the year, planted with 75lbs. of Sword wheat, together with 1cwt. of 45-grade superphosphate to the acre.

J. RZESZKOWSKI AND MATTNER BROS., Finniss (Sword).

The first prize in the Southern District Crop Competition was won by this crop of Sword wheat, and although a little thinner in places, it was a really good competition crop, promising a high yield of good quality grain.

Wild oats were rather plentiful, and other weeds consisted of cockspur, milk thistle, slender thistle, and mustard.

The crop was free from disease, except for a little rust, but some grain had shaken out from the ears. It was much truer to type than most crops of Sword, and only a light sprinkling of brown chaffed wheat was in evidence.

The crop had been carefully seeded, and very little land was missed. The field utilised was fallowed in July, 1933, and maintained in a good condition of tilth until planted with 60lbs. of Sword wheat and 100lbs. of superphosphate in the following June.

E. STUBING, Yadnarie, Cleve (Sword).

The County Jervois Crop Competition was won by Mr. E. Stubing with this crop of Sword wheat, which, considering the character of the season, had developed particularly well, and promised quite a satisfactory yield of plump, well-filled grain.

It was very free from weeds, only an occasional plant of charlock, dandelion, &c., being seen, whilst, except for a few patches of take-all, no other disease was noticed.

There was the usual admixture of brown chaffed wheat, common to the older strains of Sword. The crop had been carefully drilled, and only a few patches had been missed at seeding.

The land had been fallowed in July by means of a disc plough, harrowed in August, ploughed back with the disc in September, cultivated in October, and again in February. Seeding took place during the third week of May, when 65lbs. of Sword and 90lbs. of 45-grade super were drilled in to the acre.

F. WHITTLESEA, Jabuk (Sword).

This entry was successful in the County Chandos Crop Competition. The plants had headed well, but the grain was tending to shake out rather freely, causing an appreciable reduction in yield.

Weeds were fairly plentiful, consisting of charlock, barley grass, dandelion, and nancy. The only disease doing any harm was a little take-all on the lighter ground.

In connection with trueness to type, the variety contained rather less brown chaffed impurities than the average Sword, but on the other hand a few plants of both Cape and Malting barley were present.

The evenness was fairly good, only a little land being missed at seeding.

Since 1929 the system of cropping of the field had been oats, fallow, wheat, oats, fallow, and to carry this crop the land was ploughed in August, given a good tillage, and planted in the following June with 60lbs. of Sword wheat and 90lbs. of 45-grade superphosphate to the acre.

W. F. WURST, Laura (Nabawa).

The crop of Nabawa wheat grown by Mr. Wurst gained the first prize in the Northern Crop Competition.

It was very clean and free from weeds, only isolated plants of hogweed, barley grass, wild oats, and clustered clover being seen.

Not sufficient disease to cause appreciable damage was present, there being a little take-all, loose smut, and a few spots of rust.

There was a fair amount of admixture of other varieties, including both brown chaffed, white chaffed, and bearded wheats, together with a little barley. The drilling was good, but the crop varied considerably, being heavier, and tending to lodge on the friable land, and much lighter on the patches of hard red soil.

The land was worked on the bare fallow-wheat rotation, and for this crop was broken up in August, cultivated in October and May, and 58lbs. of Nabawa wheat, together with 90lbs. of 45-grade super, combined in to the acre at the end of July.

CARBONATE OF LIME EXPERIMENTS.

(A Talk Broadcast through 5 C.L. by R. C. SCOTT, R.D.A., Supervisor of Experimental Work, Department of Agriculture.)

In continuation of the fortnightly talks given by officers of the Department of Agriculture, it is proposed to-night to discuss the results obtained from a series of experiments dealing with the use of carbonate of lime. These experiments were conducted at a number of centres and were designed with the object of showing the value of carbonate of lime as a fertilizer for cereal crops.

Lime is an essential plant food, but on the other hand the amount removed by crops is very small, and it is exceptional to find a soil so deficient in this substance as to limit plant growth. At the same time, lime plays an important part in agriculture, because of its influence on the physical properties of the soil. It leads to an improvement in the texture of what would otherwise be sticky heavy clay land. It increases the water-holding capacity and modifies the looseness of sands, whilst it also has influence in neutralising the harmful conditions associated with sour or acid soils.

However, it is not from the point of view of carbonate of lime as an improver of the physical properties of soils that I wish to speak to-night, but to deal more directly with its value as a plant food for crops seeded on fallow land.

Notwithstanding the fact that no benefit could be anticipated, experiments dealing with this aspect became necessary because of the persistent advocacy of the use of carbonate of lime as a fertiliser by certain interested parties. As a result, a number of farmers have purchased carbonate of lime under a misapprehension as to its manurial value, and it was only by obtaining actual yields from a series of experimental plots scattered throughout the agricultural areas of the State, together with the field demonstrations thus provided, that the true position of this material could be shown.

Accordingly, arrangements were made with a number of farmers to plant experimental plots under the supervision of officers of the Department of Agriculture. In all, seventeen plots were planned. They extended from Booleroo Centre in the North, throughout the Lower North and Murray Flats to Strathalbyn in the South.

At every centre four plots of wheat were planted on fallow land, each being approximately two acres in area and receiving the following treatment:—

Plot 1—No manure.
Plot 2—1cwt. of carbonate of lime per acre.
Plot 3—1cwt. 45 grade superphosphate per acre.
Plot 4—1cwt. 45 grade superphosphate together with 1cwt. of carbonate of lime per acre.

In this experiment three comparisons were possible, namely:—

That between the yield from the "no manure" and the 1cwt. of carbonate of lime plots.

That between the yield from the 1cwt. of superphosphate and the 1cwt. of carbonate of lime plots.

That between the yield from the 1cwt. of superphosphate and the 1cwt. of superphosphate plus 1cwt. of carbonate of lime plots.

When the returns from the whole seventeen centres were averaged the following results were secured:—

No manure—18bush. 59lbs. of wheat per acre.
1cwt. of carbonate of lime—18bush. 33lbs. of wheat per acre.
1cwt. of superphosphate—23bush. 28lbs. of wheat per acre.
1cwt. of superphosphate, 1cwt. carbonate of lime—22bush. 25lbs. of wheat per acre.

From these figures it will be seen that the returns from the "no manure" and "1cwt. of carbonate of lime" plots were practically equal, indicating that no advantage was gained by the use of the latter.

A similar conditinn of affairs exists when the yield from the superphosphate only plots is compared with that from the area receiving both superphosphate and carbonate of lime.

On the other hand, if the return from plots receiving 1cwt. of superphosphate is compared with that from those receiving an equal weigh of carbonate of lime, it will be noted that there is a very marked advantage in favour of the former; in fact, practically 4½bush. of wheat to the acre.

Reviewing the results, therefore, an application of lime has not brought about an increase in yield over and above that from the "no manure" plot. Further, a combined dressing of superphosphate and lime has not given a greater quantity of wheat than the plot receiving superphosphate only. Consequently, no recommendation in favour of this material is possible.

It is true that the foregoing returns are the result of a single season's work, but it is most unlikely that weather conditions would affect the comparative yields to any extent. It is considered that, within limits, no matter what type of season was experienced, the influence would be the same on both the limed and unlimed plots. Consequently, as the experiment was fully replicated and conducted under a variety of soil conditions, it may be accepted that the results obtained are conclusive so far as the fertilising effect of carbonate of lime applied to wheat crops in this State is concerned.

It is, therefore, definitely stated that carbonate of lime must, on the average, cause distinct financial loss if used as a manure for cereal crops.

Earlier in the evening reference was made to the fact that lime occupied a definite place in improving the physical properties of soils. However, generally speaking, the wheat-growing lands of South Australia are well supplied with this material. As a rule, the greatest loss of lime occurs where there is high annual rainfall and free drainage, with the result that, except for a relatively small area of red boggy land in the Lower North, the greatest need for lime in this State occurs in the sour soils of the Adelaide Hills and South-East.

Under such circumstances, dressings of at least half and preferably 1 ton to the acre are necessary, and these should be added to the land about once in every ten years.

For suburban gardeners, who are troubled by the heavy nature of the land with which they have to deal, an application of about 1lb. of lime to the square yard is recommended.

In this connection, as ground shell consists of hard water-worn fragments of calcium carbonate, which are not readily dissolved by soil moisture, other forms of agricultural lime of a more soluble nature are to be preferred.

In conclusion, therefore, whilst lime has a certain value for improving soil conditions, the experiments show that it is not required as a fertiliser for cereal crops in South Australia.

In the following table the experiments from which the results quoted were obtained are shown.

Experimenter.	No Manure.		1cwt. Carb. Lime.		1cwt. Super.		1cwt. Super, 1cwt. Carb. Lime.

FARM SHEEP AND WOOL.

MANAGEMENT OF THE FARM FLOCK.

[By C. A. Goddard, R.D.A. (Asst. Wool Instructor, School of Mines).]

(*Continued from page* 844.)

The success of the farm flock is dependent on good management. The first essential is good stock, nevertheless the very best sheep cannot produce successfully under bad management.

The object of keeping a flock is to augment the farm revenue, and with this object in view, the flock must be run on sound, practical, and commonsense lines. It is not advisable to make the sheep entirely subservient to the agricultural side of farming, but to a large extent sheep work may be dove-tailed into the general activities, and in this way the farm may be most economically managed.

In reviewing the season's work, shearing is regarded as the beginning of the sheep year, and marketing the lambs the end.

There are many jobs in connection with sheep during the year, such as shifting the flock from paddock to paddock, cleaning water troughs, &c. This article, however, is confined to the major operations of:—

1. Shearing and branding.
2. Dipping.
3. Joining ewes and rams, and care of in-lamb ewes.
4. Lambing and lamb marking.
5. Blow-fly treatment.
6. Marketing lambs.

Shearing.

Time of shearing is the first consideration, and it should be arranged to fit in with other farm work. There is usually a slack time just before hay cutting. Shearing, therefore, should be done at this time, because if left until afterwards, there is the danger from grass seeds. The time of shearing will differ in different districts, from early August until early November. Autumn shearing which some farmers favour—is not recommended, because it means that the ewes are carrying a lot of wool during the fly season, and also when grass seeds are troublesome.

Preparing for Shearing.

The conditions under which a great number of farm shearings are conducted are so rough that it is impossible to do the work cleanly and with dispatch, and the wool—mainly due to lack of facilities—is marketed in a disgraceful manner. Shearing need not be looked upon as a distasteful job. In fact, when conditions are convenient it makes a pleasant break in the routine work of the farm. It is at shearing that the wool harvest is gathered, and every effort should be made to do it thoroughly and economically.

Few farmers can afford to set aside a building to be used only as a shearing shed, therefore one of the farm buildings—the barn is usually the best—must be used. When a farmer is building a new barn he should construct it in such a way that it may be readily converted into a shearing shed, and be used for the dual purpose of barn and shearing shed. The average farm barn can be fixed up for shearing with very little expense, and the fittings should be so constructed that they can be taken down and stored for future use.

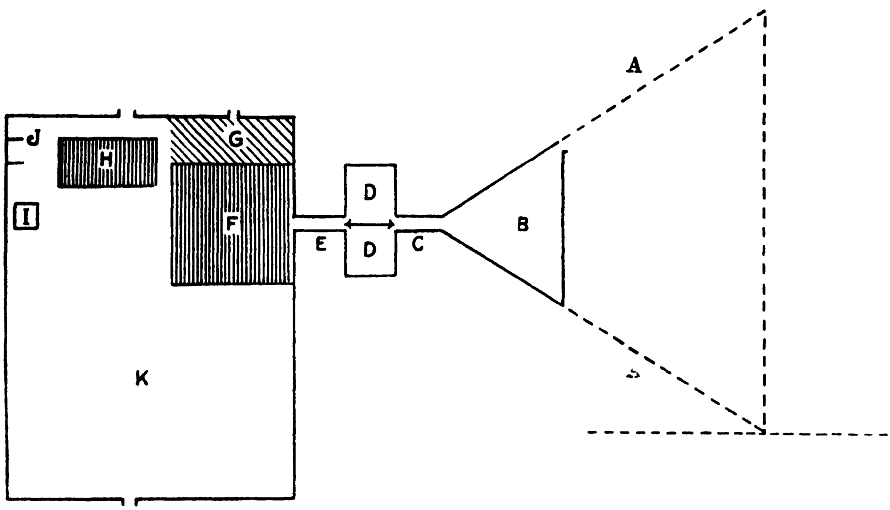
The first essential when preparing the barn for shearing is to clear it thoroughly, in order to provide ample room for the shearing. All waste chaff and straw must be removed, because they are most objectionable in wool, and reduce the value

of the clip. Elaborate fittings are not required, but everything should be convenient for working the sheep and handling the wool.

The essentials are: good, sound yards, a few sections of gratings on which to stand the sheep overnight, shearing board, wool table, box press, and at least 2 wool bins. All these can be made by a handy man, and in a number of instances a great deal of the material required is to be found on the farm, and it only requires a few days' labour to put everything in order.

YARD AND SHED ACCOMMODATION.

The following sketch will show the lay-out of the yards, and the temporary fixings in the barn.



A. & A. Wings to assist in yarding sheep.
B. Receiving yard.
C. Drafting race.
D.D. Sorting pens; also serve as forcing pens for sheding the sheep.
E. Race into shed.
F. Sweat pen with grating
G. Shearing board.
H. Wool table.
I. Wool press.
J. Wool bins.

Shearing cannot be learnt by reading articles, but there are a few special points which should be observed:—

1. Pay special care to the clean shearing of the points and breech, because woolly points collect grass seeds, and a dirty breech attracts flies.
2. When removing belly wool, do not rob the fleece of good wool by shearing too wide, at the same time be sure to take off all the belly wool.
3. Avoid second cuts, they spoil a lot of wool.
4. Do not break through the thigh when shearing the near hind leg, this robs the fleece of a large piece of wool which falls into the floor locks.

Branding the Sheep.

Branding must be carefully done to comply with the regulations of the "Brands Act." The best method is to run a few sheep into a race or small pen, if this is not done, sheep will be misbranded, and many will be smudged.

The most important of the branding regulations are:—

1. Any permanent paint mark and ear mark must be registered.

2. Any owner of sheep using a paint brand or ear mark without registration is liable to a heavy fine.

3. Sheep brands are allotted for definite positions and colours. The positions are "top of shoulders," "near ribs," "off ribs," "rump," and the colours are "black," "red," "blue," "green," and "yellow." The certificate of registration indicates position and colour, and these must be strictly adhered to. A diagram is shown in the margin of the certificate.

4. Figures 2 to 9 may be used as flock marks by owners of registered brands, on any position and in any colour.

5. No sheep may be rebranded without permission in writing from the Registrar of Brands.

6. No brand must be obliterated on a sheep or a sheep skin. The penalty is a very heavy fine or imprisonment.

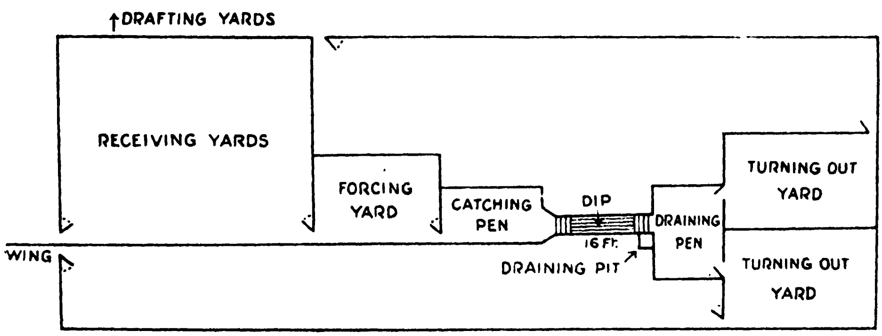
7. Paint dots or strokes must not be used as culling marks, they are registered brands and their use amounts to the infringement of another owner's brand.

Dipping.

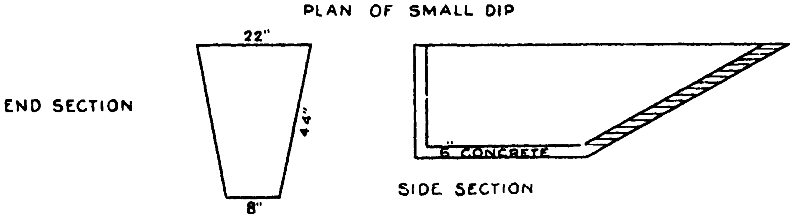
It is not advisable to travel sheep long distances to a co-operative dip. In the first instance, it knocks the animals about, and secondly, travelling on dusty roads after dipping creates a dirty tip that will remain until next shearing and reduce the value of the clip. Dipping is an important operation and is done either to destroy tick and lice, or as an insurance against infection, and the farmer should supervise the work himself, and dip when it is convenient.

It costs very little to make a small dip. Lime, sand, and gravel can usually be obtained on the farm, or somewhere adjacent and can be had for the carting; a bag or two of cement is all that need be bought. It is a mistake to make the dip too large, it costs a lot to fill a big dip, and a quantity of dipping fluid is wasted. A dip 16ft. long, 22in. wide at the top and 8in. at the bottom, 3ft. 6in. deep, will hold approximately 350galls. and requires 3 packets of powder.

The following sketch demonstrates a small farm dip:—



PLAN OF SMALL DIP



SIDE SECTION

METHOD OF CONSTRUCTION.

Make the excavation large enough to allow for a 6in. wall on each side and a 9in. bottom. The entrance, *i.e.*, where the sheep are dropped in, should be 4ft. across. Fix the concrete boards to the shape required, then pour the concrete

between the boards and the sides. The concrete should be made rich with lime, a little cement added is an advantage. Run in the bottom and when the walls and bottom are dry, smooth over with cement, and the job is finished. It is advisable to build the walls a few inches above the ground to prevent dust drifting into the dip. The sides of the entrance well should be 1ft. to 18in. above the sides to save wastage by splashing as the sheep are dropped into the dip.

There is another method of constructing a dip. It does not require concrete boards and this is its only advantage. Two sloping trenches are dug, and then filled with concrete, the middle is then dug out and the bottom put in.

When dipping sheep, there are a few important points to observe:—

1. Time to dip: When the sheep have been hand-shorn, they may be dipped almost directly after shearing, but when machine shorn, 4 to 6 weeks must be allowed for sufficient wool to grow to make dipping effective.
2. The sheep should be yarded for a few hours prior to dipping, to allow them to get rid of their droppings, otherwise the dip quickly becomes foul. Further, it is dangerous to dip sheep while over-heated from droving.
3. It is advisable to dip ewes and lambs separately and do not join them again until the ewes have been well drained.
4. Dipping must be done thoroughly to be effective, and the directions printed on each container should be strictly observed.
5. It is not advisable to dip during extremes of temperature.
6. Sheep should be left in the draining pen until they are well drained, to allow the drippings to drain back to the dip.
7. It is important that each sheep should remain in the dip long enough to be saturated.
8. When replenishing the dip, be careful to maintain the strength.

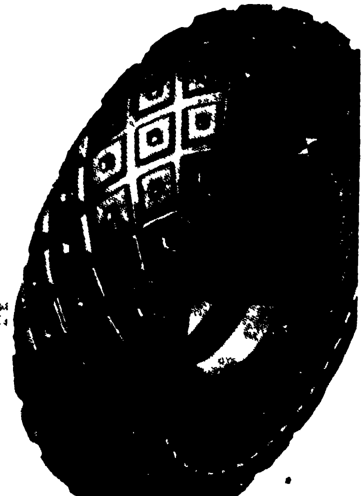
Joining Ewes and Rams.

This is one of the most important of the seasonal operations, because it controls time of lambing and to some extent lambing percentage.

It is important for lambing ewes to have greenfeed, therefore, lambing should be timed to start when it is reasonable to expect greenfeed, either as natural grasses or in the form of early barley or oat crops that have been sown for greenfeed purposes. The gestation period for ewes is 5 months, and as greenfeed can be reasonably expected in June in most agricultural districts, the ewes and rams should be joined in the first week of January. Where ensilage is available, lambing may be arranged much earlier and advantage taken of the high prices always ruling for spring lambs early in the season.

The special factors to observe in joining to ensure a successful lambing are:—

1. The condition of the breeders, good forward store condition is the best, because over-fat ewes and rams do not mate well and should the ewes be very poor, they will not come in season. It is wise to flush the ewes with good feed just before joining. This tends to bring them in season quickly, and ensures a more even drop of lambs. When using British rams, great care must be taken to prevent them from getting too fat. It is a wise precaution to bring them in and feed them on a small ration of oats for a few weeks before joining. Old rams of these breeds should never be used, because they become very sluggish with age. The rams should be well inspected, and if their feet are long, they should be trimmed.
2. Join the ewes and rams in a yard and leave them there for a few hours before taking to the paddock, and for the first 2 weeks, muster the flock every second evening and leave them yarded until morning.
3. When the flock is large enough to require 4 or more rams, it is a good plan to join only half the rams for the first week, then remove them and feed them on



oats for a week and join the remainder. This method is recommended because it is a well established fact that lambs that are "got" while the rams are fresh are always better developed than those produced by rams that are over-worked. For the last 2 weeks, join all the rams. Many farmers have the rams joined for 6 weeks and even 2 months. This is a mistake, as they should be removed after 4 weeks. Then when a month has elapsed, a Merino ram or two should be joined with the ewes. A few late Merino lambs are better than having dry ewes in the flock.

4. The percentage of rams to use will depend somewhat on circumstances; if the flock is yarded regularly 2 per cent. should be ample. If this is not done, 2½ to 3 per cent. should be used—40 ewes is generally considered enough for British rams. When Merino rams are used, the percentage may be reduced.

The In-Lamb Ewes.

The lambing percentage and the wool clip are largely dependent on the care of the pregnant ewes. With the exception of a few isolated parts, the natural grasses in the agricultural districts of South Australia are dry and non-nutritious during the gestation period, and there is not sufficient nutriment available to enable the ewes to develop the foetus and grow a good fleece of wool. Therefore, with very few exceptions, some supplementary feeding to supply protein is absolutely necessary to produce good lambings. Grain barley or oats will supply the necessary concentrates and only a small ration is required if there is plenty of roughage available. A ration of ensilage is preferable to grain, it is a better balanced ration and a preventive against twin lamb disease. Starvation and bad management are responsible for the absurdly low lambing percentages in the agricutural districts. The ewes should be disturbed as little as possible while pregnant and dogs should never be allowed near them. A few weeks before lambing is due to commence, the ewes should be yarded, crutched and well swabbed as a preventive treatment for fly strike. The crutching must be carefully done, no legging or kneeing must be allowed as this may easily cause losses when ewes are heavy in lamb. Poison baits should also be laid about this time to destroy foxes. It should be the farmer's aim to rear every lamb that is dropped, and he will never do this unless precautions are taken to combat these pests.

Lambing.

When ewes are lambing to Merino rams, little trouble need be expected, and a visit every second day should be ample, but when Merino ewes are lambing to British breeds—especially Shropshire, Dorset Horn, and Lincoln—then the flock should be visited in the early morning and the last thing at night, and assistance given to any ewes that are in difficulties. The normal presentation for a lamb is for the head with a fore-leg each side to come first, but occasionally a lamb comes the wrong way. In these cases the lamb should be gently pushed back into the womb, and every effort made to correct the position. More trouble is caused by the lamb being too big in the shoulders to allow of normal delivery. In instances of this kind assistance must be given by gently pulling the lamb in unison with the natural muscle contraction. Force should never be used as this is liable to damage the ewe. It is advisable to tie the legs of a ewe before giving assistance, otherwise in her excitement she may leave the newly born lamb; place the lamb in a convenient place for the mother to clean it, when she has done this she may be safely liberated.

Lamb Marking.

The most important factor in this work is to operate while the lambs are young, because if left until they are large, the marking will cause a serious check in growth. The work must also be done under antiseptic conditions, *i.e.*, all knives and ear markers and also wounds should be disinfected, any of the carbolic liquid

sheep dips are excellent for the purpose. Every care must be taken to avoid tetanus infection which is caused by dropping treated lambs into dust and filth. Therefore the lamb-marking should be done on clean ground. Always cut off the tip of the scrotum and do not split it to remove the testicles, dock the tail at the second joint. Another method of castration is with the Burdizzo pincers. This method is slow, but effective when carefully done, and has the advantage that it does not cause bleeding and consequent check in growth. This method is preferred when the lambs have been left until they are well-grown.

Blow-Fly Pest.

There is only one effective method of dealing with the blow-fly pest, and that is prevention. There is no excuse for owners of small flocks for having ewes struck, and preventive treatment is the only rational one, because once the ewe is struck the damage is done. She runs a fever temperature which affects the milk, the lamb receives a check, the wool develops a break and the whole fleece is frequently lost. The maggot flies are most active in late autumn and spring, and the farmer should protect his sheep in these seasons. It is also well known that any treatment may only be effective for a limited period, and sheep owners should be prepared to repeat the treatment as often as necessary. Arsenic is definitely the most effective poison and no specific that does not contain .5 per cent. of arsenic in solution should be used. An emulsion of oil and arsenic is undoubtedly the best, but often expensive, and a solution of arsenic and water may be used with safety. Boil ½lb. of white arsenic for 20 minutes with its own weight of washing soda in 1gall. of water. This will give a 5 per cent. solution by weight. For use, add 9 parts of water, or to 1 pint of the stock solution of arsenic, add 9 pints of water.

Method of Treatment.

At the first sign of trouble from flies, bring the ewes in and clean them by crutching, then swab with arsenic solution. This must be done with care because it is absolutely necessary to saturate the wool and thoroughly wet the skin. To ensure this, rub well with the hand after swabbing. In very bad seasons it may be necessary to repeat this treatment several times. The cost of the arsenic solution is very little and therefore there is only the labour to be considered.

Treatment of Affected Ewes.

A badly blown ewe is a hospital case, and should be treated as such. It should be brought in near the homestead, and treated every day until the wound has healed. First clean all dirty wool away from the affected part with shears, then remove the maggots with a penetrating fluid, such as carbolic liquid sheep dip. Castor oil may then be applied if the wound is bad. Do not use arsenic on raw wounds. Sump oil mixed with a little castor oil is most effective, but it stains the wool. It is preferable, however, to stain a little breech wool, rather than lose the ewe through septic poisoning.

Marketing Lambs.

This is the last important seasonal operation before shearing. The main factors in marketing lambs are:—

1. Lambs should always be sent to market when they are ready. Never hold them for a better market. The ideal weight for lambs is 32lbs. dressed, which means 66lbs. to 70lbs. live weight.

2. Every care must be taken not to bruise lambs when drafting and trucking. Dogs and prodding sticks must never be used.

3. The lambs should not be separated from their mothers until the last possible moment.

(To be continued.)

STATE OF SOUTH AUSTRALIA.

EXPORTS OF EGGS AND EGG PULP, JULY-DECEMBER, 1934 AND 1933.

By A. W. BOWDEN (Acting Government Statist).

Compiled from returns collected direct from Merchants.

GRAND TOTAL EXPORTS.

Quantity.—Eggs in shell and in pulp in terms of eggs in shell—July-December, 1934, 5,800,000 dozen; 1933, 5,600,000 dozen; 1932, 5,000,000 dozen; 1931, 3,500,000 dozen; 1930, 1,300,000 dozen.

Value.—July-December, 1934, £265,424; 1933, £263,819, increase £1,605. The interstate trade increased from £52,474 to £58,654, and the trade with oversea countries was slightly less than the 1933 level, £206,770 (£211,345).

The following are the details of exports, July-December, 1934 and 1933:—

State.	Eggs in Shell.		Egg Pulp.		Total Value.
	Doz.	£	Lbs.	£	£
New South Wales (Ex. B. H.) ...	163,865	5,881	560,284	18,386	24,267
Broken Hill	122,897	4,674	9,264	270	4,944
Victoria	69,223	2,291	836,150	23,526	25,817
Other States	46,427	2,107	45,664	1,519	3,626
Total Interstate, 1934...........	402,412	14,953	1,451,362	43,701	58,654
1933...........	410,738	13,997	1,415,848	38,477	52,474

1933...........	4,354,954	221,321	1,563,848	42,498	263,819

BUSH FIRES.

The Library of the Department of Agriculture acknowledges the receipt of a booklet, "Prevention and Control of Bush Fires."

In this handbook, in addition to a summary of the Bush Fires Act, 1933, there are included articles on prevention and fighting bush fires; organisation of fire prevention and fire fighting activities; prevention aids, historical items of interest, and other matters of interest to the public generally and residents of rural districts in particular. It should assist in consolidating and developing the activities of all organisations which have for their objectives prevention of, and when the necessity arises, fighting bush fires. Published by R. J. Rose, Laura. Price 7d., postage included.

SUMMARY OF PLANT DISEASE RECORDS IN SOUTH AUSTRALIA FOR TWO YEARS ENDING 30TH JUNE, 1934.

[By D. B. ADAM, B.Agr.Sc., Waite Agricultural Research Institute, University of Adelaide.]

In preparing this summary the writer has used records made by his predecessor, Mr. Samuel, for the period under review. The summary follows the same lines as those taken in dealing with earlier biennial periods and published in this *Journal*.

CEREALS.

Take-all (*Ophiobolus graminis*) in the form of "whiteheads" was more prevalent than usual in 1932. This occurrence coincided with spring conditions which for the State, taken generally, were cool and more showery than the average. The possible reasons for the association between such spring weather conditions and the more extensive development of take-all and other factors affecting the severity of take-all have been dealt with in articles published in *Phytopathology*, vol. 23, pp. 721-728, and in this *Journal*, vol. 37, pp. 664-674, 799-805, 976-983.

The stunting diseases of wheat and oats sometimes associated with eelworms (*Heterodera schachtii*) and in other cases with the fungus *Rhizoctonia solani* continue to be reported from various areas, particularly the mallee districts. These diseases affect the plants in the earlier stages of their growth. In spring, with the advent of warmer weather, the plants in a sense grow away from the disease though the earlier injury influences permanently the vigour of affected plants. Measures for the control of the *Rhizoctonia* disease have not yet been devised.

FORAGE CROPS.

Except in parts of the wetter districts where leaf spotting and collar rot due to *Ascochyta sp.* may occur, pea crops normally were little troubled by disease. In 1932, in association with wet winter conditions, a leaf-spotting disease of peas similar in general appearance to that due to *Asochyta* occurred in epidemic form in the mid-northern agricultural area. The fungus has not been definitely determined. On being referred to the Imperial Mycological Institute it was reported that the fungus showed "many features in common with *Gloeosporium pisi* Oudem.," but "that on present evidence one could not say they belonged to the same species."

FRUIT CROPS.

Brown rot (*Sclerotina fructicola*) on peaches was recorded from an orchard in the metropolitan area in 1932, and on cherries from the South-East in 1933. The occurrence in 1932 was the first time that the disease had been recorded in South Australia since 1902. Although it is possible that summer conditions are usually unfavourable for the development of this disease in South Australia generally, a careful watch for this disease should be kept, as experience elsewhere has shown that once well established, this disease is difficult to eradicate.

Powdery mildew of stone fruits (*Sphaerotheca pannosa* var. *persicae*) affecting green peach and apricot fruits prior to ripening first noted in South Australia in 1929 was recorded from a number of orchards in the neighbourhood of Adelaide. From observations made by Mr. Beaumont, formerly of the Horticultural Branch, Moorpark apricots appeared to be less susceptible to this disease than Oullin's Early.

In recent years a disease of apricot trees characterised by a local gummosis and dying back of limbs has attracted attention because of an apparent increase in its prevalence. The disease generally starts at some intermediate point on the limb. Its development is usually attended by gumming and a curious longitudinal

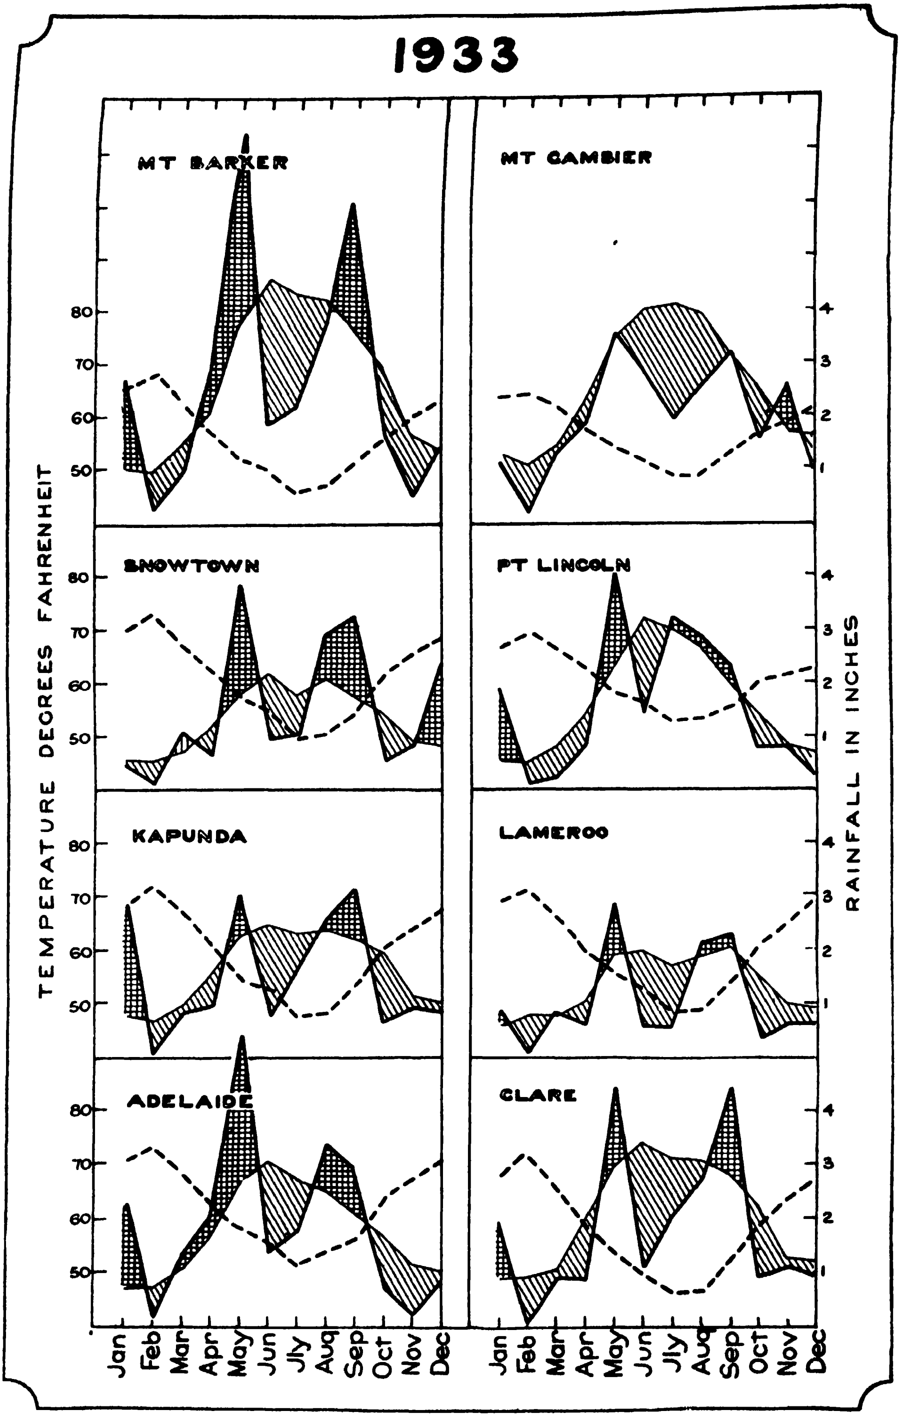

Figure 1.—Shows total rainfall and mean temperature for each month during 1933 at eight stations in South Australia;—actual rainfall each month during 1933—average rainfall for each month; single hatching shows rainfall below the average for each month, cross hatching, above the average for each month. – – – Mean temperature for each month during 1933.

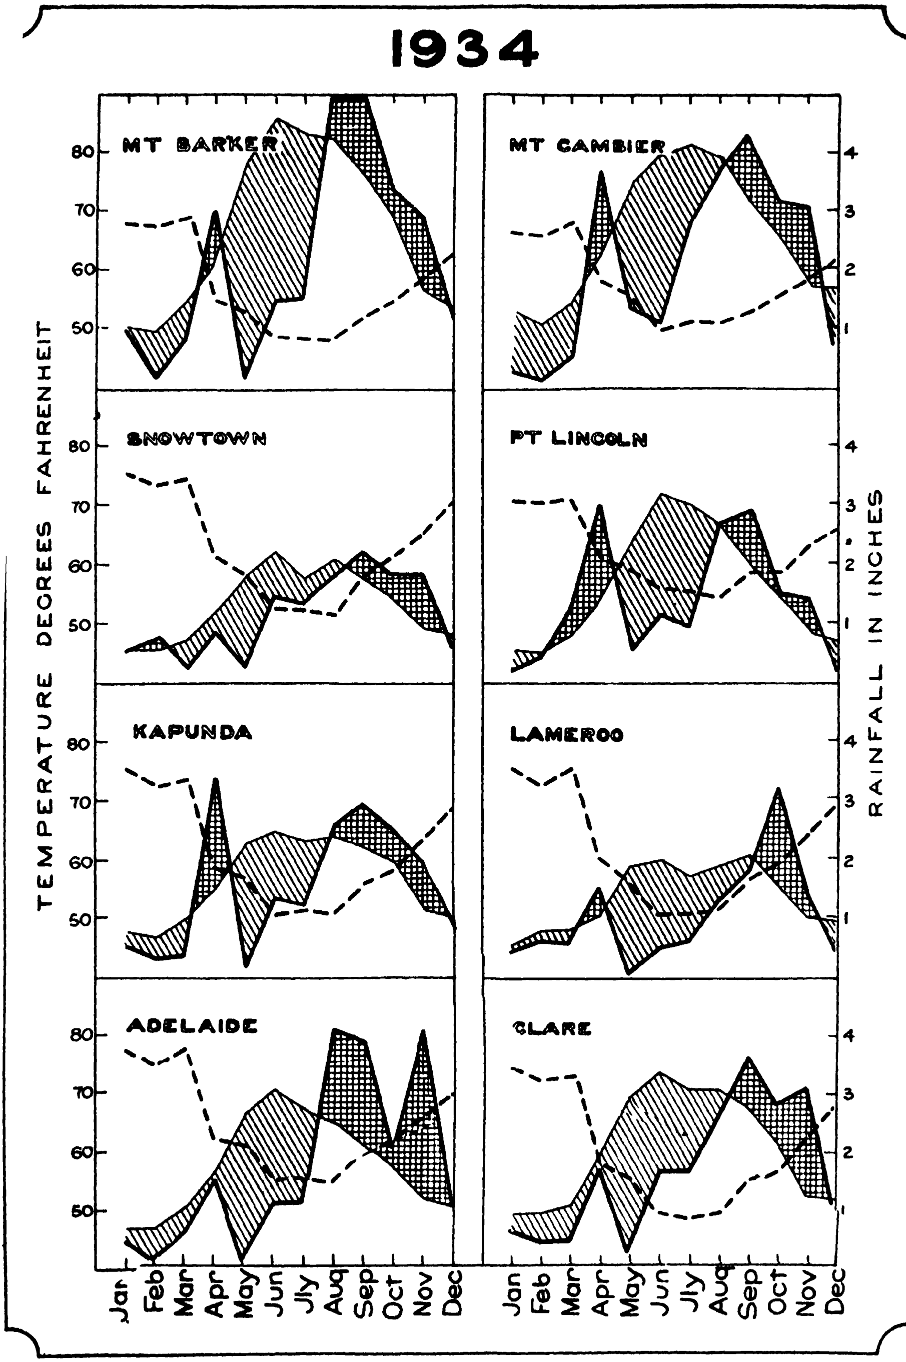

Figure 2.—Shows total rainfall and mean temperature for each month during 1934 at eight stations in South Australia;—actual rainfall each month during 1934— average rainfall for each month; single hatching shows rainfall below the average for each month, cross hatching, above the average for each month. ---Mean temperature for each month during 1933.

cracking of the bark. The wood in the infected region ultimately becomes brown and very brittle. The growth beyond the affected region is fairly normal until the disease has advanced considerably, when the death of the whole limb occurs rapidly. This sudden death occurs in early summer, the leaves drying out rapidly and remaining attached to the tree. It is quite characteristic for one limb after another to be affected, the disease ultimately reaching the butt of the tree where it completes the destruction. Observations in the field indicate that the disease is due to a parasitic agent which enters through wounds made in pruning. A fungus has been isolated consistently from the diseased areas, and its relation to the disease is now the subject of study.

The better-known diseases such as "Shothole" or "Scab" of apricots, peach "leaf curl," and pear "black spot" were in more than usual evidence in 1932, particularly in orchards where control methods known to be satisfactory were omitted or improperly performed.

VEGETABLES.

A bacterial "sore eye" disease of the potato has assumed some importance in the irrigated swamp lands along the lower part of the Murray River. The soils in this area, like those in Victoria, in which a similar disease occurs, are acid and have a high organic matter content.

Irish blight was reported from the South-Eastern district in 1932. Downy mildew of the onion and of the lettuce, Halo blight of beans (*P. medicaginis phaseolicola*), ring spot of cabbage (*Phyllosticta brassicola*) were also recorded.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

CONFERENCE OF YORKE PENINSULA BRANCHES.

Presided over by Mr. W. D. Wright (Chairman of the Boor's Plains Branch), the Annual Conference of Yorke Peninsula Branches was held at Kadina on March 6th. There was a good attendance of delegates from the Moonta, Paskeville, Bute, Kilkerran, Arthurton, South Kilkerran, and Boor's Plains Branches, and boys from the Kadina Agricultural High School. Councillor E. H. Hall welcomed the visitors on behalf of the Kadina Council, and the opening address was delivered by Mr. A. M. Dawkins (Member of the Advisory Board of Agriculture). The Department of Agriculture was represented by Messrs. H. B. Barlow, H.D.D. (Chief Dairy Instructor), R. C. Scott, R.D.A. (Supervisor of Experimental Work), C. F. Anderson (Poultry Expert), W. C. Johnston, R.D.A. (District Instructor), H. C. Pritchard (General Secretary), and F. C. Richards (Assistant Secretary Agricultural Bureau).

The following papers were read and discussed:—"The Value of Reading to the Farmer," H. K. Queale (Boor's Plains); "Horse Dipping," S. Pontifex (Paskeville); "Pig Raising," S. Chynoweth (Boor's Plains); and "Wheat Selection," L. McCarter (Boor's Plains).

Mr. Dawkins presented the following trophies to the successful competitors in the Northern Yorke Peninsula Crop Competition:—First prize, silver shield, presented by the Northern Yorke Peninsula Agricultural Bureau Field Trial and Show Society, Messrs. G. E. and H. M. Meier; second place, Mr. C. Rodda, silver cup; and third place was won by Mr. J. H. Bussenschutt, silver hot water jug.

The Boor's Plains Crop Contest resulted:—Mr. L. E. Yelland, silver cup, and Mr. T. A. Stanway, silver rose bowl, equal, 92 per cent.; third, Mr. M. D. Wright, 91.3 per cent.

Junior Crop Competition.—First prize, Edgar Drewett, with Donald Garner second. They were given books on farming.

The Boor's Plains Branch entertained delegates at luncheon, after which the Conference inspected the Amscol Factory.

It was decided that the arrangements for the 1936 Conference should be undertaken by the Arthurton Branch. The following resolution was carried:—Mr. O. Heinrich (Kilkerran) moved and Mr. F. Koch seconded, "That this Conference urges an amendment of the law affecting the fire raking of stubble, making it possible for one man to do fire raking of stubble without the consent of a fire controller." Conference concluded with an address, "The Care and Management of Poultry," delivered by Mr. C. F. Anderson.

The secretarial duties of the Conference were in the able hands of Mr. S. Chynoweth.

ARTIFICIAL WATER CATCHMENTS.

[*The article published below forms portion of a report submitted by the Engineer-in-Chief (Mr. J. H. O. Eaton) in reply to an Agricultural Bureau Congress resolution asking the Government to review the water situation in districts where permanent wells or springs have not been found, and which are not likely to be reticulated for some time from a reliable reservoir.*]

The information in respect to artificial catchments given hereunder includes that gathered from various sources, and is only intended to give such data as may permit an interested person to become acquainted with the method of construction and possibilities of this form of water supply.

LOCATION FOR USE.

In districts where the rainfall is small and the ground is porous or sandy, an artificial catchment is necessary to provide an effective run-off so that water may be collected and stored during even light showers.

For many years past, open sheds have been erected for settlers on Eyre's Peninsula; usually two sheds are constructed of the gable or lean-to type as may be selected by the settler, the over-all dimensions being 30ft. x 34ft. 6in. (115 sq. yds.). Each shed has two galvanized iron tanks of 2,500galls. capacity each (see accompanying sketches). These sheds serve a double purpose, one closed in may be used as a dwelling, and the other as a shelter for implements, &c. The roof serves as an artificial catchment, and water is stored sufficient for the limited demand during the early years of settlement. The sheds and tanks are erected by private contractors after tenders have been called by this Department. The settler is allowed to repay the Government for these improvements by instalments, covering principal and interest, spread over a term of years. Following development, this limited supply becomes inadequate for domestic purposes, horses for working the section, and any stock that may be acquired.

The section may be located within a few miles of a reticulated supply but the elevation of the property may preclude a supply by gravitation, and pumping would be uneconomical. In such cases water may be obtained by carting from the nearest standpipe provided on the reticulated system, or other permanent supply in the locality, but the time necessary for such purposes either restricts the stock that can be carried or affects the time that can be spent on development work, &c.

For land of the nature referred to, in locations far removed from a permanent supply, the artificial catchment appears to be a proposition worthy of serious consideration.

FORMS OF CONSTRUCTION.

The construction of artificial catchments may be divided into two types:—

1. Treatment of the ground to make surface impervious.
2. The use of some impervious material:—
   (*a*) Bitumastic sheeting.
   (*b*) Galvanized iron (flat sheets).

In either case the site must be sloping and approximately uniform or graded.

1. Impervious Ground Surface.

For this method of construction the prepared surface is treated with Colas, Laykold, Mexphalte, or some bitumastic preparation. Experimental areas were constructed in the above manner on Eyre's Peninsula near Kimba in May, 1929. Eighteen plots were laid down of varying mixtures and, after exposure for 17

months without re-dressing it, it is reported that only two plots so treated stood up to the tests. The details of the manner of treatment of these two plots are as follows:—

Penetration Laykold on Limestone Rubble.—Two inches of limestone rubble screened to remove fines up to half an inch, and coarse more than one and a half inches laid on graded and rolled natural surface, and well rolled after laying. Penetrated with 1gall. to square yard; the ½in. screenings spread, and the whole well rolled. Second coat, ¼gall. per square yard applied, then sanded and well rolled.

Colas and Laykold on Limestone Rubble.—Same as above, but using Colas for penetration coat and Laykold for top coat.

It is evident that this type of construction would require periodical re-dressings, which would result in high maintenance costs.

2a. Bitumastic Sheeting.

This type of construction was also included in the experimental plots and method of construction is as follows:—

Malthoid Heavy.—Five rolls were laid on dry, graded, and rolled natural surface, with 2in. side laps and 4in. end laps. Joints sealed with hot floatine applied with brush. Approximate cost per quarter acre (5-ply), £130. This method of construction gave a quick run-off, and at the end of 17 months was in good condition. It is doubtful, however, whether the base of any form of bitumastic sheeting could be preserved in its original condition for any extended period, owing

to the weathering of the basic material and loss of volatile oils during successive periods of high temperature as may be experienced in the Far Northern districts. Strict attention to maintenance and repeated re-dressing would no doubt extend the life of the material. A loss of tensile strength of the material would make treatment more difficult, and maintenance cost would progressively increase.

2b. Galvanized Iron.

Method of construction (extracted from brochure prepared by Mr. A. S. Kenyon) is as follows:—

The site is prepared by grading to a uniform slope and even surface. For the catchment 6ft. x 3ft. sheets of galvanized plain iron of 26 gauge are used, the sides bent up 1½in. The sheets are laid on the ground in rows in the direction of the slope (a sheltered position is preferable). The overlap varies, being 4in. for slopes up to 1 in 20, and less when steeper. Alternate rows start and end with half-length sheets so that all lap joints are staggered. The longitudinal rows are fastened together by punching a ½in. square hole through the bent-up edges with a special tongs punch which clamps the edges together. This forms a strong and extremely economical joint, which has the advantage of being readily opened should it be necessary to make repairs or insert new sheets.

At a cross-line two sheets from the upper end, the whole catchment is fastened to a timber sill which is bedded in the ground. This allows for the necessary expansion of the iron without any creeping down hill. Around three edges, the top and two sides, the catchment is similarly secured by nailing to logs. The catchment on the lower end discharges into a drain leading to the storage tank.

Consideration should be given to the nature of the soil upon which the iron is to be laid, and if considered necessary a tar or bitumen coating or other form of preservative applied; when the ground is thoroughly dried out, no corrosive action would be expected. A cut-off trench immediately above catchment would remedy any tendency for ground water to flow under the catchment area. A margin should be allowed around the catchment to give room for planting trees to prevent sand drift, and to give protection from winds. The whole to be suitably fenced.

Size of Catchment.

As the use of artificial catchments may be considered to be in the experimental stage, it is advisable to keep the initial outlay as low as possible, and for this reason consideration has been given to the quarter acre (1,210 sq. yds., including the area of tank roof) as the unit section. The adoption of a relatively small area for the catchment has the advantage that a suitable location can be more readily selected, and experience of practical value obtained with a minimum initial outlay. In some instances a single unit might so restrict the period of water carting that it would not be considered a great inconvenience to the occupant, but if a second unit is required advantage may result in its location at another part of the section. Standardisation would facilitate the work being done by contract with expectations of keen competition in respect to prices, to the advantage of the settler.

TANKS.

The type of tank adopted will depend on conditions at the site. An ample supply of suitable stone would permit the construction of a masonry tank or the lining of an excavation to form a storage. When the grade of the catchment site is suitable a tank built on the surface would be preferable, the pipes from the collecting drain at the lower end of the catchment leading into the top of the tank. This arrangement would obviate raising water by a hand pump and the consequent attention to fill troughs which could be controlled by float valves.

Excavated Tanks.

An excavated tank for the storage of 35,000galls. would have internal dimensions of, say, 48ft. x 25ft. at top water level, and 30ft. x 7ft. at bottom, with a maximum depth of 9ft. of water. If masonry or concrete lined, allowance is to be made for thickness of lining.

For masonry work the stone should be well bedded in lime or cement mortar, and after completion water-proofed by painting with a tar of bituminous compound.

For concrete lining the mix should be, say, 1 part of cement to 2½ parts of sand and 6 parts of broken stone. The cement used should be perfectly dry and free from any hard lumps; the sand clean and graded from fine to coarse; and the stone broken to pass a 1½in. ring gauge, graded, and the whole rejected by a ⅛in. screen. All the ingredients should be turned over dry three times, then mixed with water, using the least amount that will produce a workable mixture, then well tamped into position within 15 minutes of mixing.

For lining with Malthoid the material should be laid on an even surface of excavation. At 3in. lap to join strips, using hot floatine or similar material for jointing, the top to be secured.

Surface Tanks.

Masonry Tank.—A masonry tank built on the surface would be about 35ft. internal diameter by about 6ft. 6in. deep to suit stone available, the stone to be well bedded in lime or concrete mortar, painted inside to make impervious.

Concrete Tank.—A concrete surface tank would require forms and steel reinforcements, and would require skilled labour.

Squatter's Tank.—The squatter's tanks are standard construction made in sections for erection on site.

Designs of each typical tank could be prepared together with specifications to cover all details of work. Connection between catchment and tank may be either a concrete or metal drain at the bottom end of the catchment with openings to allow water to enter the excavated tank, or by pipe to surface tank.

ESTIMATES.

In the following estimated costs the prices of material have been taken at the rates at which settlers could expect to purchase for cash from retail firms.

The estimates are intended to be typical only, and are subject to modification to agree with any special local conditions. A general allowance of 150 miles railage from Port Lincoln and 12s. per ton cartage from the railway station has been assumed for arriving at the cost of transport of materials.

The approximate estimates are as follows:—

"Ironclad" Artificial Catchment.

(Using 26-gauge galvanized flat sheets.)

Area (including area of tank roof) ¼ acre.

	£	s.	d.	
Materials—				
Sheets, 6ft. x 3ft. (640 required), 4 tons at £25 10s.	102	0	0	
Jarrah, 4in. x 2in., 90ft. at £1 10s. per 100	1	10	0	
Jarrah pegs, 4in. x 4in. x 1ft. 6in., 46 at 11d.	2	2	0	
Cement, 10 bags at 6s.	3	0	0	
Sundries	0	10	0	
Sales tax on cement and jarrah	0	7	0	
	£109	9	0	say £110
Transport—				
Freight to Port Lincoln	6	5	0	
Railage	8	10	0	
Cartage	3	0	0	
	£17	15	0	say £18
	(including cartage, £3)			
Labour—				
Clearing and grading site	5	0	0	
Fixing jarrah pegs and sill	1	10	0	
Cutting and placing holding-down logs (using local timber)	6	0	0	
Laying down sheets to form catchment (including bending, punching, and fastening)	6	0	0	
Constructing concrete drain (allowing for obtaining sand and stone locally)	6	0	0	
Allowance for plant and tools	1	10	0	
	£26	0	0	

Tank.

Concrete-lined Excavated Tank, capacity 35,000galls., internal dimensions at top water level, say, 48ft. x 25ft., at bottom 30ft. x 7ft., with 9ft. maximum depth of water. Corrugated galvanized iron roof with fall to centre, supported on 4in. x 1¾in. steel joists.

	£	s.	d.	
Materials—				
Cement, 202 bags at 5s. 6d.	55	11	0	
Bitumen filler (2 coats on concrete), 15galls. at 9s. 6d.	7	3	0	
Sundries	5	0	0	
Sales tax	3	2	0	
	£70	16	0	say £71
Transport—				
Freight and railage	20	0	0	
Cartage	5	0	0	
	£25	0	0	

(including cartage, £5)

Labour—

	£	s.	d.	
Excavation, 220 cub. yds. at 5s.	55	0	0	
Stone (including collecting, breaking, and carting), 38 cub. yds.) at 12s.	22	16	0	
Sand (including collecting, washing and carting), 23 cub. yds. at 8s.	9	4	0	
Mixing and placing concrete, 45 cub. yds. at 10s.	22	10	0	
Painting surface with filler, 180 sq. yds. at 3d.	2	5	0	
	£111	15	0	say £112

TANK ROOF.

Materials—

	£	s.	d.	
Steel joists, 16/26ft. lengths, 18.6cwts. at 18s.	16	15	0	
Galvanized corrugated iron, 26 gauge, 90/9ft. sheets ..	17	3	0	
Timber around edge	1	13	0	
Bolts and nuts, 95lbs. at 4d.	1	12	0	
Sales tax	1	0	0	
	£38	3	0	say £38

Transport—

	£	s.	d.	
Freight and railage	8	14	0	
Cartage	1	4	0	
	£9	18	0	say £10

(including cartage, £1)

Labour—

Erecting roof	—	say £6

ALTERNATIVE.

Squatter's Tank (capacity 35,000galls.) for ¼ acre catchment. Galvanized iron roof but no bottom, black iron sides, painted with Siderosthen.

Materials—

	£	s.	d.
Squatter's tank	90	0	0
Inlet pipe, 2in. galvanized wrought iron, 1½ chains	5	0	0
Connections, outlet pipe, valve, &c.	5	0	0
Siderosthen bituminous paint, 2 coats on sides	2	0	0
Sales tax	5	0	0
	£107	0	0

Transport—

	£	s.	d.
Freight and railage	4	10	0
Cartage	0	10	0
	£5	0	0

(including cartage, 10s.)

Summary of Alternative Estimates.

A.—Catchment and Lined Excavated Tank.

	£
"Ironclad" artificial catchment materials	110
Concrete-lined tank materials	109
Transport of materials (omitting cartage)	44
Labour—Catchment, £26; tank, £118	144
Supervision	20
	£427

B1.—Catchment and Squatter's Tank (sides black iron painted, top galvanized corrugated iron, clay bottom).

	£
"Ironclad" artificial catchment materials	110
Squatter's tank materials	107
Transport of materials (omitting cartage)	20
Labour—Catchment, £26; tank, £15; bottom, £8	49
Supervision	14
	£300

B2.—Catchment and Squatter's Tank (as above, but concrete bottom).

	£
"Ironclad" artificial catchment materials	110
Squatter's tank (as above), £107; cement, £29	136
Transport of materials (omitting cartage)	29
Labour—Catchment, £26; tank, £15; bottom, £16	57
Supervision	16
	£348

The above estimates do not include the cost of carting iron, timber, and cement, which the settler could always provide for, but allow for all other anticipated labour costs. Usually, however, this also could be provided by the settler, and the following estimates are, therefore, given as an indication of the minimum amount for which a handy settler could secure the suggested water supply if he were able to supply all labour required and was only required to pay for materials:—

A.—Catchment and Lined Excavated Tank.

	£
"Ironclad" artificial catchment	110
Concrete-lined tank	109
Transport	44
	£263

B1.—Catchment and Squatter's Tank.

	£
"Ironclad" artificial catchment	110
Squatter's tank (black iron sides, clay bottom)	107
Transport	20
	£237

B2.—Catchment and Squatter's Tank.

	£
"Ironclad" artificial catchment	110
Squatter's tank (black iron sides, concrete bottom)	136
Transport	29
	£275

If the settler is unable to pay in cash for these improvements, the following table gives the amounts at which the capital costs of the different schemes could be repaid if a loan were granted the settler, repayable in 60 equal instalments due every six months, with interest at 5 per cent. per annum. On £100 the half-yearly instalment at 5 per cent. equals £3 4s. 8.5d. The following amounts are calculated proportionately:—

	Scheme A.			Scheme B1.			Scheme B2.		
	£	s.	d.	£	s.	d.	£	s.	d.

NITROGEN IN RELATION TO CEREAL CULTURE.

[By A. E. V. RICHARDSON, M.A., D.Sc., and H. C. GURNEY, M.Sc., Waite Agricultural Research Institute, University of Adelaide.]

[Paper read before the Australian and New Zealand Association for the Advancement of Science, Melbourne, January, 1935.]

The remarkable response of Australian soils to soluble phosphates has in the past led to an intensive study of the phosphate problem, and the investigation of the response of crops and pastures to various forms and quantities of phosphatic fertilisers.

Partly owing to this circumstance, and partly owing to the fact that in Australia wheat is usually grown on a well prepared bare fallow, which is normally unresponsive to nitrogen, comparatively little attention has hitherto been given to the role of nitrogen in cereal culture. Wheat is the most important of the cultivated crops of Australia, and the area annually sown averages 15 million acres. Whilst the greater part of the wheat belt lies within the 10-20in. line of rainfall, quite a considerable portion has a rainfall of over 20in., of which 70-80 per cent. falls during the growing period of the crop—May to November.

The climate of the wheat belt is mainly of the Mediterranean type with marked seasonal winter rainfall and a long period of summer drought. This is particularly true of the wheat areas of Western Australia, South Australia, and a substantial portion of Victoria and New South Wales.

The normal practice in the older settled areas of the wheat belt is to precede the wheat crop with a well worked bare fallow. The benefits of fallowing ([1]) in areas of light to moderate rainfall are explained on the following grounds—(*a*) conservation of soil moisture, (*b*) accumulation of nitrate nitrogen in the fallow, (*c*) reduction of competition with weeds, (*d*) promotion of tilth and a firm seed bed. A further practical advantage is that it tends to distribute the work of the farm evenly throughout the year and enables the grower at seed time to have large areas of clean land, appropriately tilled when the seasonal rains commence.

Moisture conservation is important in regions of moderate rainfall, since the extra moisture conserved by bare fallowing may represent a considerable proportion of the soil moisture actually "available" for the crop, *i.e.*, the amount of soil moisture in excess of that at which wilting of the plant occurs. The problem of moisture conservation becomes less important in regions of liberal rainfall (over 20in.) since the seasonal rainfall is usually sufficient for the transpirational demands of heavy crops.

Earlier investigations at the Waite Institute suggested that the nitrogen factor was more important than was formerly supposed.

(1) Comparisons of wheat grown in rotation with peas and with bare fallow showed that over a period of years the yield of wheat after peas was approximately equal to that of wheat after bare fallow.

(2) The application of nitrogen to cereal crops on stubble ploughed land invariably resulted in a substantial increase in yield, whereas the response to nitrogen on fallowed land was negligible.

(3) Comparisons of the moisture and nitrate nitrogen content of the soil at seed time showed that the most striking differences between fallowed and non-fallowed land were to be found in the nitrate-nitrogen content and not in the moisture content of the soil.

(4) Hitherto practically all field experiments with fertilisers for wheat in Australia had been conducted on well prepared fallow which normally contains an abundance of nitrate nitrogen. Under these conditions, *i.e.*, with a high nitrate nitrogen level, the response of phosphates would be marked, but substantial responses to nitrogen could hardly be expected except in wet seasons. Nevertheless, small responses had been recorded at Roseworthy (2) and Booborowie (3) on fallowed land.

For these reasons, a series of investigations was commenced at the Waite Institute in 1928 to determine the response of wheat to varying quantities and forms of nitrogen on fallow and on stubble ploughed land for a period of five years. In 1933, tests with barley and oats on stubble were commenced.

CLIMATIC CONDITIONS.

The Waite Institute is situated 3½ miles from Adelaide near the foothills of the Mount Lofty Ranges.

The climate of the Adelaide district, in common with the greater part of the wheat belt, is of the Mediterranean type with regular winter rainfall succeeded by summer drought.

The mean monthly rainfall and number of rainy days for the five years during which the wheat experiments were conducted are summarised in the following table.

EFFECT OF NITROGENOUS FERTILISERS ON GROWTH AND YIELD OF WHEAT.

For the five years 1928-32, investigations have been conducted to determine the effect of various quantities of nitrogen on the yield of wheat after bare fallow and after wheat.

The field plots were in all cases replicated six times, the method of plot arrangement throughout the five years being the randomised Latin Square method devised by Fisher (4). The moisture and nitrate nitrogen content of the soil were determined at periodical intervals and census studies were made to correlate differences in yield with observed differences in the crop throughout its growth. The unit plot was a 9-hoe drill strip 5 chains long and $\frac{1}{25}$ acre in area.

In order to remove the possible influence of phosphoric acid as a limiting factor to production, a basal dressing of 288lbs. superphosphate per acre was applied with the seed to all wheat plots in each year of test.

EFFECT OF SULPHATE OF AMMONIA ON YIELD OF WHEAT.

The mean yields of total produce (grain and straw) and grain for each of the five years 1928-32 and the average yields of each treatment are summarised in the table.

TABLE II.—*Effect of Various Quantities of Sulphate of Ammonia on Yield of Wheat when Grown after*—(a) *bare fallow,* (b) *wheaten stubble (stubble ploughed land), Waite Institute,* 1928-32.

† *Statistical analysis shows that the value of z for treatments is significant. The standard error of the difference between these means values for* 1928-32 *is* 1.03 *bushels.*

It will be seen that whilst the sulphate of ammonia had no appreciable effect in increasing the mean yield of grain with wheat after bare fallow, it had a marked effect on both total produce and grain with wheat after wheat.

An application of ½cwt. of sulphate of ammonia gave a mean increase in yield of 5.2cwts. total produce or hay and 3.16bush. grain. Similarly an application of 1cwt. per acre gave increases of 9.9cwts. of total produce and 5.39bush. per acre of grain. Both these applications were profitable with current or with mean prices for wheat and fertiliser.

The profit resulting from the application of sulphate of ammonia on the basis of these results is dependent upon the relative prices of grain and total produce (wheaten hay) on the one hand, and the cost of the fertiliser on the other. The relationship between profit per acre and wheat and fertiliser prices is shown in the diagram of the solid model.

The upper surface of the model indicates the amount of net profit per acre resulting from the application of 1cwt. sulphate of ammonia with prices of wheat ranging from 2s. 6d. to 5s. per bushel, and with sulphate of ammonia at prices ranging from 13s. to 9s. per cwt.

As the price of wheat decreases and the price of fertiliser increases, the amount of profit from the use of the fertiliser falls. Conversely, as wheat prices increase and fertiliser prices decrease, the profit per acre from any given application increases.

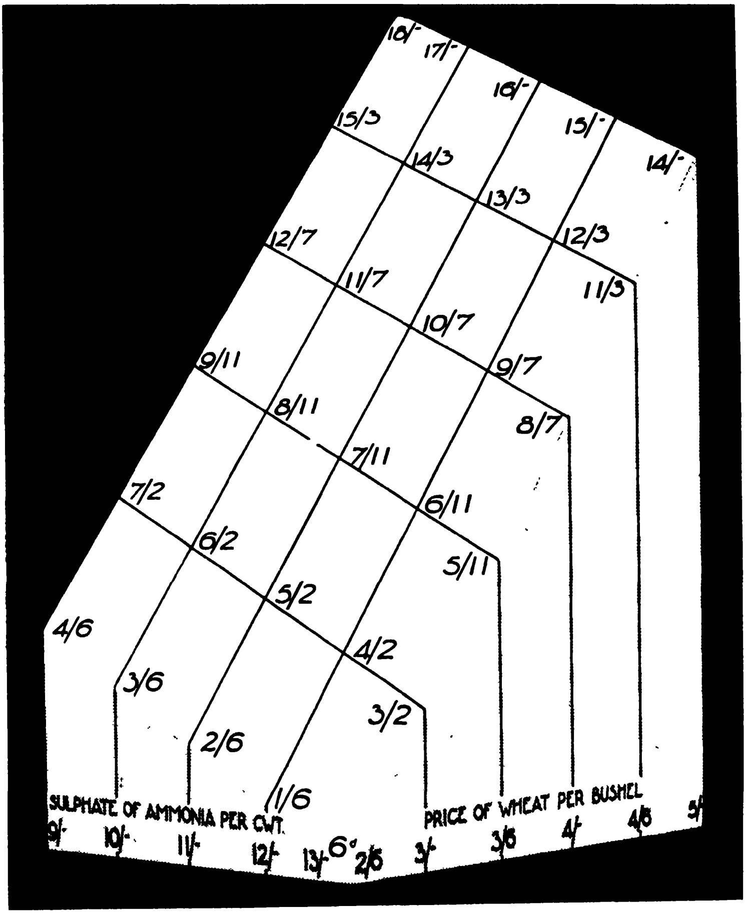

Figure 1.—Photograph of solid model showing on upper surface the net profit per acre from an application of 1cwt. of sulphate of ammonia, with varying prices for the fertiliser and for wheat.

EFFECT OF EQUIVALENT QUANTITIES OF NITROGEN IN VARIOUS FORMS OF FERTILISERS.

Investigations were conducted over five seasons (1928-32) to determine the effect of equivalent quantities of nitrogen (23.4lbs. nitrogen per acre) as nitrate of soda, sulphate of ammonia, nitro-chalk, urea, and diammonium phosphate.

Six replicates of each treatment were sown in the form of a randomised Latin square. A basal dressing of superphosphate was applied with the seed at the rate of 288lbs. per acre to all plots except those receiving diammonium phosphate.

The results for the five seasons are summarised in Table III.

TABLE III.—*Effect of Equivalent Quantities of Nitrogen (23.4lbs. per acre) applied in the form of Nitrate of Soda, Sulphate of Ammonia, Nitro-Chalk, Urea, and Diammonium Phosphate on Yield of Wheat after Wheat, Waite Institute,* 1928-32.

Treatment.	Total Produce. (Cwts. per Acre.)	Grain. (Bush. per Acre.)	Mean Increase due to Nitrogen.	
			Total Produce. (Cwts.)	Grain. (Bush.)
No nitrogen	33·02	27·99	—	—
Nitrate of soda	45·50	35·62	12·48	7·63
Sulphate of ammonia	42·67	33·77	9·65	5·78
Nitro-chalk	43·35	34·12	10·33	6·13
Urea	42·00	33·14	8·98	5·15
Diammonium phosphate	39·23	30·82	6·21	2·83

Statistical analysis shows that the value of ~ for treatments is significant. The standard error of the difference between the mean values for grain for 1928-32 *is* .81*bush.*

From the results over five seasons we may conclude that—

(1) nitrate of soda gives the largest increase, both in hay and in grain yields;

(2) there is no significant difference in the increases given by sulphate of ammonia, nitro-chalk and urea; the increase given by these three being not so great as that obtained with nitrate of soda;

(3) diammonium phosphate gives the smallest increase.

All plots (except the no nitrogen controls) received equivalent amounts of nitrogen (23.4lbs. per acre). All plots, including the controls, received an equivalent dressing of phosphoric acid. The differences in yield over the no nitrogen controls measure the efficiency of the various fertilisers on an equivalent nitrogen basis. Nitrogen in the readily available form of nitrate of soda gave the highest mean return.

In assessing the values of the yields, it must be borne in mind that whereas the amount of nitrogen applied per acre was the same, the actual quantities of fertiliser needed to supply equivalent weights of nitrogen varied considerably. The following quantities of the various fertilisers were used to supply equivalent quantities of nitrogen (23.4lbs. per acre), viz., nitrate of soda 150lbs., nitro-chalk 150lbs., urea 50lbs., sulphate of ammonia 112lbs., and diammonium phosphate 112lbs. The standard dressing of 1cwt. of sulphate of ammonia per acre gave over a five-year period an increased yield of appoximately 10cwts. hay or 5¾bush. wheat per acre, increases approximately the same as those recorded for the previous experiment (Table II.).

The comparatively low yield of the plots receiving diammonium phosphate was due to the fact that in the first two seasons (1928-29) this fertiliser was sown broadcast.

Investigation ([6]) showed that when diammonium phosphate was drilled with the seed there was no significant difference in the yield between diammonium phosphate and an equivalent amount of phosphoric acid and nitrogen applied in the form of superphosphate and sulphate of ammonia.

MOISTURE AND NITRATE NITROGEN CONTENT OF THE SOIL AT SEEDING AND AT HARVEST.

During 1929-32 the moisture and nitrate nitrogen contents of the soil on fallow and stubble ploughed land were determined at critical periods during the growth of the crop. In all cases the soil and subsoil were sampled at four depths, namely, 0-9in., 9-18in., 18-27in., 27-36in., and for each sampling 12 holes were bored to a depth of 3ft. The wilting point of each layer was determined according to the method described by Briggs and Shantz (6) by growing wheat in ten replicated series of pots and observing the point at which permanent wilting took place in a saturated atmosphere. The moisture and nitrate nitrogen content of the stubble and fallow soils at seeding for each year are summarised in Table IV.

TABLE IV.—*Mean Moisture and Nitrate Nitrogen Contents of Soil to a depth of 3ft. on a Bare Fallow and Stubble Ploughed Soil at Seeding and Harvesting of Wheat,* 1929-32.

	Moisture Content.		Nitrate Nitrogen.	
	Fallow.	Stubble.	Fallow. Parts per Million.	Stubble. Parts per Million.
	%	%		
At seeding	21·95	20·4	8·5	4·8
At harvest	12·7	13·1	2·2	2·5

The mean moisture content of the fallowed soil at seeding for four seasons was 21.95 per cent. as compared with 20.4 per cent. for the stubble ploughed soil. Seeding normally takes place in June. This difference is equivalent to .6in. of rain. The moisture really available for the wheat crop is that above the point at which permanent wilting takes place, which for the first 3ft. averages 15.6 per cent. The growing crop used up all the moisture which fell as rain (about 16.7in. during the growing period), and in addition reduced the moisture content of the fallow to 12.7 per cent. at harvest and that of the stubble ploughed land to 13.1 per cent.

The most striking difference, however, between the fallow and the stubble ploughed land at seeding was not in the moisture content, but in the nitrate nitrogen content. The mean nitrate nitrogen content of the fallow soil at seeding was 8.5 parts per million to a depth of 3ft., as compared with 4.8 parts per million for the stubble ploughed soil. The difference in favour of the fallow was therefore 3.7 parts per million of nitrate nitrogen equivalent to 34.4lbs. per acre of nitrogen, or approximately 1½cwts. per acre of sulphate of ammonia. In other words, the fallow soil at seeding has an available nitrogen supply equivalent to 1½cwts. of sulphate of ammonia per acre, over and above that of the stubble ploughed soil, apart from the additional advantage of extra moisture equivalent to .6in. of rain.

It will be noted that at harvest the values for nitrate nitrogen on both types of soil are practically the same.

The graphs show that the fallow soil at seeding has a larger supply of available moisture and particularly of nitrate nitrogen than the stubble soil. After the two soils have produced their crops (December) the nitrate and moisture contents of both soils are practically identical, the larger crop on the fallow having removed the extra supply of nitrate and moisture. Further, the graphs indicate that the two factors are not of equal importance, the lack of nitrate in the stubble soil being relatively

more serious than the lack of moisture. The deficiency in nitrates may be made good by the application of nitrogenous manures but only up to the limit of the moisture supply. The latter, of course, will vary with the rainfall of the region.

CENSUS STUDIES ON WHEAT.

Census studies on the growing crop were made during the three years 1930-32 on the wheat grown on stubble land to determine the effect of sulphate of ammonia on plant establishment, tillering, percentage survival of tillers and ear characters.

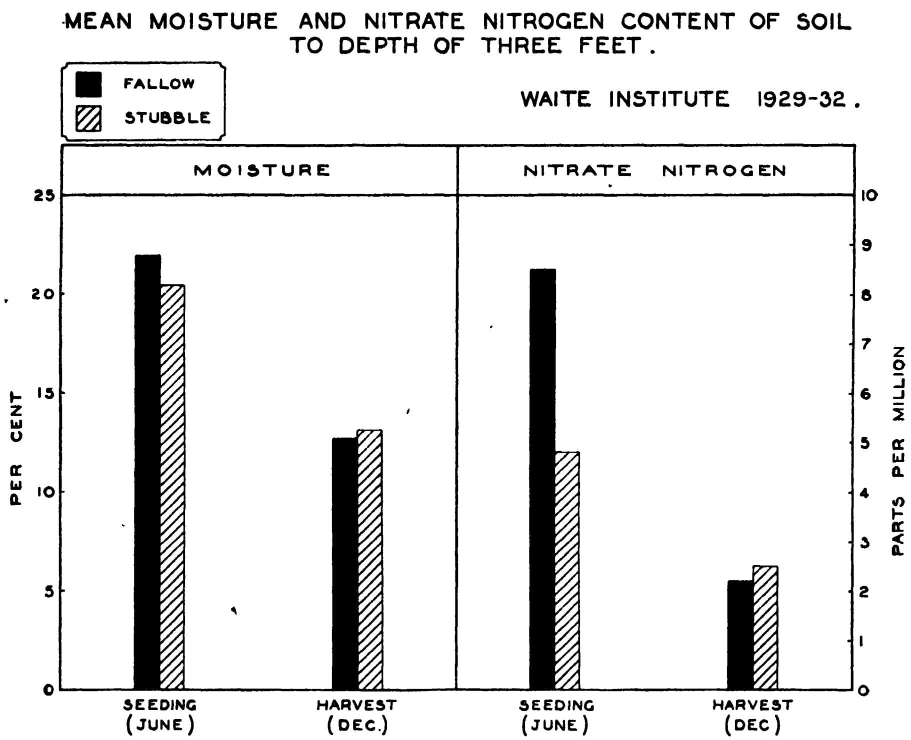

Figure 2.—Graph showing the mean moisture and nitrate nitrogen content of the soil to a depth of 3ft. on (1) fallow, (2) stubble, at seeding (June), and at harvest (December), for seasons 1929-32.

For purposes of comparison, similar records were also made on the no nitrogen plots on fallow. The technique employed consisted of sampling from a systematised scatter of foot-lengths of drill row in each plot to be studied: 18 samples were taken from each of the six replications, making 108 samples for each treatment. The positions of the foot lengths were marked with light jarrah stakes and numbered pegs, and throughout the sampling the foot-length was taken as the unit.

The results for the seasons 1930-31-32 are summarised in the following table.

TABLE V.—*Results of Census Studies on the Growth of Wheat on Fallow and Stubble Land, with and without Nitrogenous Manures, Waite Institute,* 1930-32.

Treatment.	No. of Grains Sown per Foot.	No. of Plants at Tillering Stage per Foot.	No. of Tillers at Maximum Tillering per Foot.	Ear-bearing Tillers at Harvest per Foot.	Final Yield in Bushels per Acre.
1. Stubble, no nitrogen	9·3	7·6	24·2	12·2	34·6
2. Stubble, 2cwts. Sulph. of ammonia	9·3	7·5	39 0	16·6	44·9
3. Fallow, no nitrogen.	9·3	6·8	35·0	17·5	44·3

Plant establishment, that is the average number of plants per foot-length of row, was found to be slightly better on stubble land than on fallow land. This was due mainly to the fact that with the liberal rainfall characteristic of the seeding period (June) at the Waite Institute, the tilth of the soil is normally better on the stubble than on the fallow soil. The main effect of sulphate of ammonia on wheat grown on stubble was to cause a vigorous burst of tillering, which is almost entirely responsible for the increased yield.

The percentage survival rate of the tillers producing ears is lowered by dressings of sulphate of ammonia. Over a period of three seasons with the plots receiving no nitrogen, 50 per cent. of the tillers observed at maximum tillering produced ears. The plots receiving sulphate of ammonia on stubble produced the greatest number of tillers during September, but only 42.5 per cent. of the tillers survived to produce ears.

Were it not for the lowering of the survival rate, we should expect much larger increases in yields from nitrogen treated plots on stubble. The mortality among the tillers produced with nitrogen on stubble is so much higher than among the tillers on the fallow, that the final yields per acre are brought closer together than one would expect from the number of tillers present at the maximum tillering stage.

The number of ear-bearing tillers at harvest is almost directly related to the yield.

Sulphate of ammonia increases the length of ear on stubble although not the length of the ear on fallow. No significant differences appear to occur in the weight of grain per ear.

EFFECT OF SULPHATE OF AMMONIA ON BARLEY AND OATS.

Wheat occupies a dominant position in South Australian agriculture. It provides the main source of income for thousands of farmers, and the success of the crop largely influences the financial position of the grower. It is not unnatural therefore to find that wheat receives preferential treatment in respect to cultivation over other cereals. Whatever bare fallow is available is rightly devoted to wheat, and oats and barley are almost invariably and necessarily sown on land more or less hastily prepared in the autumn from stubble or temporary pasture.

Investigations with wheat recorded above have shown that at harvest the moisture content of the soil under the wheat crop is reduced below the wilting point and that practically the whole of the available nitrate nitrogen has been used up by the crop. The dry soil conditions which normally follow the harvest in the South Australian environment are unfavourable for fresh supplies of nitrate nitrogen to be formed in the soil until the seasonal break in the weather occurs in the late autumn. Consequently, oats and barley grown on such stubbles cannot produce heavy yields even with liberal dressings of superphosphate on account of

the low nitrate nitrogen level of the soil. If, however, the necessary nitrogen is applied as fertiliser, it is frequently possible, at least in the Adelaide environment, to raise the yield either of oats or of barley to a level approaching that obtained from a well worked bare fallow.

In view of the fact that the greater part of the barley and oats are normally sown on stubble ploughed land, it would appear that the possibility of increasing the yields of barley and oats on stubble by the use of dressings of nitrogen should be thoroughly tested.

On the permanent manurial plots at the Waite Institute it was found that a dressing of 12½lbs. nitrogen per acre (equivalent to 60lbs. sulphate of ammonia), either in the form of sulphate of ammonia or of nitrate of soda, increased the yield of barley over a period of eight years by 4.8bush.

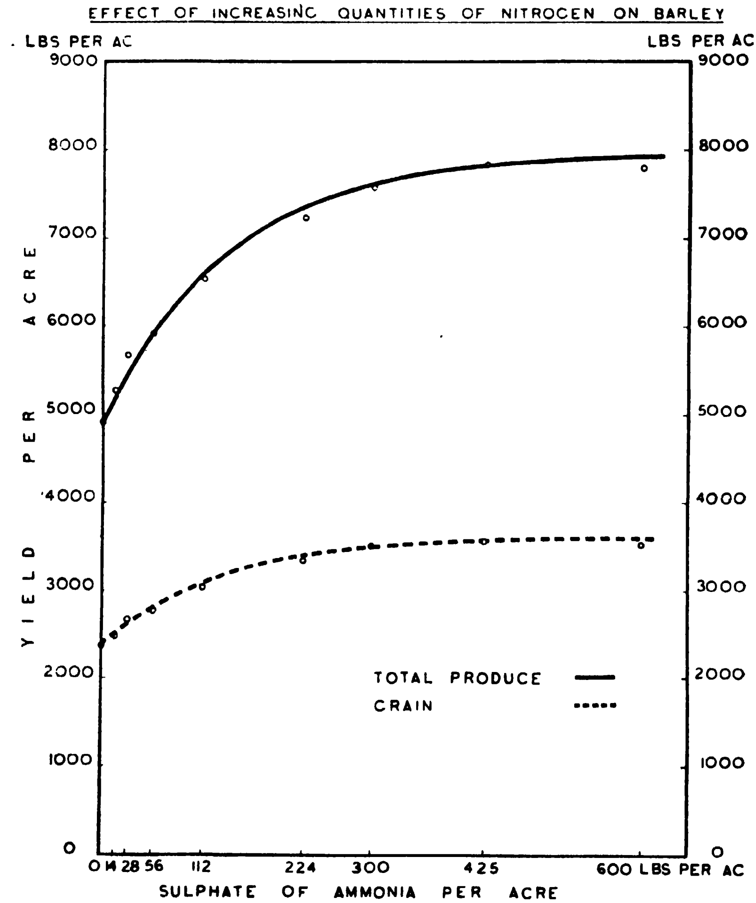

Figure 3.—Graph showing relationship between the quantity of sulphate of ammonia applied per acre and yields of total produce and grain.

A comprehensive test was therefore designed in 1930 to determine the effect of sulphate of ammonia on barley in quantities ranging from 14lbs. to 600lbs. per acre. Nine manurial treatments with nine randomised replications of each treatment were sown in the form of a Latin square. The plots were sown on the stubble of an unmanured oat crop grown in 1929. To remove the possibility of soluble phosphate being a limiting factor to nitrogen, the whole of the plots were treated uniformly with a basal dressing of 288lbs. superphosphate drilled in with the seed.

The results of this investigation have already been recorded ([6]), and a brief summary is shown in the attached graph.

Without nitrogen, but with the basal dressing of superphosphate, the yield per acre was 47.5bush. The increased grain yields over the no nitrogen controls with dressings of ½cwt., 1cwt., and 2cwts., were respectively 8.1bush., 13.4bush., and 19.5bush per acre. These increases were very profitable, and demonstrated very clearly that in the Adelaide environment there were great possibilities of increasing barley yields by moderate applications of sulphate of ammonia. The results of this quantitative test showed that the increments in yield due to successive moieties of sulphate of ammonia became progressively smaller and furnished an interesting example of the Law of Diminishing Return ([7]).

Mitscherlich ([8]) attempted to formulate a law for plant yield based upon the relation between the yield of the crop and the intensity of the environmental factor (fertiliser). According to Mitscherlich, if all the conditions were ideal a certain maximum yield would be obtained, but in so far as any essential nutrient is deficient, there is a corresponding shortage in the yield. Further, the increase in crop yield produced by a unit increment of the lacking factor, in this case nitrogen, is proportional to the decrement from the maximum attainable yield.

If A is the maximum yield obtainable when the lacking factor is present in excess, and y = yield when x = the amount of fertiliser added, then

$$\frac{dy}{dx} = A - y \text{ or } \operatorname{Log} (A - y) = C - kx.$$

Figure III. shows graphically the relationship between the yields of total produce and grain of barley and the quantities of sulphate of ammonia applied to produce the yield.

The calculated yields as determined by this equation, were found to agree fairly closely with the yields actually observed for quantities of sulphate of ammonia ranging from 0 to 425lbs. per acre. The calculated yields all fell within the limits of the observed values and their mean errors.

Broadly, the observed results show that when adequate amounts of phosphate are available, nitrogen becomes a limiting factor on stubble land, and the yield of barley, both for total produce and grain when fertilised with increasing amounts of sulphate of ammonia, follows the Law of Diminishing Return. In the light of the above investigations, it would appear that the use of sulphate of ammonia offers a means of augmenting the production of feed barley where such is grown on stubble ploughed land, or of increasing the stock carrying capacity of the barley crop if it be used for pasture.

For the production of malting barley the effect of the sulphate of ammonia on the grain must be considered.

It is well known that the "steely" quality of the grain is associated with a high percentage of protein in the grain, and that the "mealy" quality of the grain is associated with a low percentage of protein.

If the application of sulphate of ammonia to barley increases the nitrogen content of the grain to any marked extent, we should expect to obtain poorer malting samples with increasing dressings of the fertiliser. It was shown ([6]) that quantities of sulphate of ammonia up to 56lbs. per acre produced no effect on the nitrogen content of the grain. With an application of 1cwt. and 2cwts. per acre of sulphate of ammonia, the nitrogen content of the grain was raised from 1.50 per cent. (no nitrogen treatment) to 1.59 per cent. and 1.68 per cent. respectively, and the grain was slightly less valuable as a malting sample. Dressings in excess of 2cwts. per acre had an appreciable effect in raising the nitrogen content of the grain and in affecting its value as a malting sample.

In any individual year the nitrogen content of barley grain is subject to variations attributable to the soil on which the crop is grown, the variety, the time of sowing, whilst between two seasons very large differences may be found due to different weather conditions. The differences in nitrogen content of the grain caused by seasonal variations re usually greater than the differences which are obtained by moderate dressings of nitrogen (*i.e.*, up to 1cwt. sulphate of ammonia per acre).

In 1932, two series of field experiments were laid out to determine the effect of sulphate of ammonia on the yield of (1) oats, (2) barley, in a rotation series of wheat, oats, barley, fallow. It is intended to continue the experiments for five years, but the results of the first two seasons' work are sufficiently conclusive to justify recording them at the present stage.

With both barley and oats the same lay-out of plots was used. Thirty-six plots, each consisting of a 9-hoe drill strip 5 chains long, were used in each experiment, and all plots received a basal dressing of 2cwts. superphosphate with the seed. Six manurial treatments were used, each of which was replicated six times in the form of a Latin square.

During each season, tiller counts were made, on both barley and oats, in the manner already described for wheat (*vide supra*). In addition, determinations of the nitrate nitrogen content were made to a depth of 3ft. at various stages of growth on the barley plots.

The rainfall for the two seasons is summarised in the accompanying table.

Table Showing Monthly Rainfall 1933, 1934, *and Number of Rainy Days, together with Rainfall June to November.*

June-November	12·494	17·560	103	105

The two seasons show rather striking differences. In 1933, there was a marked break in the weather in April, and liberal rains fell during the period immediately prior to seeding (June). Winter and early spring rains were satisfactory, but late spring rains were abnormally light.

Almost the antithesis of these conditions was experienced during 1934. The rainfall till the end of July was extraordinarily light, and at no time during the first seven months of the year was the rainfall sufficient in amount to bring about the usual saturation of the soil to a depth of 3ft. Following on this long, dry period, the rainfall from August to November was considerably above the average.

The results of the tests with barley for the two seasons are summarised in the following table.

TABLE VI.—*Showing Effect of Sulphate of Ammonia on—*(a) *Total Produce,* (b) *Grain Yield of Barley.*

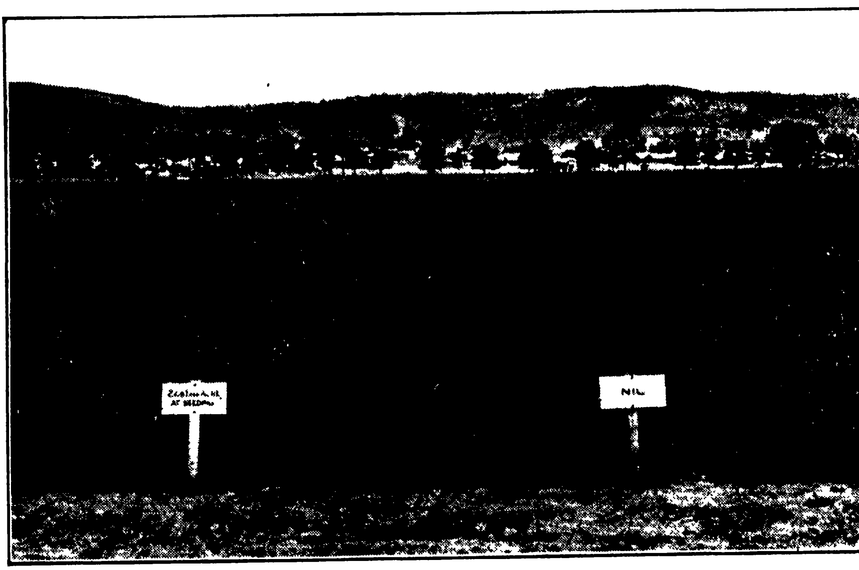

Figure 4.—View of barley plots on stubble ploughed land which received (1) 2cwt. per acre of sulphate of ammonia at seeding, and (2) no sulphate of ammonia.

The effect of sulphate of ammonia on barley, as shown in the above table, is very striking.

Without sulphate of ammonia, the mean yield of total produce for the two seasons was 22.8cwts., and 26.59bush. of grain per acre.

The application of 1cwt. sulphate of ammonia resulted in a yield of 43.95bush. per acre, *i.e.*, an increase due to sulphate of ammonia of

17.36bush. per acre. With 2cwts. per acre sulphate of ammonia, the mean yield was increased to 55.7bush., an increase of 29.11bush. per acre.

The effect of sulphate of ammonia on the yield of oats for the two seasons was no less striking than that shown with barley.

The following table summarises the yield for the two seasons 1933-34:—

TABLE VII.—*Showing Effect of Sulphate of Ammonia on*—(a) *Total Produce,* (b) *Grain Yield of Oats, Waite Institute,* 1933-34.

* *Statistical analysis shows that the value for z for treatment is significant. The standard error of the difference between mean values for* 1933-34 *is* 1.22*cwt. per acre.*
† *Statistical analysis shows that the value for z for treatment is significant. The standard error of the difference between mean values for* 1933-34 *is* 1.38*bush. per acre.*

Without sulphate of ammonia the mean yield of produce is 28.88cwts. per acre, and 40.91bush. of grain per acre.

An application of 1cwt. sulphate of ammonia increased the yield of total produce by 17.53cwts., and the yield of grain by 18.73bush. per acre. The application of 2cwts. per acre sulphate of ammonia increased the yield of total produce by 32.14cwts., and that of grain by 34.1bush. per acre.

Both with barley and with oats the application of 1cwt. sulphate of ammonia at seeding gave a better return than the application of a similar quantity in spring.

The striking increases in yield of total produce of oats with application of sulphate of ammonia are of special significance to growers in the better rainfall areas, since oats are largely used for hay and are frequently sown on stubble ploughed land or after wheat.

Census studies were made during the two seasons both on the barley and on the oats. The main result of interest was the large increase in the number of tillers in September, both on oats and barley, with liberal dressings of sulphate of ammonia. The results for the two seasons are summarised in Table VIII.

TABLE VIII.—*Showing Results of Census Studies on Growth of Barley and Oats, Waite Institute,* 1933-34.

Census.	Barley. No nitrogen.	Barley. 2 cwts. sulphate of ammonia	Oats. No nitrogen.	Oats. 2 cwts. sulphate of ammonia
1. No. of grains sown per foot-length of drill	9·9	9·9	15·1	15·1
2. Plant establishment per foot	6·0	5·6	10·2	10.0
3. No. of tillers per foot at maximum tillering	21·2	34·7	22·6	41·0
4. No. of ears (Barley) or panicles (oats) per foot at harvest........................	11·7	20·0	14·4	15·3
5. Percentage survival of tillers	55·2%	57·4%	63·7%	37·4%
6. Mean yield of grain (bush. per acre)	26·59	55·70	40·91	75·01

The most interesting features revealed by the census were:—

(*a*) Plant establishment was not significantly affected by the application of 2cwts. of sulphate of ammonia per acre, when the fertiliser is sown broadcast with a drill on the surface.

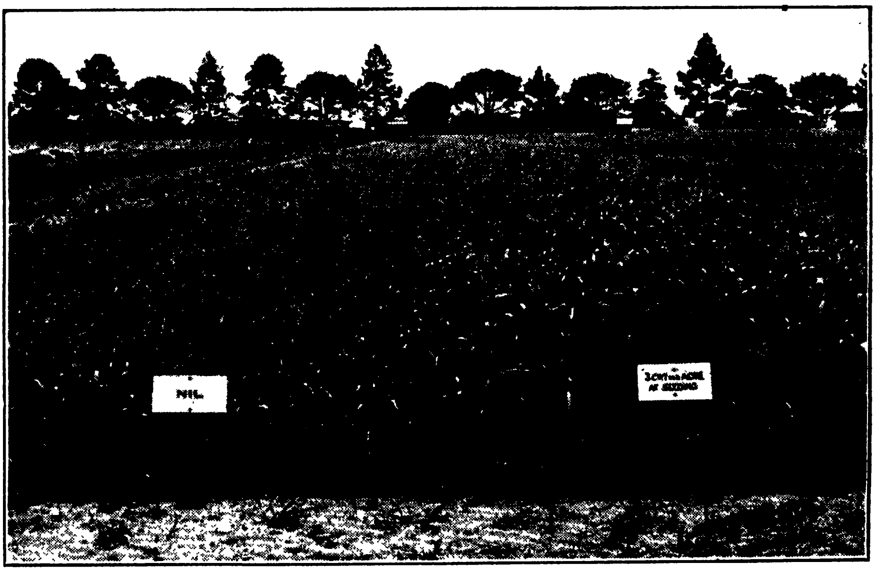

Figure 5.—View of oat plots (14/10/33) on stubble ploughed land which received (1) no sulphate of ammonia, and (2) 3cwt. sulphate of ammonia at seeding.

(*b*) Sulphate of ammonia has a very marked effect in increasing the number of tillers per foot length of row both with barley and with oats. At the period of maximum tillering (September) a dressing of 2cwts. sulphate of ammonia increased the number of tillers by 64 per cent. with barley and 83 per cent. with oats.

(*c*) The number of tillers at the period of maximum tillering is greatly in excess of the number of tillers that produce ears (barley), or panicles (oats).

(*d*) With barley, out of 21.2 tillers per foot present in September on the no nitrogen controls, only 11.7 tillers succeeded in producing ears. On the nitrogen plots, there were 34.7 tillers in September and of these 20.0 tillers produced ears. The ratio

of ear-bearing tillers on the two plots of barley was 11.7 to 20.0, and since the mean yield of barley grain was 109 per cent. higher on the plots treated with sulphate of ammonia as compared with the no nitrogen controls, and as the number of ear-bearing tillers was only 71 per cent. greater it would appear that while the greater part of the barley increase resulting from the application of nitrogen was due to the increase in ear-bearing tillers, portion of the increase in yield was due to increased length of ear.

(*e*) The position with regard to oats is of interest. At the period of maximum tillering 22.6 stalks per foot were found on the no nitrogen plots, as compared with 41.0 stalks per foot on the plots treated with nitrogen. The nitrogenous dressing therefore increased the formation of tillers by 83 per cent.

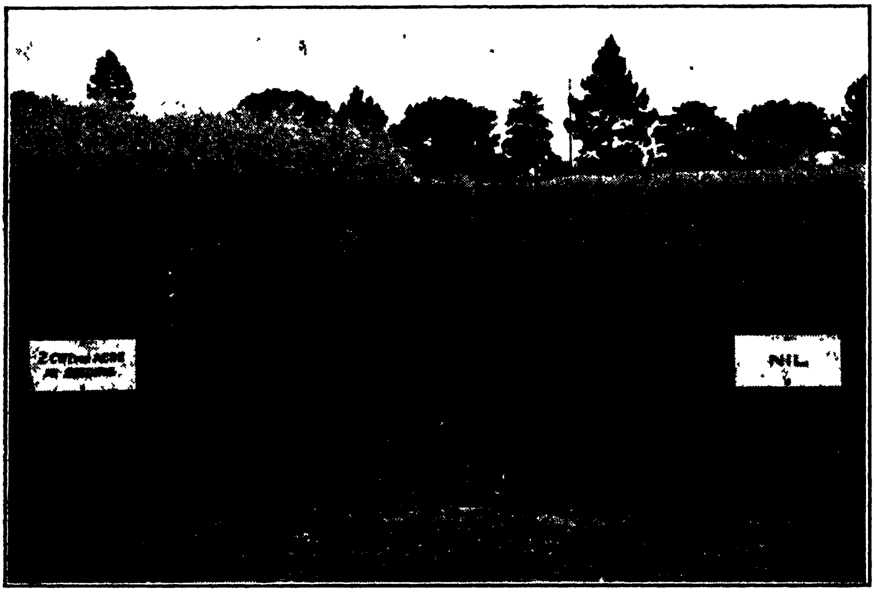

Figure 6.—View of oats (16/11/33) on stubble ploughed land which received (1) 2cwt. sulphate of ammonia at seeding, and (2) no sulphate of ammonia.

A substantial proportion of these tillers failed to produce panicles, but the proportion is much higher on the nitrogen than on the no nitrogen plots. Only 37.4 per cent. of the total tillers produced panicles on the nitrogen treated plots, whereas on the plots receiving no nitrogen 63.7 per cent. of the tillers produced panicles.

The census study shows that at harvest the actual number of oat panicles produced per foot was not increased materially by the nitrogen. This was due to the fact that the advantage gained by increased tillering was lost by a high mortality rate among the tillers, so that at harvest the number of oat panicles per foot on the no nitrogen controls and the nitrogen treated plots was respectively 14.4 and 15.3 for the two seasons. The mean grain yield, however, was 75.0bush. per acre on the plots receiving nitrogen as compared with 40.91 on the no nitrogen controls. Thus, though the grain yield of oats was increased by 83 per cent. by an application of nitrogen, the number of seed bearing panicles per foot was only slightly

The effect of sulphate of ammonia on the general development and size of the oat panicles was very striking in comparison with panicle development on the no-nitrogen plots. This improved size and development of the panicles was mainly responsible for the large increase in grain yield observed during each of the two seasons.

Nitrate nitrogen determinations were made during the two seasons 1933-34 on the soil to a depth of 3ft. on the no nitrogen barley plots. The mean amount of nitrate nitrogen at seed time for season 1933-34 to a depth of 3ft. was 3.6 parts per million. As the crop developed, this amount was gradually reduced and at the stage of maximum tillering amounted to 2.75 parts. As the crop advanced towards maturity, the amount of nitrate nitrogen increased, presumably because the amount formed by nitrification during late spring when temperature and moisture conditions in the soil were favourable, exceeded the nitrogen intake by the crop. At harvest it was found that the mean nitrate nitrogen content of the soil, to a depth of 3ft., amounted to 3.5 parts per million, practically equivalent to the amount present at seeding.

DISCUSSION.

During a period of low prices for primary products, farmers naturally seek to impove the efficiency of their farming methods; no avenue which may lead to greater production at an economic cost can be neglected. The use of the best cultural methods, selection of appropriate varieties, and the application of fertilisers at the most economic rate become essential for the profitable continuance of cereal growing under existing conditions.

In most wheat districts the application of superphosphate equally with the use of a well prepared bare fallow is rightly regarded as a standard procedure for the growth of a good wheat crop. The cultural practice of growing wheat after bare fallow has obscured to some extent the merits of nitrogenous fertilisers for the wheat crop, and incidentally to such crops as are normally sown on stubble, *e.g.*, barley and oats.

While the precise physical, chemical, and biological changes which take place in a soil during the process of bare fallowing are incompletely known, it has been established definitely that a fallow soil contains more nitrate nitrogen at the end of the fallowing period than at the beginning. Moreover, it has been shown that the organisms responsible for nitrification work most actively in late spring and autumn provided the conditions regarding soil moisture are favourable ([9]). The net result of this activity in the soil is that sufficient nitrate nitrogen is produced in the surface layers of a well-worked fallow to meet the needs of prolific wheat crops. On the other hand, the conditions in stubble ploughed soil are very different. Here the available nitrate nitrogen, and indeed the soil moisture have been practically exhausted by the previous season's crop, and the conditions in the stubble soil during the dry summer are unfavourable for the nitrifying organisms in the soil. The nitrate nitrogen content of the stubble soil before seeding is therefore always inferior to that of a well-worked fallow, and indeed these investigations show that the stubble soil rarely contains sufficient nitrates to meet the requirements of a good cereal crop. Hence the application of a nitrogenous fertiliser to a stubble ploughed soil removes one important limiting factor for the growth of the crop. Whilst it is true that the fallow soil usually contains more moisture at seeding than the stubble ploughed soil, yet the difference between the fallow and the stubble ploughed soil in regard to moisture content is not as great as is generally supposed, at least under conditions similar to those that obtain at the Waite Institute.

The evidence obtained at the Waite Institute shows that the nitrate nitrogen accumulated in the fallow soil is a major factor in accounting for the heavy increase in crop yield from fallow as compared with stubble. Moreover, if the shortage of nitrate nitrogen in the stubble be made good by the application of nitrogenous fertilisers, the yields of wheat on stubble, in a district of liberal rainfall, will not fall far short of those obtained on well-worked fallow.

The application of nitrogenous manures to wheat on fallow has not materially increased the yield of wheat on bare fallow over a five-year period at the Waite Institute. On stubble land, however, the mean increase in yield over a five-year period was found to be 5.4bush. per acre for an application of 1cwt. of sulphate of ammonia.

The value of this increase is dependent on the relative prices of wheat and sulphate of ammonia, and reference to the photograph of the solid model will show that the amount of profit is considerable when wheat prices are favourable.

The greater proportion of the wheat in Australia is sown on a bare fallow. Under these conditions the use of nitrogenous fertilisers would not be necessary, since, as has been shown above, the fallow normally contains an abundant supply of nitrate nitrogen, and, moreover, even under the liberal rainfall conditions of the Waite Institute, the application of nitrogen on bare fallow does not give a material increase in crop yield.

Unfortunately for Australia, however, there is still a considerable area of the wheat crop which is not normally sown on bare fallow. It is difficult to obtain precise data on this point, but probably one-third of the area annually planted is sown on stubble ploughed land. It is on this portion of the wheat area, particularly in districts of liberal rainfall, that nitrogenous fertilisers may be used with advantage, especially if prices for wheat improve.

The position regarding barley and oats is very different from that of wheat. Wheat, as the main source of income for tens of thousands of farmers in the cereal cultivation belt, receives, not unnaturally, preferential treatment as compared with oats and barley. Thus in most districts wheat is, or should be, sown only on well-worked fallow, and when the seasonal break in the weather occurs it usually receives the undivided attention of the grower until the last acre of wheat is sown. Oats and barley, on the other hand, are almost invariably and necessarily sown on land more or less hastily prepared from grass or stubble which, as shown above, are normally deficient in nitrate nitrogen at seedtime.

Under these conditions, one would expect a favourable response to nitrogenous fertilisers, and the experiments recorded above show that most striking and profitable increases in yield are obtained from these crops with nitrogenous fertilisers.

The mean increase in yield at the Waite Institute for the two seasons for 1cwt. of sulphate of ammonia are for barley 17.4bush. per acre and for oats 18.7bush. per acre. The increase in oaten hay yield for 1cwt. of sulphate of ammonia was 17.5cwts. and for a 2cwt. dressing, 32.1cwts. These striking increases in the yield of oaten hay and grain are of special significance to growers in the better rainfall areas since oats are largely used for hay and are frequently sown on stubble land after wheat.

Confirmation of these results of the value of nitrogen on stubble soils with oats and barley have been obtained during the past season at a number of centres in Victoria and South Australia ([10]).

SUMMARY.

Investigations on the effect of nitrogenous fertilisers on the growth of wheat, oats, and barley have been conducted at the Waite Institute for seven seasons.

1. Comparisons made over a five-year period to determine the effect of nitrogen on the yield of wheat sown on bare fallow and on stubble ploughed land gave the following results:—

(1) The response of wheat to nitrogenous fertilisers on well worked fallow was not sufficient to be profitable.

(2) On stubble ploughed land sulphate of ammonia in quantities ranging from ½cwt. to 2cwts. per acre gave profitable increases in crop yield, at normal prices for wheat and fertiliser. The mean increase in yield for five years with wheat on stubble was 5.4bush. per acre for an application of 1cwt. sulphate of ammonia.

(3) Census studies on the growing crop showed that with wheat the main effect of sulphate of ammonia was to cause a vigorous burst of tillering resulting in a greater number of ear bearing tillers at harvest and that this was the major factor accounting for the increase in yield.

(4) The moisture content of the fallow soil to a depth of 3ft. was found to be slightly higher than that of stubble ploughed soil at seeding. The nitrate nitrogen content of the fallow soil was found to be considerably higher than that of the stubble ploughed soil at seed time. These two factors are not of equal importance in a region of liberal winter rainfall as the lack of nitrate nitrogen in a stubble soil is relatively more serious than lack of moisture.

(5) Equivalent quantities of nitrogen (23.4lbs. N. per acre) applied in various forms showed that over a period of five years nitrate of soda gave the largest increases. No significant differences occurred between the increases given by sulphate of ammonia, nitro chalk, and urea.

2. The results obtained with barley and oats show that striking increases in yield are obtained with sulphate of ammonia on stubble land when the supply of soluble phosphate is adequate.

(1) An application of 1cwt. sulphate of ammonia per acre increased the mean yield of barley grain by 17.4bush. per acre for seasons 1933-34. An application of 2cwts. per acre increased the grain yield by 29.1bush. per acre.

(2) With oats the addition of 1cwt. per acre of sulphate of ammonia increased the grain yield by 18.7bush. per acre and the yield of total produce (hay) by 17.5cwts. per acre for the seasons 1933-34. An application of 2cwts. sulphate of ammonia increased the hay yield by 32.1cwts. per acre and the grain yield by 34.1bush. per acre.

(3) The stubble soil was poorly supplied with nitrate nitrogen at seeding as the previous crop of wheat had reduced the available moisture and nitrate supply to a low level at harvest, and nitrification did not proceed actively during the summer and autumn periods owing to the dryness of the soil.

(4) Census studies showed that with barley the major part of the increased yield following an application of sulphate of ammonia was due to an increase in the number of ear bearing tillers. With oats the increase in grain yield was due mainly to the improved panicle development following an application of nitrogen.

(5) The striking increases in yield with these crops are of special significance to growers in the better rainfall areas of Australia since both barley and oats are frequently sown after wheat.

THE STATE EXPERIMENT ORCHARD, COROMANDEL VALLEY, NEAR BLACKWOOD, SOUTH AUSTRALIA.

[Report 1908-1934 by GEO. QUINN, Chief Horticultural Instructor, Department of Agriculture.]

ORIGIN AND OBJECTS OF THE ORCHARD.

During the first decade of the present century, the various sections of the Agricultural Industries of the State had definitely begun to emerge from the veritable "slough of despond" which had enveloped them for upwards of a generation.

It may be claimed that this substantial revival was directly attributable to the more general adoption of improved cultural practices, and although perhaps more applicable to the wheat farmers, it also applied—though with less spectacular results—to other minor land industries such as fruit and vine growing.

It was just then becoming recognised—though somewhat tardily perhaps—that the utilisation of these improved methods had largely evolved from the teachings and demonstrations conducted at the Agricultural College supported by the propaganda instituted by the Agricultural Bureau working in conjunction with a few field Instructors employed by the Government to specialise on stimulating certain forms of rural production. Of these Officers—who subsequently formed the nucleus of the technical staff of the Department of Agriculture—the present Director of Agriculture (Professor Perkins) and the writer of these notes form the only remaining Official links.

Having realised by experience gained during this transitional period how futile it was to endeavour to conduct with reasonable accuracy in privately owned plantations, tests and demonstrations on fruit trees or grape vines over a sufficiently long period of years to secure reliable results, the writer resolved to try to induce the Government of the day to enter upon the establishment of a State-owned orchard in which this work might be carried on continuously under trained supervision. Having already instituted a policy of conducting State experiment farms in some of the newer wheat-growing areas, the Government took a sympathetic view of the proposal and agreed to the suggestion.

In 1906, an area of some 13 acres of deep alluvial land situated within the city boundaries adjoining the Botanic Garden on one side and abutting on to Hackney Road on the other was granted for an Experiment and Demonstration Orchard. This land had formerly been used for many years by the Adelaide Hospital for the Insane for orchard, vineyard, and general garden purposes, when that institution was located on the eastern end of North Terrace, Adelaide, but since its removal to other quarters, the land had lain unused, the trees and vines unpruned, and over-grown with weeds—the resort of pilferers and pestiferous bird life. The allocation of this particular area of land, as the following facts indicate, arose from certain circumstances which afterwards had a direct bearing on the establishment and subsequent scheme of planting followed in the Blackwood State Orchard in Coromandel Valley. Briefly stated, these were as follows:—

In the mid nineties of last century, the late Hon. Thomas Playford—whose private business was that of a fruitgrower and market gardener at Norton's Summit—went to London as Agent-General for this State. He naturally became interested in matters pertaining to fruit growing and

trading as carried on in Great Britain and soon realised that the nomenclature of many of the varieties of fruits he had known in South Australia was much confused and he at once took practical steps to try to remedy the position.

After consultation with Pomologists and other authorities he procured from leading British fruit tree nurserymen, type trees of a good many of the sorts he now knew to be growing under wrong names in South Australian orchards. In due season, these trees were despatched to the Government in Adelaide.

When they arrived, there being no Agricultural or Horticultural Department in existence to receive them, the trees were handed by the Treasury Department to the Director of the Adelaide Botanic Garden for planting at his discretion. The arrival of further lots of fruit trees from the same sources caused the Board of Governors of the Botanic Garden to take some thought respecting what should be done with them. On appeal to the Government of the day, they were offered a portion of an aboriginal reserve of densely timbered land situated in the Onkaparinga River Valley near the village of Mylor for the purpose of establishing a Type Orchard. This land was in an isolated position, difficult of access, and its only recommendations lay in the facts that it cost nothing and was in the Mylor district, largely occupied by a large number of recently settled lessees of homestead leases who were endeavouring to make a living by growing fruits and vegetables under extremely difficult conditions.

A portion of this land was cleared of timber and rocks at great expense and a plantation of varieties of fruit trees begun. The then Director of the Adelaide Botanic Garden (Dr. W. M. Holtze) entered upon the project most enthusiastically and in the course of a few years collected from European and Australian nurseries an immense collection of varieties of fruit trees of all kinds grown in temperate and sub-tropical climates, and planted them in the Mylor Type Orchard. It was soon found, however, that many sorts of fruit trees which hailed from the warmer climates would not tolerate the wet, frosty winters experienced in that part of the Onkaparinga Valley. As most of the soil in this orchard was of exceptionally poor quality and lacked adequate under-drainage, such features only added further difficulties to the task of maintaining them in a thriving condition.

It was at this juncture that the writer's desire to establish a State controlled demonstration and experiment Orchard first became known to the Botanic Garden Board. That Board generously offered to forego a prior claim they had established over the land adjoining their domain in Adelaide—to which previous reference has been made—and agreed to the suggestion that it be granted to the Horticultural Section of the then newly formed Agricultural Department, and further, that the kinds of fruit trees found to be unsuited to the Mylor conditions of soil and climate, be transferred to the Hackney Road site and thus preserved from extinction. This suggestion was adopted, and early in 1907, a nursery was formed under the writer's supervision on the southern end of the land adjacent to the Waterfall Gully creek, and a start made to propagate the varieties of peach, apricot, plum, fig, citrus, grape vine, almond, olive, and other fruits found most intolerant of the Mylor conditions. Whilst this work was in progress, the remainder of the 13 acres of land was cleared of old fruit trees, grape vines, and ornamental forms of trees and shrubs planted by the former occupants. The land was ploughed and subsoiled and reticulated with water pipes preparatory to being planted in orchard form. This preparatory work was scarcely completed when the

Price Government intimated that the major portion of the area would be very desirable as a site for the erection of a central car depot and block of administrative offices for the then recently formed Municipal Tramways Trust.

It had been foreseen from the outset that the location of this land from the point of view of conducting, without molestation, experiments in fruit culture had many drawbacks.

After further negotiation, some nine acres were surrendered for the above-named Tramway purposes, and the writer, authorised by the Government to secure offers for land "up to 100 acres" in area which might be deemed more suitably placed for the purpose of establishing an orchard in which to conduct experiments and demonstrations in fruit culture, and to test varieties of fruits not common to the State. The remaining four acres of land at Hackney Road was, owing to its proximity to the city, and good soil, retained for nursery and demonstration purposes, and the State collections of citrus trees and grape vines grown therein. At the present time, this small plantation is officially known as the Adelaide Demonstration Orchard.

With the generous assistance of two local orchard owners—the late Hon. G. R. Laffer and Mr. W. L. Summers—the writer was enabled early in 1908 to secure the purchase by the Government from Mr. J. Dall for £800 of 52½ acres of land, being part section 867 in the hundred of Adelaide, situated in Coromandel Valley, within one mile of the township of Blackwood. On this land, the plantations now known as the Blackwood Experiment Orchard have since been established. During March, 1908, the Government entered into possession of the land, and with the opening of the rainy season in May preparatory operations were begun under the supervision of the first orchardist, Mr. C. G. Savage, who now occupies the important position of Director of Fruit Culture in the Department of Agriculture of New South Wales.

Coromandel Valley is situated in the first fold of the Mount Lofty Ranges on the western side where the frontal ridges overlook the plains of Adelaide, and the waters of Gulf St. Vincent. Its northern end, where the State Orchard is located, is about 9½ miles from Adelaide by the main bitumen road to Clarendon and other southern districts in the Ranges. This road traverses almost the entire length of this picturesque valley, and through which it follows the winding course of a small stream known as the Sturt River, which drains the surrounding countryside into Gulf St. Vincent.

The prevailing climatic conditions are intermediate between those of the hotter and drier plains of Adelaide, and the wetter and colder regions located higher up in the Mount Lofty Ranges.

The Experiment Orchard, which is located on the eastern or rising side of the Valley, has an elevation ranging between 700ft. and 800ft. above sea level. The meteorological data collected therein indicate that the average annual rainfall recorded from 1909 to 1933—a period of 25 years—has been 29.66in. The average monthly distribution of this throughout a calendar year may be seen in the following table:—

January	**0.76in.**	**May**	**4.10in.**	**November**	**1.35in.**

		September	**3.57in.**		
Total	**4.73in.**	**October**	**2.12in.**		
		Total	**22.21in.**		

It will be noted that approximately 75 per cent. of the rain falls during what may be termed the winter and spring season, viz., May to October, and only 25 per cent. during the hotter months—November to April—of summer and autumn, when the mean monthly temperatures range from 60° F. upwards in the shade. During the above period, the rainfall exceeded 40in. (highest 42.82 in 1923) during two years only, and the lowest, and only registration below 21.15in. (the Adelaide Plains average for 95 years) was 15.06in. in 1914—the noted year of drought throughout Southern Australia.

The average monthly occurrences of temperatures of 32° F. and under. recorded on the grass during the colder and wetter seasons—May to October—throughout the 10-year period 1924-1933 inclusive, were as under:—

May	3.5 days	August	6.4 days
June	6.4 days	September	2.6 days
July	6.9 days	October	0.7 days

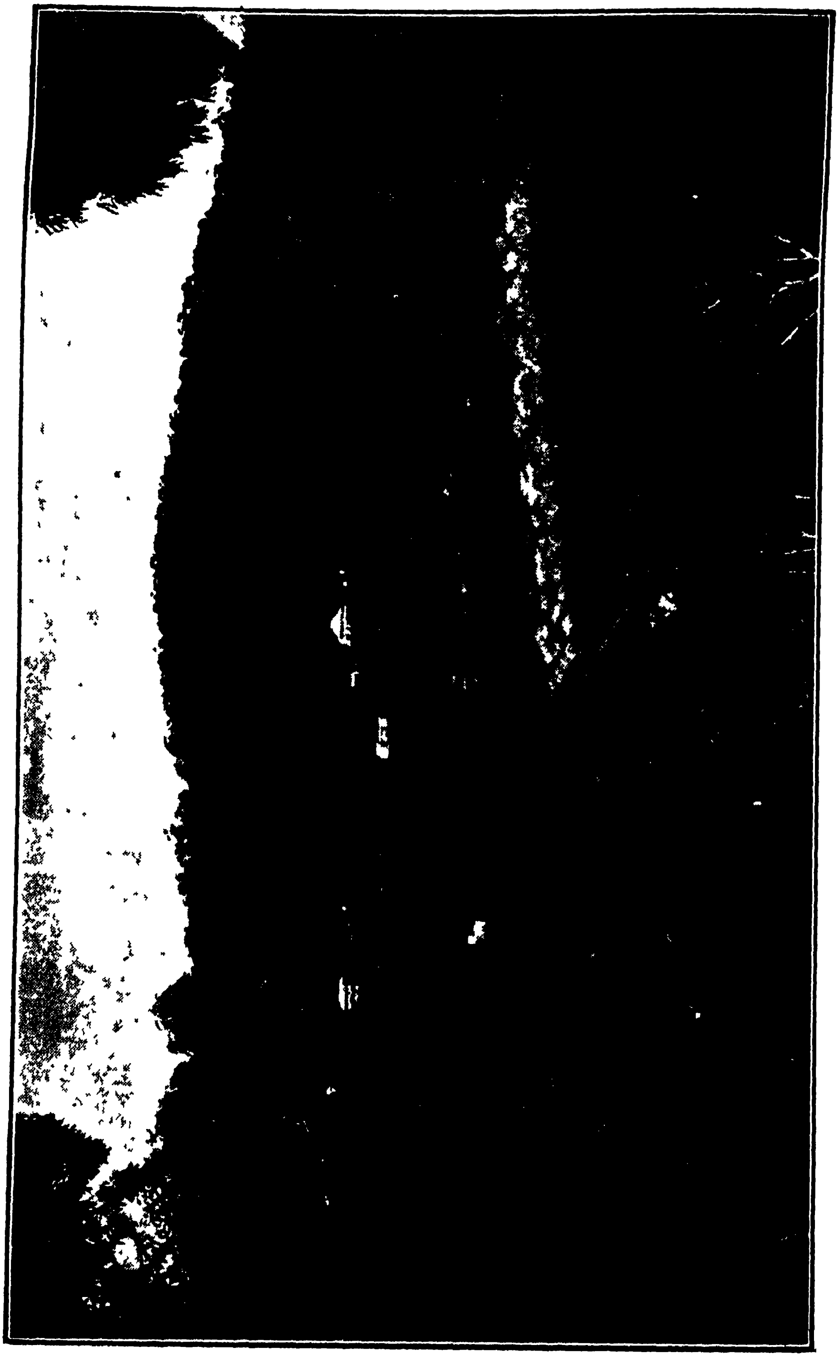
The average monthly registrations of summer heat of 100° F. and over as recorded in a standard shade screen 4ft. 6in. above ground level through the hotter months—November to March—during a 10-year period from December, 1924, to March, 1934, were as follows:—

November	0.7 days	February	3.6 days
December	3.2 days	March	2.2 days
January	4.9 days		

Taking at this juncture a 3-year period only (1931-32-33) from the accumulated daily data of 25 years, the respective monthly averages of minimum and maximum air shade readings and soil temperatures indicate monthly means approximating to the following:—

	Under shade screen 4ft. 6in. above ground. ° F.	Under soil 18in. below surface. ° F.
January	71.5	75.0
February	69.5	72.0
March	67.0	68.0
April	60.0	59.5
May	57.5	55.0
June	51.5	49.0
July	49.5	46.5
August	51.0	48.5
September	55.0	52.5
October	58.8	56.0
November	63.5	65.0
December	68.0	72.5

The eastern side of Coromandel Valley consists of a series of rolling ridges displaying a general fall to the west, thus allowing the small water-courses which have formed between them to empty the surplus rains of winter into the Sturt Creek. In the panoramic view of the central portion of the State Orchard presented herein, it will be seen that the land of which the orchard is composed is made up of two main slopes, one from the northern, and the other from the southern sides of two of these more or less parallel ridges. The winding channel of the small water-course which drains them, as well as the higher ridge further eastward may be



Panoramic view of the central portion of Blackwood Experiment Orchard, looking eastward.

readily traced at the base of the left-hand slope which faces south. The steepness of this slope is well displayed by the belt of dark pine trees which have been planted up over the ridge to afford shelter from the winds to the trees planted on that portion of the eastern half of the slope which is hidden from view. On the top of this slope and eastward of the pine belt, a small plateau of several acres is located in the north-eastern corner of the orchard block. This small creek traverses the full length of the orchard, and, as will be noted on the accompanying plan, it junctions almost at right angles with another larger creek coming from the northwards. This creek drains the National Park near Belair and cuts off several acres of land yet unplanted along the western boundary of the orchard property. The creek which bisects the orchard lengthways is actually an artificially made ditch dug by the orchard staff around the contour of the base of the slope. The natural watercourse—as shown in dotted marginal lines in the plan—followed a very tortuous channel through which a dark plot of citrus trees is now seen in the picture, and along the base of the slope on the right-hand side. By utilising its deeply scoured, irregular bed as a repository for many hundreds of tons of stone outcrops which were removed from the hillsides when preparing the land, and eventually covering these deeply with the good soil taken from the present ditch, several acres of valuable land were reclaimed, and the general tillage of the lower parts of the slopes facilitated for all time.

The slope on the right, which faces northwards, is not nearly so steep or undulating on its surface as is the opposing one which turns away from the sun; neither does it present such great variations in soil textures.

When the land was purchased by the Government, the slope facing northwards on which a large white patch of trees is shown in the picture, was clear of timber and had been cultivated for some years by the former owner for hay growing purposes. The opposing slope which is only partly seen on the left-hand side of the panoramic view, was covered with a strong growth of South Australian Red Gum trees (*Eucalyptus rostrata*), approximately 20 years or more old. Scattered between the half dozen trees which were standing on each acre of land, were hundreds of dead stumps of similar gum trees which had been killed some years previously to admit light and promote the growth of herbage for stock grazing purposes, to which use it had been applied by the previous owner.

The close, clay-like structure of the soil body which covers the surface of the orchard area, clearly indicates that it has been mainly derived from the decomposition of the original slates—mud-stone-rocks—which now underlie it at varying depths and occasionally may be seen on the unbroken area in the form of shelving surface outcrops. Blended with this, fragments of quartz of various sizes are found, evidently having been carried by erosion from the higher ridges of the range and deposited, together with ironstone gravel and silicious materials, in a finer state of subdivision over the surface of the land. This mixture of mineral components is blended with a very small proportion of substances of organic origin, excepting in small pockets on some of the northern slopes or in the narrow flats along the sides of the watercourses. In these latter positions the surface soil is deeper, more sandy, and of a highly humified character. Numerous soil profiles examined along the slopes and on the flats indicate that clay preponderates in the surface loams. These surface soils vary in depth from 5in. to 13in. on the slopes with an average depth of 8¼in. in 25 tests. On the narrow flats the surface soil is deeper, and nine tests range from 7in. to 24in. with an average of 15in. in depth.

In the same series of examinations, the underlying subsoils of red or yellow—deep chrome yellow-clays ranged in depths from 9in. to 41in. or an average of 26in. on the slopes. In the flats, the range was less, viz., from 16in. to 32½in., and averaging 25in. These very plastic clays were frequently mixed with nodular or broken gravel-like slate and quartz stones; occasionally larger, loose, unstratified slate stones impeded boring, and had to be removed by crowbar. Calcareous nodules were found in only two of the tests. In many of these holes, roots of the fruit trees were found deep in the clay and stony mixtures. These soundings were carried down until a solid bottom of stone or extremely hard soil mixture was met. On the sloping land the average depths to solid stone were 32in. ranging from 44in. to 21½in. below the surface, found in 11 testing positions. On the flats two positions in nine tests showed solid stone at 47in. and 40in. deep respectively. Solid earth was found in the remaining seven at an average depth of 44in. No solid stone bottom was reached in 14 positions on the slopes when tested to depths varying from 51in. to 26in. to a non-rocky solid formation deemed capable of resisting root penetration. The average depth to this stratum was 39in.. These lower soundings certainly indicate the shelving towards the surface of the slate rock formation at irregular intervals over the area. It may be accepted that in this surface loam, the clay factors predominate, thus rendering the land somewhat heavy to till and prone to set rapidly into a hard crusted condition after a few hours of spring or summer heat or drying wind. In actual practice, spring ploughing may, in certain seasons, require the immediate accompaniment of the harrows or scarifier to prevent the encrusting of the upturned sods to such a condition of resistance that without soaking rain falls at once, only the use of a very heavy roller will enable the orchardist to bring the surface to a desirable fine state of tilth. This type of surface soil, unless well blended with organic matter and roots of herbage, particularly, has a great tendency to suffer from erosion, more especially when violent thunder showers fall upon the land when it is covered with the finely pulverised layer deemed so desirable as a summer condition in this climate. This tendency doubtlessly accounts for the shallow layer of loam previously referred to as overlying the sloping hillsides. The loss, in the aggregate, of hundreds of tons of this surface soil from the steeper slopes of the Blackwood Orchard site has confirmed these statements throughout the quarter of a century under review.

It may be claimed that a very large proportion of the land devoted to fruit culture in the coastal districts of this State closely approximates to that described above. This decomposed "mudstone" basis forms the principal bulk of the soil body, the variations consisting chiefly of differing proportions of silicious sand and quartz, calcareous (lime) and organic compounds blended therewith in the different districts, and in different orchards, and even extending to various areas of the same orchard or vineyard in a district. During recent years, an effort has been made at Blackwood to stop these losses of the more valuable surface loams by endeavouring to grow winter cover crops consisting of peas, beans. barley, mustard, &c., between the rows of fruit trees, and plough them into the soil during early spring. The objective is a long distance one, but it is the way of Nature's laws, and no shorter cuts are possible without enormous expenditure in returning from extraneous sources the lost fertility and texture of the land.

No extensive efforts to evaluate the potential elements of fertility in these soils as possible of revealment by chemical analysis have been made.

In 1912, the Government Department of Chemistry analysed eight samples of soils and subsoils drawn from certain test plots located along the southern slope. The results of these indicate that the average percentages of the principal elements of fertility deemed to be present in the top 9in. may equal:—

Nitrogen.	Phosphoric Acid.	Potash.	Lime.	Fine Earth.
				(Passing 1 M.M.
(N)	(P_2O_5)	(K_2O)	(CaO)	Mesh Sieve)
.019%	.043%	.165%	.219%	91%

By way of comparison, similar data from analyses made of samples of surface soils drawn from a like depth in 10 fair average orchards and vineyards located in seven different districts in this State, indicate an average content of these plant foods to approximate to:—

N.	P_2O_5	K_2O	CaO
.082%	.046%	.324%	.517%

Further samples tested from two orchards located in the richest types of lands in the Mount Lofty Ranges show:—

N.	P_2O_5	K_2O	CaO
.205%	.151%	.471%	.454%

In the older countries of the world, it has been claimed that a soil to be classed as reasonably fertile, should contain at least:—

N.	P_2O_5	K_2O	CaO
.1%	.1%	.2%	2 to 3%

If judged from the two last quoted standards, the surface soils in the southern half of the Blackwood Experiment Orchard would appear to be weak in all of these elements so desirable for the healthy growth of plants. With the exception of Phosphoric Acid—which is also low—they fail to reach the standard of fertility displayed in the soils of the 10 fair average orchards and vineyards scattered throughout seven different parts of the State.

Analyses made of the subsoils to a further 9in. in depth revealed in the Blackwood samples that apart from the nitrogen content being appreciably lower and the Potash a little more abundant—which might be expected in these clays—there was little difference in the quantitative distribution of these fertilising elements to a depth of 18in. below the surface of the land.

During the winter of 1908, the right-hand slope—which faces the sun—previously used for hay growing, was ploughed and sub-soiled. For the ploughing, a heavy single-furrowed steel Cockshutt plough, cutting a 12in. wide furrow as deeply as two strong horses could manage, was used. In this furrow, an American type of subsoil plough with a goose neck shaped body fitted with a chisel pointed share on the sole plate, was drawn by four horses, breaking up its bottom as deeply as possible. Although this slope had been ploughed many times by the former owners, the land had not been disturbed for a greater depth than 3in. or 4in. It was soon found that the huge root systems of the original red gum trees still remained in a perfectly sound condition—in so far as the main roots were concerned—just below the above depth. The removal of these by means

of explosives and hand labour entailed a good deal of delay and expense. The presence of smaller roots and isolated slate stones which had been detached from the underlying reefs increased the difficulty of securing anything like a regular depth of disturbance of the sublayers. Finally, this was fairly well accomplished to depths varying from 9in. to 16in. over the block. The land was then scarified and brought to a workably smooth surface prior to pegging it out for planting.

This type of subsoiling plough was deemed to be too weak and the preparatory work applied subsequently to the remainder of the orchard area was done by the use of a very heavy disc plough capable of cutting a furrow upwards of a foot deep. This was drawn by eight bullocks which worked on the steep, slippery slopes without injury, although they often fell to the ground. This plough was accompanied by three workmen using picks and grubbing tools to remove loose stones or roots which, in places,

Preparing steep hillside land at Blackwood Experiment Orchard, South Australia.

obstructed the disc. The soil slice was thrown over in the direction of the lesser slope of the land, thus clearing the furrow and assisting the workmen in locating and removing obstructions. On the steeper portions of the land, the ploughing was all done down the slope, and the team returned with the plough riding free.

This procedure was slow, but it resulted in a splendidly prepared planting bed for the reception of the trees.

As indicated in the plan printed herein, the area was mapped out into blocks—afterwards distinguished by letters of the alphabet. This was effected by dividing up the slope with longitudinal roadways running east and west, and bisecting these by cross roadways which intersect them at right angles. Block A, as shown in the plan, is located at the eastern boundary end between the central longitudinal roadway, and the southern boundary of the Orchard. The tree positions in each row are numbered from left to right—as printing is ordinarily done on the pages of a book. The rows which run north to south up the slope are numbered consecutively in each block. In the blocks occupied by the collections of

varieties of different fruits, each individual label bears a complete history of the location, origin, and age of the tree to which it is attached. This label gives the specific orchard number allotted to that particular variety in the permanent record books in the office. This number is printed on the top left-hand corner. Next comes the alphabetical letter by which the block is known. In the same alignment, the number of the row in the block is stated, followed by a figure or figures indicating the tree's position in that row.

Below this line, the name of the kind of fruit is stated, and below that, the name of the variety. On the fourth line on the left-hand side, the name of the nursery of origin and on the right-hand side, the name of the State or country whence it came. On the bottom right-hand corner, the year when the tree was planted is given. A typical specimen label made of 24-gauge iron, and which measures 6in. x 4in. is shown herein. It has a dark-blue vitreous kiln enamelled surface on which the letters and figures are enamelled in white. The label is perforated with holes and may be hung on the tree or fastened to a stake, and without violence

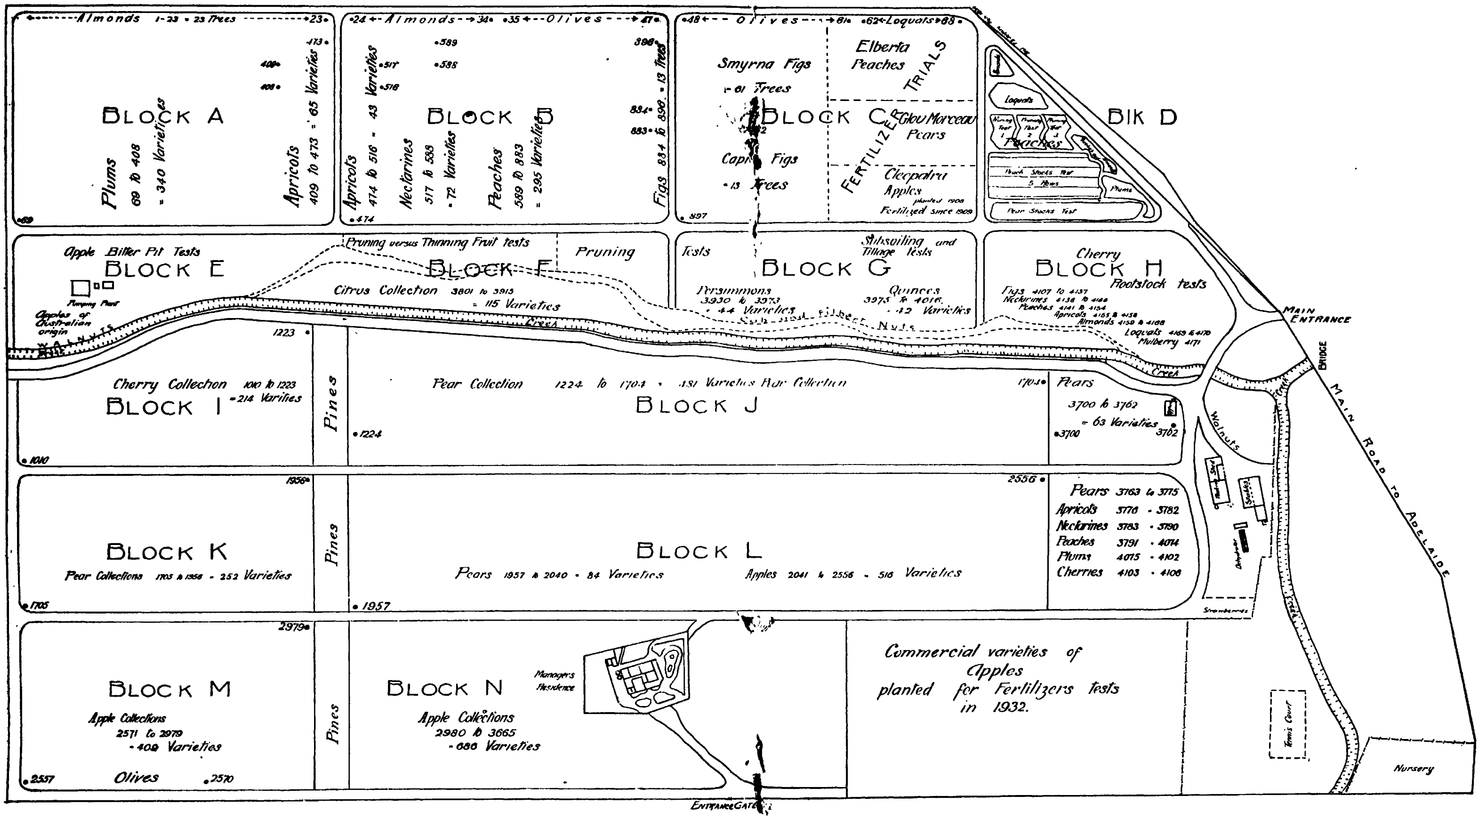
NECTARINE
COOZA
WICKS S. AUST.
/25

be applied to it, it is practically everlasting and decipherable throughout its lifetime. These labels are made locally and cost the Government 1s. 4d. each complete in Adelaide.

So simple and complete is this system, that there would be no difficulty on the part of anyone in replacing on its own respective tree, any one of the 4,000 odd labels, providing one knew the identity of the first block (A) in the Orchard.

The system of spacing the trees adopted in the Blackwood Orchard is known as the septuple, hexagonal, or equilateral triangular system. In this system, lines drawn to connect any three adjacent trees in two adjacent rows will form an equilateral triangle. As the perpendicular height of this triangle is only .866 of the length of any of its sides, it follows that the positions for the trees in parallel rows are farther apart than the distance between the rows themselves. The planting distance between the trees set out on the southern slope of the Blackwood Orchard is 20ft., and consequently, the distance between the parallel rows is 17.32—not quite 17ft. 4in.—wide. This distance and system was chosen in preference to the more popular 20ft. x 20ft. square system of spacing



COROMANDEL VALLEY GOVERNMENT ORCHARD

adopted in commercial orchards, because in planting collections of varieties it was desired to place a greater number of type trees over each acre of land. It must be realised, however, that compared with the 20ft. x 20ft. method, each tree, instead of being allowed an area of 400 square feet in which to spread its roots and tops, it has approximately only 346.4 square feet available.

During the winter of 1908, the blocks marked A, B, and C on the right-hand or southern slope were planted with the collections of varieties of plums, apricots, nectarines, peaches, figs, almonds, olives, and loquats, which had been propagated at the Hackney Road (Adelaide) nursery from scions mostly collected from the Mylor Type Orchard. When these collections of varieties were set out, the names of those of each kind of fruit were placed in alphabetical order. Their respective orders of blossoming or ripening of the fruit, or of the specific origin were not considered. For instance, in the plum collection, the so-called Japanese (*P. triflora* or its hybrids), and those of American origin were included in the general alphabetical lists of the more numerous purely European varieties (*Prunus domestica*).

Whilst affording a ready means of finding the location of any variety in the block, it was found that the work of recording blossoming or ripening periods or any other characteristics peculiar to the varying types or strains, was vastly increased by the method adopted.

In 1908, a plot of land in Block C was also selected for the establishment of a permanent Fertiliser Trial. It was planted with equal numbers of trees of the Cleopatra Apple, Glou Morceau Pear, and Elberta Peach, as representing at that time, the leading commercial varieties of those respective kinds of fruits. Barrier rows of trees of other varieties of the above fruits were planted alternately with the kinds and varieties quoted above. No manures or fertilisers were applied until the following year to the land occupied by these young trees.

THE OBJECTS OF THE ORCHARD.

At an earlier stage in this report it has been stated that the Government of the day had authorised the purchase of land for the establishment of an orchard in which to conduct experiments and demonstrations in various phases of fruit culture, and to grow under correct names and test the qualities of new varieties of fruits not common to the State. In this latter regard, it was at first desired that the work still being done by the Botanic Garden Board at the Mylor Type Orchard should not be duplicated at Blackwood. Subsequent events, however, showed that the then Director of the Botanic Gardens (Dr. Holtze) and his Board rather favoured the transfer of the whole of the collection of fruits grown at Mylor to the then newly established Departmental Orchard at Blackwood. This was partly due to financial reasons, and partly that they acknowledged that Fruit Culture matters generally, had now developed into the concern of a separate Government Department. It was subsequently indicated by Dr. Holtze that as an alternative the Board was not averse to the Mylor Fruit Plantations being taken over by the Horticultural Section of the Agricultural Department.

An exhaustive examination of the Mylor plantations and site, together with the records kept of the collections, was made by the writer, who, owing largely to the inferior nature of the soil and severity of the winter climate, added to the difficulty of access to the property, reported in favour of transferring the remaining collections of varieties of the kinds of fruits still retained there, to the Blackwood site. This proposal was accepted, and Dr. Holtze subsequently rendered all assistance necessary to enable

ERRATA.—The total 4,637 under the table of varieties on page 985 should read **4,237**, and 4,500 should read **4,100**.

the orchardist in charge at Blackwood (Mr. Savage) to procure from time to time scions of all of the kinds and varieties we had not already obtained from Mylor.

A nursery was established on the Blackwood property, and every kind of fruit was eventually propagated by Mr. Savage personally, on rootstocks procured from leading nurserymen in Victoria and South Australia, until he was transferred to the State Irrigated Orchard at Berri in 1917. As a similar procedure had been previously followed at the Adelaide (Hackney Road) nursery, we are in the position of knowing the specific origin of any rootstock on which any tree planted in the Orchard is worked —whether it belongs to the collections of varieties or is set out in any of the various trials. From time to time, additional varieties were obtained from various overseas Countries or States of the Commonwealth, and scions from these have been worked on rootstocks of local origin prior to to being planted in the Orchard. When the latest census was taken in 1927, the numbers of named varieties in the collections of the various kinds of fruits were as under:—

Almonds	46	Nectarines	80
Apples	1,624	Olives	34
Apricots	115	Peaches	362
Citrus	112	Pears	893
Cherries	218	Persimmons	43
Figs	137	Plums	379
Filbert and Cob Nuts	30	Quinces	42
Loquats	17	Walnuts	12
Grape Vines	93		

The latter are planted in the Adelaide Orchard, making a total of 4,637 varieties. Allowing for synonyms, there are now approximately 4,500 distinct varieties in the Orchard.

Since the above date, a few varieties, chiefly of peaches and cherries, have died, but their numbers have been more than covered by later acquisitions of new varieties of other kinds of fruits.

As far as the writer is aware, such a huge collection of varieties of so many kinds of tree fruits is not to be found growing in one plantation in any other country in the world. The collections occupy approximately 37 acres of land in Blocks A, B, parts of C, E, F, G, H, on the southern slope, and in I, J, K, L, M, N, on the northern slope as indicated in the plan herewith. Descriptive records have been made from the fruits of practically all of the varieties, and data relative to the flowering and fruit ripening periods of each one placed on permanent record. These latter data mostly extend over periods of 10 years, and upwards. The qualities of the fruits as detected at Blackwood have been duly noted, as has the comparative resistances also of the trees of most kinds to the attacks of certain common pests and diseases.

A great many tests have been made in respect to the cold storing qualities of large numbers of varieties of apples and pears growing in these collections, as well as into the drying and canning qualities of many sorts of plums, prunes, apricots, and peaches. This is a phase of the Orchard's activities in which much yet remains to be done, more particularly in relation to the many varieties of pears and apples which show much promise.

EXPERIMENTAL TESTS AND DEMONSTRATIONS.

Based on the cultural practices in vogue, and a knowledge of the problems usually discussed by fruitgrowers in this State at the time the Blackwood Orchard was established, the writer compiled the following plan of permanent experimental and demonstration work to be undertaken in respect thereto.

Rootstocks.

Their comparative *compatibilities* and influences in relation to *fruit cropping* and *tree development* in respect to:—

Cherry trees—embodying 5 varieties; 3 trees of each worked on 4 rootstocks and/or stem combinations.

Pear trees—4 varieties; 3 trees of each on 2 rootstocks.

Peach trees—4 varieties; 2 trees of each on 6 rootstocks.

Rootstocks and/or Intervening Stem Pieces.—Their influence, if any, *on the prevalence of "Bitter Pit" in the fruits,* comprising 4 susceptible varieties of apples, each worked on 3 different rootstocks, and 5 different intervening stem pieces.

Pruning Trials—Influence on Tree Development and Fruit Production.

A. *Peach Trees.*—4 varieties, 2 trees of each.
  (1) Pruned in winter only.
  (2) Pruned in winter and summer.
  (3) Pruned in summer only.

B. *Intermittent* (*Biennial*) V. *Annual Pruning* (on spur fruiting kinds of trees).—

Cherry trees	4 varieties, 1 tree of each
Plum trees	4 varieties, 1 tree of each
Apple trees	4 varieties, 1 tree of each
Pear trees	4 varieties, 1 tree of each

C. *Pruning and Thinning Fruit* V. *Pruning Only.*—Apple trees—4 varieties, 2 trees of each under each treatment.

D. *No Pruning—Fruit Thinned* V. *No Pruning—Fruit Not Thinned.*—Apple trees—4 varieties, 2 trees of each under each treatment.

Tillage—Preparatory and Subsequent to Planting—Influence on Tree Development and Fruit Production.

(*a*) *Subsoiling* V.	(*b*) *No Subsoiling.*
Apple trees, 2 varieties, 1 tree of each	Apple trees, 2 varieties, 1 tree of each
Pear trees, 2 varieties, 1 tree of each	Pear trees, 2 varieties, 1 tree of each
Plum trees, 2 varieties, 1 tree of each	Plum trees, 2 varieties, 1 tree of each
Peach trees, 2 varieties, 1 tree of each	Peach trees, 2 varieties, 1 tree of each
Apricot trees, 2 varieties, 1 tree of each	Apricot trees, 2 varieties, 1 tree of each

Both (*a*) and (*b*) plots were ploughed every year in autumn and again in spring, and scarified several times during the summer.

(*c*) *Subsoiling.*—

Apple trees	2 varieties, 1 tree each
Pear trees	2 varieties, 1 tree each
Plum trees	2 varieties, 1 tree each
Peach trees	2 varieties, 1 tree each
Apricot trees	2 varieties, 1 tree each

This plot was ploughed every year in spring only, and scarified several times during the summer similarly to (*a*) and (*b*) plots.

Fertilisers—Influence in relation to Shoot Growth, Stem Enlargement, Fruit Production and Quality, and presence of "Bitter Pit" in the fruit of apples.

Trials with 10 fertilisers and/or combinations in comparison with unmanured check trees:—

Apple trees (Cleopatra), 3 trees in each trial.
Pear trees (Glou Morceau), 3 trees in each trial.
Peach trees (Elberta), 3 trees in each trial.

In the light of the developments which have taken place in the technique applied to planning horticultural experiments and research work in respect to fruit trees, particularly in Great Britain during the past 10 to 15 years, the above programme must appear not only very ambitious, but in many respects unsound. This would appear to be more particularly so, in so far as the reliability is concerned, of the results obtainable from any attempt at making a quantitative analysis of the data collected.

The writer believes, however, that there are features presented in the varying behaviours of the trees in many of these trial plots during the quarter of century which has elapsed since most of them were first submitted to the various treatments, that may perhaps, be deemed to possess some slight interest and value in a qualitative sense to fruit growers working under similar conditions of soil and climate in South Australia.

In presenting his subsequent statements and comments on these trials, he would ask those who may have been privileged to have been trained in modern methods of horticultural research, to try to visualise the position which existed in that field of work at the time these trials were instituted. They will, it is confidently assumed, be prepared to admit that it has been largely out of the faulty and often negative results of the work of earlier experimenters that the evolution of more accurate methods has been hastened and the achievement of more definite results has been stimulated.

It is fully recognised that in so far as planning and carrying into effect any such long distance experiments and research work in this orchard in the future is concerned, these recently developed forms of procedure must be adopted. Briefly stated, any such experiments will necessarily be composed of trees in each of which the chief component factors—rootstocks and scions—shall be as uniform as parentage and propagational methods can determine. There shall not only be a considerably greater number of such trees used in each comparative test, but they must also be distributed in numerous replications throughout the area devoted to the trial.

Apart from the above programme of comparatively permanent work, problems of a seasonal character such as the methods of preventing the ravages of fungoid and insect pests from which fruit trees suffer, have occupied a considerable degree of attention from those in charge of the orchard.

The effects of the application of many spraying and dusting compounds when used in accurate proportions and at definite periods, as well as the use of various insect traps and bandages, have each been the object of specially designed trials.

The introduction, breeding, and distribution of the minute parasitic wasp (*Aphelinus mali*)—of which the American Woolly Aphis of the apple tree is the principal host—has been a signal success, and gratifying results have been achieved from its assistance by numerous apple growers located in the cooler districts of the State to whom it has been distributed. The results of all of these trials have been carefully recorded and published in the Departmental *Journal of Agriculture* and in bulletin form from time to time.

(*To be continued.*)

NITROGENOUS FERTILISER EXPERIMENTS WITH BARLEY AND OATS IN SOUTH AUSTRALIA.

[By R. C. Scott, R.D.A., Supervisor of Experimental Work.]

During the past season (1934-5) a series of experiments dealing with the value of sulphate of ammonia was carried out in South Australia in co-operation with Nitrogen Fertilisers, Ltd.

The object of the experiment was to endeavour to determine the effect of this fertiliser when, in addition to a basal dressing of superphosphate, varying quantities were drilled in with crops of barley and oats seeded on non-fallowed land.

The work was confined to the better rainfall districts since previous experience has shown that in areas where rainfall is the limiting factor, and ripening conditions for cereal crops relatively severe, full benefit from applications of nitrogenous fertilisers cannot be anticipated.

Further, only non-fallowed ground was utilised as, by work at both the Waite Research Institute and the State Experimental Farms, it has been clearly indicated that crops sown on well worked bare fallow do not appreciably respond to nitrogenous fertilisers. Consequently, if sulphate of ammonia is to be of any importance to South Australian farmers it must be as a manure for stubble-sown crops of which barley and oats are typical in this State, whilst finally it must be pointed out that a nitrogenous fertiliser can in no way replace superphosphate, but must be used as an addition to that manure.

Plots were established at 11 centres extending from the South-East of the State, South of Adelaide, and the Lower North to Yorke Peninsula and Kangaroo Island. Barley was seeded in eight instances, and oats in four, both cereals being planted in the plots situated at Gawler River.

The basic dressing was 1cwt. of 45 grade superphosphate, and in five series the nitrogenous manure added comprised ½cwt., 1cwt., and 2cwt. applications of sulphate of ammonia. However, in all other cases only the two first-named quantities, namely, the ½cwt. and 1cwt. dressings were applied in addition to the phosphatic fertiliser. In all plots the experiment was fully replicated so as to eliminate any errors that may have occurred because of soil variation. The results obtained are shown in the following table:—

EXPERIMENTS WITH SULPHATE OF AMMONIA, 1934-35.

Experimental Farm, Kybybolite .	7.7	7.9	9.0	—

In connection with the above returns, it should be kept clearly in mind that they are the results obtained in a single season, and therefore must be confirmed before any definite conclusions can be drawn.

Moreover, they were secured in a season in which the weather was far from normal, being severe on slow-developing plants in the early stages, and favourable for full maturity of bulky crops in the later stages. However, the results obtained appear to indicate that, under special circumstances, sulphate of ammonia is of value in the cultivation of stubble sown cereal crops, but, on the other hand, unless these special conditions obtain, its use is not economic.

The particular circumstances mentioned appear to be connected with the previous history of the field to be seeded and the character of the plants or herbage which it has carried.

Where the land normally produces strong growing leguminous pasture plants or has recently carried a good leguminous crop, the response of stubble-sown cereals to sulphate of ammonia applications is not appreciable, but in the case of land on which leguminous plants have not been abundant the effect of this fertiliser is much more marked.

The experimental fields at Hawk's Nest, Wisanger, and Gawler River may be included in the latter class, and the mean barley yield from the plots at these three centres is as follows:—

	Bush. Per Acre.
1cwt. superphosphate	22.6
1cwt. superphosphate, ½cwt. sulphate ammonia	32.7
1cwt. superphosphate, 1cwt. sulphate ammonia	39.6

It will be seen from these returns that considerably higher yields followed the sulphate of ammonia applications, and that such increases were distinctly profitable. On the other hand, if the returns from the remaining five centres, where the land on which the experimental plots were placed normally carries a strong leguminous pasture, are examined, the average return is:—

	Bush. Per Acre.
1cwt. superphosphate	32.3
1cwt. superphosphate, ½cwt. sulphate ammonia	35.7
1cwt. superphosphate, 1cwt. sulphate ammonia	36.9

In this case the cash value of the increased yield following the sulphate of ammonia dressing is just above the price of the fertiliser when ½cwt. is applied, and insufficient to meet the cost of the manure when 1cwt. is added.

The same position occurs with the oaten plots, and when the yields from those at Gawler River are excluded the mean returns for the remainder are 11.1bush. for 1cwt. superphosphate, 12.2bush. for 1cwt. superphosphate plus ½cwt. sulphate of ammonia, and 13.8bush. for 1cwt. superphosphate plus 1cwt. of sulphate of ammonia. The differences, therefore, are not appreciable, whereas at Gawler River the yields were very materially increased by sulphate of ammonia dressings.

From the foregoing returns it is evident that the influence of this fertiliser varies considerably from centre to centre. Consequently, the experiment must be continued and further information gained before any conclusions can be arrived at or recommendations made.

IMPORTANT WEEDS OF SOUTH AUSTRALIA.

[By G. H. CLARKE, B.Sc., Botanist at the Roseworthy Agricultural College.]

No. 11.—HOARY CRESS.

Lepidium Draba, L.

Hoary Cress, known also as "White Weed," and sometimes as "Chalk Weed" on account of a supposed preference for calcareous or chalky soils, has already been described in the pages of this *Journal*. In the issue of June, 1933, there appeared a brief but excellent account by Mr. W. C. Johnston, District Agricultural Instructor for the Lower North.* A more comprehensive account by A. Morgan, B.Agr.Sc., Weeds Research Officer of the Victorian Department of Agriculture, is to be found in the *Journal of Agriculture* of Victoria for August, 1931, October, 1931, and, more recently, January, 1934. An extensive series of observations and experiments carried out over a period of several years at the State Research Farm at Werribee, Victoria, has enabled the last-named writer to supply much useful information as to the habits of the plant and valuable data bearing upon its control and eradication, and the interested reader is referred to Morgan's papers for a full discussion of the problems involved. The following notes aim to stress the importance of early recognition in the case of this most important weed, and to make available to South Australian farmers, in a summarised form, the main conclusions reached by Morgan as a result of his experience at Werribee.

The name "Hoary Cress" is on account of the slight hoariness or whitish appearance of the foliage, due to a covering of very fine hairs. The plant is an introduced Cruciferous weed, native originally to Europe, whence it has spread to Western Asia, and, in fact, to most temperate countries of the world. On account of its deep-rooted and perennial habit, it is rightly considered to be one of the most serious weed pests of arable land, and in view of its very wide distribution in this as well as in other States of the Commonwealth, its early recognition and control are matters of unusually great importance to the farming community of South Australia. It is especially troublesome in wheat lands, from which its eradication is extremely difficult, and though the older plants are easily recognisable when in flower, it has been found that flowers are not formed until the second year of growth, by which time the root system is sufficiently well developed to present difficulties in eradication. This means that very often the presence of the weed is noticed only after it has become firmly established in the new situation.

The individuals vary somewhat in appearance at different stages of their growth and development. Young plants, and especially those growing on summer fallows, usually have a "rosette" form, consisting of one or more circlets of leaves, which arise close to the ground from a stem which is very short and inconspicuous. These rosette or radical leaves are of a different shape from those subsequently formed on the stems, and are continuous at the base with a slender leaf-stalk or petiole, which is absent from the stem leaves. The rosette plants are usually to be found connected with neighbouring plants by means of horizontal roots of considerable length, from which they arise mostly as buds. Towards the flowering period the older plants develop an erect stem, which grows to a height of about 18in., and bears leaves alternately at the nodes. The stem leaves are about 3in. long, and an inch or more broad, oblong-lanceolate or oblong-ovate in shape, with irregularly serrated edges and wavy margins. They differ from the rosette or radical leaves in being devoid of a stalk, and in being provided at the base with a

*See also E. W. Pritchard, *S.A. Journal of Agric.*, July, 1928.

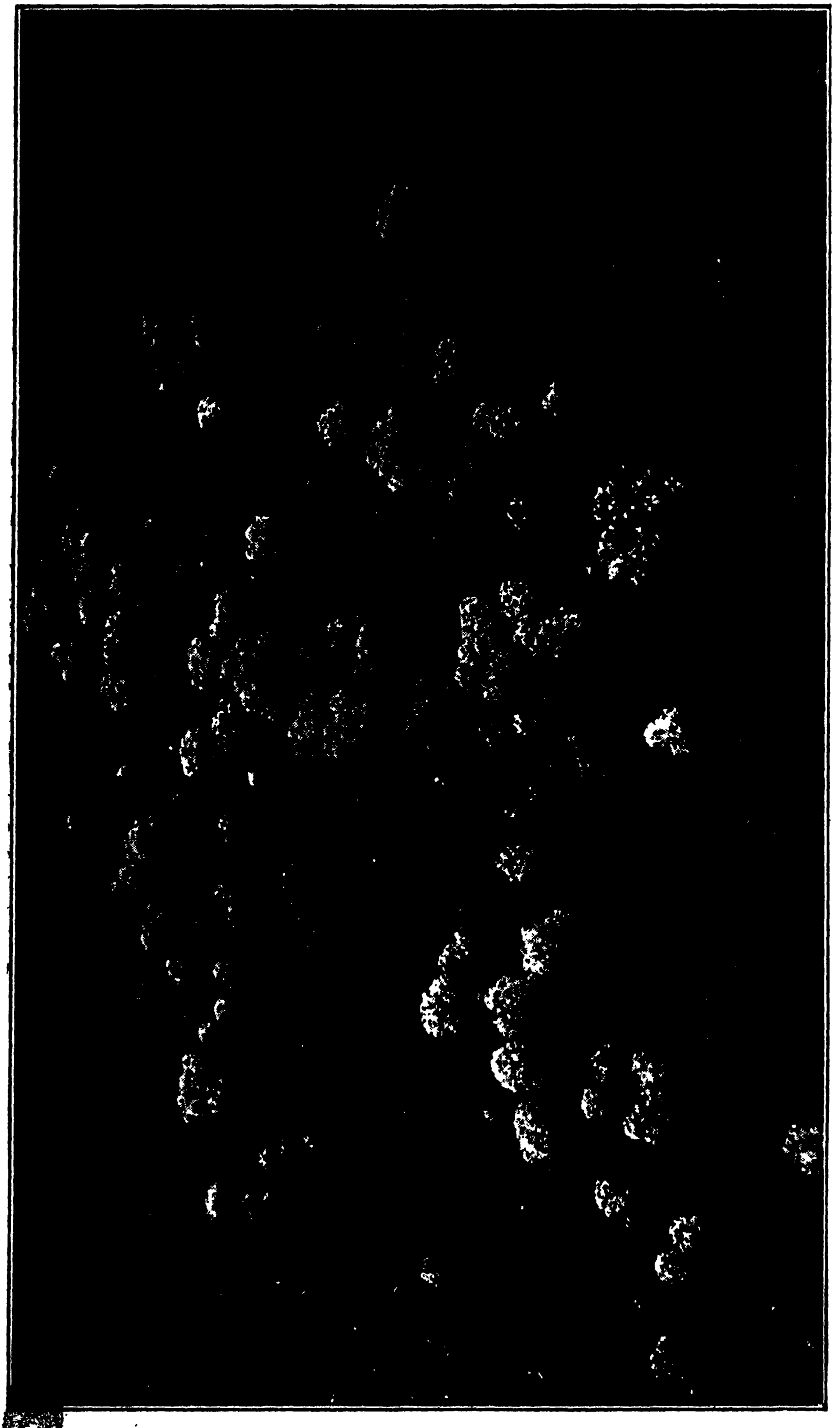
pair of auricles which clasp the stem at the node. Branches arise in the upper leaf-axils, and these in turn branch again and again to form the characteristic flat-topped inflorescence of small crowded white flowers.

Botanical Name and Classification.—*Lepidium,* from the Greek *lepis* "a scale," is said to be in allusion to the scale-like form of the pod in many species of the genus; the species name is probably based upon some resemblance to *Draba,* another genus of *Cruciferae.* The derivation of this name (Greek *drabe* meaning "pungent" or "acrid") expresses a character which is extremely common in *Cruciferae,* but by no means confined to either *Lepidium* or *Draba,* namely, the presence of pungent or sharp-tasting substances in the plants, *e.g.,* mustard, radish, etc.

The family *Cruciferae,* to which these plants belong, forms a very natural and well-defined assemblage of about 2,000 species contained within more than 200 genera, and among which are many plants of economic value as vegetables, *e.g.,* cabbage, cauliflower, kohl-rabi, Brussels sprout, turnip, swede, radish, etc.; or as condiments, *e.g.,* mustard; while a host of others have a negative importance as weeds, *e.g.,* Charlock, Wild Mustard, Wild Turnip, Hoary Cress, etc. A very common Cruciferous character is the flat-topped or corymbose inflorescence of small flowers, which are most often white or yellow in colour. This inflorescence usually becomes racemose or cylindrical as the fruits mature, due to lengthening of the stem or main axis. The individual flowers are very uniform in structure, and the cross-like arrangement of the normally four flower petals gives to the family its name (Latin *crux, crucis,* "a cross", and *fero,* "I bear"). The Cruciferous flower is regarded by most authorities as having been derived from a structure consisting of an axis bearing six superimposed whorls of parts arranged alternately at right angles, each whorl consisting of two segments, *viz.,* two whorls of sepals, one of petals, two of stamens, and one of carpels. The actual occurrence of four segments in certain whorls, as for example, in the petaline and inner staminal whorls, is supposed to have resulted from the splitting or branching into two of originally single primordia. Thus the typical Cruciferous flower consists of an axis bearing two whorls each of two sepals, a single whorl of four petals diagonally arranged, an outer whorl of two stamens laterally placed, an inner whorl of four stamens, which are longer and situated in pairs close to the median plane, and a single whorl of two united and superior carpels (see floral diagram on the accompanying plate). The fruit is a pod of varying length, usually divided laterally into two compartments by a membranous partition or septum. This septum often remains attached to the stalk at maturity after the lateral walls have fallen away and set free the seeds. In a few cases, *e.g.,* in the radish (*Raphanus spp.*) the pod undergoes transverse segmentation, and in some, *e.g.,* Hoary Cress, it is indehiscent. The pod of *Cruciferae* is termed a *siliqua* when its length exceeds its breadth, and a *silicula* or *silicule* when it is broader than long.

While the characters of the family itself are very sharply defined, the separation of the *Cruciferae* into genera is a matter of considerable difficulty. The presence of short flattened scale-like siliculae with the valves or sidewalls folded and keeled at right angles to the median septum, and with only a single seed in each lateral compartment, is characteristic of two genera of *Cruciferae,* namely, *Lepidium* and *Iberis* (garden Candytuft). *Lepidium* is distinguished from species of Candytuft by its smaller flowers, and by having the petals, when present, equally developed, whereas in *Iberis* the two outer or anterior petals of the flower are larger than the two inner or posterior ones.

Lepidium comprises about 100 species, spread over the temperate and warmer parts of the globe, but not present in alpine regions. Species of the genus are often referred to as "Pepperwort" or "Cress," the latter name being due to the Asiatic species *L. sativum,* L., which is the garden Cress. The name "Cress" is



Hoary Cress growing in pasture.

applied also to certain other Cruciferous plants, *e.g.*, Swine Cress (*Coronopus spp.*) and Water Cress (*Nasturtium officinale*, R. Br.). It may be mentioned in passing that the last-named has no connection with the so-called garden "Nasturtium" (*Tropaeolum majus* L.), which belongs to an entirely different family. The genus *Lepidium* is well represented in Australia, and in this State, where there are some 12 native species, in addition to the introduced *L. Draba.*

Hoary Cress is to be distinguished from other Lepidiums, firstly, by the inverted heart-shaped pods, which are not winged or notched at the summit, and are borne on pedicels much longer than the pods themselves; secondly, by the broad and auriculate stem-clasping leaves; and, thirdly, by the great depth and extensiveness of the root system.

Botanical Description.—An erect hoary perennial with rigid stems; leaves oblong-lanceolate or oblong-ovate, sinuate-toothed, 2 to 4in. long, 1in. or more broad, the radical ones petiolate, the cauline ones sessile and clasping the stem with acute auricles; flowers numerous, small, in a terminal corymbose panicle; petals white, twice as long as the sepals, each with a slender claw; stamens 6; fruiting pedicels 2 to 3 times as long as the pod, which is cordate, neither winged nor notched, indehiscent, and surmounted by the prominent style. Period of flowering:—August to December.

Properties.—Hoary Cress is almost entirely useless, and though stock may eat it to some slight extent, any value it may have in this regard is more than offset by the very severe competition to which it subjects more valuable plants, with consequent reductions in yield from both crops and pasture. Considered as a weed, the plant exhibits three formidable characters—it spreads rapidly, establishes itself quickly in the soil, and when once established is extremely difficult to get rid off. It forms large numbers of small fruits, which are easily transported to new situations, and it spreads locally by the formation of new shoots which arise as buds from the more superficial parts of the root system. The difficulty of eradication is mainly due to the great development and vigour of the underground parts. The roots contain large reserves of food, and even small detached fragments are capable of forming new aerial plants, so that occasional cultivation merely spreads and stimulates the growth of the weed. The main roots extend downwards in the soil to a depth of 6ft. of more, producing, at some distance below the ground level, lateral branches, which also penetrate deeply, and, at a higher level, horizontal branches which extend laterally below the surface and may form new plants before turning finally downwards into the deeper parts of the soil.

Control and Eradication.—Under dry farming conditions the advantage in competition lies with Hoary Cress unless its vigour has been reduced by previous cultivations sufficiently to give the crop an advantage which can be successfully maintained; and in the case of large infested areas, where considerations of cost preclude any systematic attempts at eradication, and where the land is required for cropping purposes, the application of measures designed to this end is about as much as can be done, though eradication is not achieved thereby, nor indeed is there any lasting impairment of the vigour of the weed. In irrigated areas, however, the advantage in competition can be maintained, as Morgan points out, by lucerne or permanent pasture, given adequate watering and manuring and proper grazing management. Under such conditions Hoary Cress is forced "under cover," and can be effectively controlled, though here again there is no actual eradication, subsequent ploughing up of the ground being followed by a luxuriant growth of the weed.

In the case of small areas of infestation eradication is possible, and is worth while, though the operations may be both laborious and costly. Omitting plant competition, which has already been mentioned, Morgan discusses the methods of control under four headings, namely, cultivation, salting, carbon bisulphide, and chemical sprays.

As regards cultivation, he recommends persistent cultivation at regular fortnightly intervals for a period of not less than two years. In the experiments conducted at Werribee complete eradication was effected by this method, shallow cultivations being made, using a weed knife attached to the cultivator. In the case of small patches the use of the hoe is recommended.

The value of salt as a weedicide is dependent upon the type of soil in which deep-rooted perennial weeds are growing, and, in such cases, is not of much use unless the subsoil is sufficiently permeable to allow of penetration of the salt in

Mature plant of Hoary Cress.

lethal amounts to a depth of at least 2ft. Given the required conditions of subsoil permeability, however, salt is stated to be an effective means of eradicating Hoary Cress, the amount required varying, according to the density of the infestation, from 5 tons to the acre upwards. A disadvantage of using salt is the residual effect it leaves upon the soil, but this, however, is not necessarily permanent.

Carbon bisulphide is very useful in situations where the soil is both porous and dry, though the cost is too great to allow of its being employed on a large scale. Quantities of from 1½ozs. to 2ozs. of the liquid are introduced into holes specially bored in the ground to a depth of 18in., and situated about 2ft. apart, the holes being then sealed up so as to allow the vapour to diffuse into the soil air in

sufficient concentration to kill the roots of the weed. This method is said to be extremely valuable in the case of small patches, given the required conditions of soil porosity and dryness.

As regards chemical sprays, the most important are the *chlorates,* especially sodium chlorate, and *arsenical* compounds, such as arsenic pentoxide and acid sodium arsenite. The chlorates have the advantage of being non-poisonous to stock, excepting in large amounts, but they are liable to cause clothing, &c., to ignite spontaneously when it becomes dry after being wetted with the spray solution. Though sodium chlorate has been used with success in this State, the experiments conducted by Morgan at Werribee tend to show that the chlorates are inferior to arsenical sprays as eradicants of Hoary Cress. From the reports of other workers referred to by Morgan, it seems likely that it may be possible to raise the efficiency of chlorate sprays by adding certain other materials. As with salt, the soil is adversely affected by the application of chlorates, but not for so long a period.

As regards the arsenical compounds, a 6 per cent. solution of arsenic pentoxide, applied as a misty spray under a pressure of 100lbs. to the square inch, and at a rate of 120galls. per acre, was originally recommended by Morgan. In a more recent paper, however, he advises the use of an acid sodium arsenite spray as being much cheaper and equally effective. A stock solution is made by mixing 4lbs. of white arsenic and 1lb. of caustic soda in 2½ pints of water, stirring until dissolved, the spray solution being prepared by making up 1 part of stock solution in 100 of water, and adding slowly, and with constant stirring, 5 parts of sulphuric acid.

To ensure success, it is necessary to kill all the roots to a depth in the soil sufficient to prevent their forming new shoots capable of reaching the surface. Experiments carried out by Morgan in order to determine the critical depth of root-kill showed that, under favourable conditions, the root system was killed to a depth of 2ft. or more, but that the depth of penetration varied considerably, and was influenced by a number of factors. It was found that the conditions most favourable to "remote penetration" by the spray are those producing a high rate of transpiration, namely, high temperatures, low atmospheric humidity, and decrease in soil moisture. On the other hand, such conditions favour the evaporation of the spray fluid, thus hindering its absorption by the plants, a difficulty which can be overcome, however, by spraying late in the day or by re-spraying with water the following morning. Thus Morgan concludes that—

> ". . . . the absorption and translocation of the arsenical spray within the root system of the plant is directly due to the establishment within the vascular system of the plant of a 'water deficit' or 'sub-atmospheric pressure' as a result of the excess of water lost through transpiration over that absorbed from the soil."

The arsenical spray kills the surface cell layers of the plant, and also renders them permeable. The arsenical solution becomes mixed with the sap and enters the conducting vessels, its downward passage to the roots being facilitated by the negative pressure in these vessels. Accordingly, the essentials for the successful use of arsenical sprays are summarised by Morgan as follows:—

(*a*) Apply in hot, dry weather, when the transpiration rate is high, and late in the day in order to obviate poor absorption, due to evaporation of the spray fluid. If necessary, re-spray lightly with water the morning following spraying.

(b) Apply to plants whose root systems have not been disturbed by cultivation for some considerable time, otherwise root fragments in the soil devoid of top growth will not receive any weedicide.

(c) Apply to well-grown plants whose leaf and stem surface is sufficient to hold a reasonable amount of the spray fluid during the time required for absorption. This ensures the absorption of the poison in sufficient quantities; also, since the reserves of food in the roots are probably lowest at this time, plants sprayed at this stage doubtless have less chance of recovery.

(d) Apply only to plants under dry-farming conditions, since the water deficit of plants growing in moist situations is rarely large enough to ensure good absorption and penetration of the weedicide.

INSECTS OBSERVED ON CROPS IN SOUTH AUSTRALIA DURING PERIOD JUNE, 1932, TO JUNE, 1934 (1).

[By J. DAVIDSON, D.Sc. (Waite Agricultural Research Institute, University of Adelaide).]

The incidence of insect pests is closely associated with meteorological events. In South Australia, with its characteristic winter rainfall and summer dryness, rainfall is the dominating factor. In Figs. 1 and 2, monthly rainfall and temperature data for the two years under review are shown graphically for eight selected stations in the State. The stations have been chosen, as far as practicable, so as to embrace the more important agricultural centres. The total monthly precipitation at each selected station is shown as being above or below the average rainfall for the month at the station; the latter averages are based on records extending over a long series of years. The temperature line shows the average daily temperature for the month $(\frac{\text{max.} + \text{min.}}{2})$; the departures from the mean temperature for the month, based on a long series of records, are too small to allow of their being illustrated by the hatching method adopted in the case of rainfall.

It is more suitable to retain the normal full year for presentation of the meteorological data, although the insect records are more conveniently closed at the end of June.

I am indebted to Mr. H. Womersley and Mr. A. L. Tonnoir for considerable assistance in the identification of specimens; also to officers of the Department of Agriculture who have so kindly co-operated with me in obtaining records.

1. CEREAL CROPS.

No particular observations to record.

2. PASTURE AND FORAGE CROPS.

The scarab beetle (*Aphodius tasmaniae* Hope) has developed into an important pest in certain districts of the South-East. The beetles normally make flights in swarms about February, and eggs are laid in the soil in favourable situations. The grubs (larvae) become active with the onset of the autumn rains. They make vertical burrows in the soil 6-8in. deep, from which they emerge at night and eat clover and grass seedlings; the soil from the burrows is scattered over the infested area, which assists in smothering the damaged seedlings: this results in bare patches developing in the pastures (D. C. Swan, *Journ. Agric. S. Aust.* 37, 1149-1156, 1934).

The wandering grasshopper (*Chortoicetes terminifera* Walk. = *Calataria terminifera* Walk.) occurred in plague numbers during 1933 and 1934. The swarms of winged grasshoppers originally spread from northern areas of the State. It appears that the pastoral country about the 10in. annual isohyet may be considered as the main region permanently inhabited by the species. In years which favour its multiplication in mass numbers, the winged forms migrate southwards over the agricultural districts. This occurred in the summer and autumn of 1933-1934, and eggs were laid freely in the infested northern agricultural areas. Hoppers hatched freely from these eggs in the spring of 1934, and the infestation

[1] Third series of records. For the second series, see this *Journal*, vol. 36, pp. 283-286, 1932.

became widespread over the northern and mid-northern agricultural districts during the summer of 1934-1935. Considerable damage was caused in pasture areas and wheat crops in some districts.

The Government of South Australia passed the "Noxious Insects Act, 1934," and regulations under this Act defined the responsibilities of occupiers of land and district councils with regard to control measures. This ensured an efficient co-ordination of control measures throughout the State. A general account of the control measures adopted in similar campaigns is given by J. Davidson (*Journ. Agric. S. Aust.* 37, 619-624, 1934).

Experience of previous grasshopper infestations in this State shows that the invasion of the agricultural areas is temporary, and the insects normally disappear after one or two seasons. It is possible that the species may occur permanently in small numbers, more or less solitary, in suitable local areas in the agricultural districts. A survey is being made by the Waite Agricultural Research Institute in co-operation with the Department of Agriculture and the Pastoral Board, in order to define the areas in the State where the species is permanently established. A study is being made also of the causes which result in plague infestations in particular years.

The lucerne flea (*Smynthurus viridis* L.) did not occur in widespread infestation numbers during 1934; this was associated with low rainfall during the early winter months. Control measures under South Australian conditions are discussed by J. Davidson (*Journ. Agric. S. Aust.* 36, 994-1006, 1933; and Bull. 286, Dept. Agric. S. Aust., 1933). This species is a serious pest of clover and lucerne pastures in the winter rainfall areas of Australia (see J. Davidson, *C.S.I.R. Aust.*, Bull. 79, 1934).

The Bdellid snout mite (*Biscirus lapidarius* Kramer), a predator of the lucerne flea, was placed in certain experimental pasture areas in South Australia during July and August, 1933 (see G. H. Currie, *Journ. C.S.I.R. Aust.* 7, 9-20, 1934); a few individuals were found in two centres the following winter, but the colonies have not made progress in these situations. It is possible that owing to the low rainfall in the early winter of 1934, the conditions were too dry; from its known distribution in Western Australia and Tasmania, the species appears to be best suited to cooler, wet situations.

An allied species (*B. intermedius* Sig. Thor.) has been found in several districts in the better rainfall areas of the State. A preliminary account of the snout mites (Bdellidae) in Australia is given by H. Womersley (*Trans. Roy. Soc. S. Aust.* 57, 97-107, 1933).

The hay-itch mite (*Pediculoides ventricosus* Newport) which appears to be associated with a skin irritation occurring from time to time amongst agricultural workers handling hay and chaff, has been isolated from haystacks and chaff in certain districts. An account of investigations made on the species is given by D. C. Swan (*Journ. Agric. S. Aust.* 37, 1289-1299, 1934; and *Med. Journ. Aust.* 2 (21st yr.), 573-578, 1934).

3. FIELD AND MARKET GARDEN CROPS.

The red-legged earth mite (*Halotydeus destructor* Tucker) is extending its range as a pest in South Australia. It favours particularly weedy situations from which it invades seedlings of various market garden crops; in south-western districts south of Adelaide, it is becoming more widely established as a pest of seedling vegetables in gardens. Up to the present it is not a pest of clover pastures, which appears to be the case in Western Australia. Damage was caused in tomato

glasshouses on sandy soils on the Adelaide Plains, by the mites feeding on seedling tomato plants; the mites invade the houses from adjacent weedy ground, at night or on dull days. The present position regarding this species is discussed by D. C. Swan (*Journ. Agric. S. Aust.* 38, 353-367, 1934). The blue oat mite (*Penthaleus major* Dugés) occurs commonly in the same situations as *H. destructor*; its habits are similar, but it appears to favour grasses. This species was originally described by Froggatt as *P. bicolor*. It has been established recently by H. Womersley that the species agrees with the European *P. major* (see D. S. Swan, *Journ. Agric. S. Aust.* 38, 365, 1934).

The potato moth (*Phthorimaea operculella* Zeller) was particularly in evidence in potato crops in the field during 1934; this is associated with the unusual dry conditions. The larvae mine freely in the leaves and haulm, and the plants become black and withered, resulting in decreased yield. Clouds of moths were observed in a potato crop in the Mount Barker district in autumn, 1934. In the dry soil the tubers become readily infested with the caterpillars; special precautions are desirable in order to ensure that the tubers are well drilled.

The lucerne flea (*Smynthurus viridis* L.) destroyed four acres of seedling mangolds near Noarlunga in October, 1932; two sowings of the crop were destroyed.

The Rutherglen bug (*Nysius vinitor* Berg) was troublesome on potatoes in the Adelaide hills district in December, 1932.

The gladiolus thrips (*Taeniothrips gladioli* Moulton and Steinweden 1931) is developing as a serious pest of gladioli; it has been observed in several gardens in the Adelaide district. The thrips may be present in the corms before planting; they congregate particularly in the leaf sheaths of the growing plant, and scarify the surface of the developing leaves. The latter present a bleached and mottled appearance in the summer, and the blooms may be weak and distorted. I am informed by Miss H. V. Steele, who has been making a study of thrips, that this species is the same as *Physothrips simplex* Morison 1930, so the latter name will have priority. Miss Steele's observations on this matter will be published shortly.

4. FRUIT CROPS AND VINES.

The apple blossom thrips (*Thrips imaginis* Bagnall) was present in smaller numbers during the spring of 1932 compared with 1931, and infestation of apple blossom was unimportant. The general fluctuations in the numbers of this insect are closely correlated with weather factors. The numbers are small during midsummer months owing to dryness; there is a rise in numbers in autumn (autumn rise) which falls with the onset of the winter months; there is an increase in the early spring (first spring rise), which is followed by a later increase (second spring rise); there may be subsequent increases in numbers due to development of later generations. If the spring weather is favourable and the first spring rise occurs early (August or early September), a large second spring rise may develop in October at the time when the apple is in blossom. With favourable weather, this may result in a heavy infestation of the blossom. Owing to the cold, wet conditions in October, 1932, the peak numbers did not develop until early December. Observations on the factors affecting the seasonal fluctuations of this species in South Australia are discussed by J. W. Evans (*Journ. C.S.I.R. Aust.* 6, 145-159, 1933; and 7, 61-69, 1934). Some observations on derris and pyrethrum dusts used in experiments on the control of this species are given by H. W. Wheeler (*Journ. C.S.I.R. Aust.* 7, 70-72, 1934).

The present position regarding the investigations on this species is described by J. Davidson (*Fruit World of Australasia,* Melbourne, 35, 667-669, 1934).

The following species of blossom-inhabiting thrips commonly occur in South Australia in association with *Thrips imaginis* in flowers and fruit blossom:—The

onion thrips (*Thrips tabaci* Lind); the Eucalyptus thrips *Isoneurothrips australis* Bagnall); *Haplothrips victoriensis* Bagnall. *Taeniothrips* (*Physothrips*) *kellyanus* Bagnall has been taken in the blossom of lemon trees.

The pear and cherry slug (*Caliroa limacina* Retz = *cerasi* Linn.) appears to be generally distributed throughout the fruit-growing areas of the lower South-East of the State. It also occurs in the Adelaide hills district.

The codlin moth (*Cydia pomonella* Linn.) was normal. Mr. R. Fowler has described the results of further experiments on the control of this pest (*Journ. Agric. S. Aust.* 36, 647-661, and 1368-1370, 1933).

The light-brown apple tortrix moth (*Tortrix postvittana* Walk.) was observed damaging the rind of oranges in July, 1932. This species, which is a native of Australia, is not a pest of the apple tree in this State, as appears to be the case in the cooler countries, New Zealand and Tasmania. It may be controlled on apple trees in this State owing to the spraying schedule againgst codlin moth. The laryae frequently occur on grape bunches on vines, and in generel it has a fairly wide range of hosts. A useful paper on this insect has been written by L. J. Dumbleton (*New Zealand Journ. Sci. Techn.* 14, 83-92, 1932).

The orange butterfly (*Papilio anactus* Macleay) is occasionally seen on the Adelaide plains, and in irrigated orange groves on the River Murray. The yellow-banded larvae were taken feeding on young leaves of Pomeroy orange.

The larvae of the painted apple moth (*Orgyia anartoides* Walk.) occurred in numbers on young apple trees in the Millicent district in January, 1933; also at Cherry Gardens in March and April. It was found damaging leaves of quince in Myponga district. The larvae feed on the green tissues of the leaves, affected leaves being reduced to a skeleton.

The flea beetle (*Arsipoda kingensis* Blkb.) occurred in large numbers on apricot and mulberry trees in an orchard at Berri in February, 1934. It was also recorded on fruit trees at Waikerie.

The cherry green beetle (*Diphucephala colaspidoides* Gyll.) occurred in plague numbers in the Mount Compass district in November, 1932; it damaged the foliage and fruit of apple trees.

The dried fruit beetle (*Carpophilus hemipterus* Linn.) damaged pears on the drying racks at Berri in 1934. This beetle may cause serious damage to dried pears in store; treatment with sulphur-di-oxide is generally adopted.

The Coreid bug (*Serinetha lurida* Dallas)* invaded figs on the trees in large numbers at Berri in March and April, 1934.

The cockroach (*Phyllodromia supellectilium* Serv.) was recorded heavily infesting mature sultana grapes on vines at Renmark in the autumn of 1933.

The tree Katydid (*Caedicia olivacea*) was found feeding on the rind of oranges (Thompson's improved navel) at Berri; serious surface blemishes were produced on some of the oranges.

The pear leaf blister mite (*Eriophyes pyri* Pagenst.) was active in certain districts in the Adelaide hills during October and November, 1932.

The green peach aphis (*Myzus persicae* Sulz.) was present in fair infestation numbers on peach trees only in a few local situations. Infestation may develop during August to November. Winged re-migrants were observed returning to peach trees in the Light's Pass district in May and June, 1932, and at Blackwood Orchard in April, 1933. In the latter case, sexual females were present on the trees at the end of April.

*Kindly identified by Mr. K. McKeown, Australian Museum, Sydney.

From 100 peach twigs collected in Angaston district in July, 1932, 21 viable eggs were obtained. Several eggs had hatched, and newly hatched aphides were present; most of the eggs on the trees had hatched by the end of August. From 150 peach twigs taken from Blackwood Orchard on July 14th, only 11 eggs were obtained. Where tar-distillate dormant sprays have been employed, satisfactory control of the pest has been obtained. A useful paper on this species is written by K. M. Ward (*Journ. Dept. Agric. Vict.*, vol. 32, 1934).

The cherry aphis (*Myzus cerasi* Fab.) commonly occurs on cherry trees in the Adelaide hills district, but infestations are generally light.

The apple leaf hopper (*Typhlocyba australis* Frogg.) occurs on apple trees in some districts in the Adelaide hills; in certain years it causes considerable mottling of the leaves. A useful paper on this species is contributed by L. J. Dumbleton (*New Zealand Journ. Sci. Techn.* 16, 30-38, 1934).

5. MISCELLANEOUS OBSERVATIONS.

Mole crickets (*Gryllotalpa coarctata* Walk.) were more troublesome than usual in the late summer and autumn 1933-1934 owing to dry weather. They caused damage in tomato houses, lawns, and seedbeds in nursery gardens on the sandy soils of the coastal regions of the Adelaide plains. Where practicable, as with lawns, covering with straw and flooding brought the insects to the surface; they could be then readily destroyed, and satisfactory control was obtained. Injection of carbon-disulphide into the soil also gave satisfactory control.

Zinc phosphide bait appears to give good control of mole crickets in Italy (*Ett. Malenotti, Giornale di Agricol. d. Dominica*, December 8th and 29th, 1929).

The common species of blowflies in the Adelaide district are:— *Lucilia sericata* Meigen, *Chrysomyia rufifacies* Meig., *Microcalliphora varipes* Macq., *Calliphora stygia* Meig., *C. novica* Hardy. Their seasonal occurrence is described by J. Davidson (*Journ. Agric. S. Aust.* 36, 1148-1153, 1933).

The weevil (*Ethemaia sellata* Pascoe) was found in large numbers feeding on a dense patch of Malva (*M. parviflora* L., *M, nicaeensis*) near Adelaide; the dense growth of the weed was defoliated by the insects early in the winter, but the plants made vigorous regrowth again in early spring. The insect has now been found to occur on wild mallow throughout the Adelaide district.

The fern weevil (*Neosyagrius cardipennis* Lea) was found damaging maiden hair ferns near Adelaide in the summer of 1933. The Tenebrionid beetle (*Pterohelaeus piceus* Kirby) was recorded in large numbers around the base of orange trees. As many as 100 beetles were taken round one tree, and it appeared that the rough bark at the base of the tree had been eaten.

The beetle *Polyphrades pella* Blkb. was feeding on the foliage of Tuart gum trees (*Eucalyptus gomphocephala*) at Barmera in March, 1934, together with the case moth (*Animula herrichi* Westw.).

The ladybird *Orcus australasiae* Boisd. was found actively feeding on colonies of *Pineus pini* L., on *Pinus radiata* in December, 1933; the mite, *Oribatula tibialis* Nicolet, is commonly associated with it. The beetle *Bruchus pisorum* L. was found in a consignment of peas from India. This species is not recorded from South Australia; the allied species *B. obtectus* Say. and *B. chinensis* Thunb. have been recorded.

The drug store beetle (*Sitodrepa panicea*) was found infesting seeds of tomato.

The clothes moth (*Tineola biselliella* Haw.) heavily infested fleeces of wool stored in a barn.

Eggs of the cactus moth (*Cactoblastis cactorum*) were introduced from Queensland in March, 1934, by a resident near Adelaide, and placed on a small localised area of *Opuntia monacantha*. In July there was evidence of the working of the larvae, several of which were found.

Larvae of the moths *Eucosma triangulana* Meyrick and *Orgyia anartoides* Walk. were taken feeding on seedlings of *Pinus radiata* in Mount Gambier district.

Larvae of the tortrix moth (*Tortrix divulsana* Walk. = *gratirana* Meyrick) caused damage to seedlings of *Pinus radiata* in the same district. The seedlings were about a foot high; the caterpillars bind together the needles of the terminal shoot, line the chamber with silk, and pupate there; affected seedlings are recognised by the bunched appearance of the growing tip; this destroys the leader of the young tree. Dr. Jefferis Turner kindly identified the moths bred out from affected material.

The Psyllid *Cardiaspis brunneus* Frogg. was found heavily infesting leaves of red gum (*E. rostrata*) in the South-East; the leaves of affected trees were discoloured and dry. The Cercopid *Bathylus albicincta* Erichson was present in large numbers on *Acacia* sp. at Penola in January, 1933.

The March flies *Tabanus bassi* Ferguson and *T. petasta* Walk. occur commonly in certain coastal districts in the South-East.

The cattle louse (*Linognathus vituli* L.) was taken from calves near Adelaide. The animals were heavily infested and in poor condition.

The "ti-tree itch mite," which is a larval form of *Trombicula hirsti* Sambon, occurs commonly in districts around Robe; the mites cause skin irritation where they pierce the skin. An important paper on the Trombid and Erythraeid mites of Australia, by H. Womersley, has been published recently (*Records S. Aust. Mus.* 5, No. 2, 1934).

The bulb mite (*Rhizoglyphus echinopus* F. and R.) was found infesting a consignment of imported bulbs. This mite commonly occurs on bulbs in Adelaide hills district.

The springtail (*Hypogastrura armata* Nic.) occurred in pest numbers in beds of cultivated mushrooms near Adelaide. The species *Onychyurus fimetarius* L. often occurs in large numbers in damp situations in decaying garden vegetable matter and damp humus soils. The insects were stated to be damaging strawberry plants near Murray Bridge in November, 1933. Many species of springtails are of considerable economic importance. H. Womersley has contributed important papers on the Australian forms (*C.S.I.R. Aust.*, Pamph. 34, 1932; *Trans. Roy. Soc. S. Aust.* 57, 48-71, 1933; 58, 86-138, 1934; *Stylops* 2, 241-247, 1933).

VETERINARY LODGES.

[In our February issue reference was made under "Veterinary Instructors" to the establishment of Veterinary Lodges. Through the courtesy of the Balaklava Veterinary Lodge, the appended rules are published for the information of Branches of the Agricultural Bureau or other organisations contemplating the formation of Lodges in other districts.]

1. The name of the lodge shall be "Balaklava Veterinary Lodge."

2. The object of the lodge is to provide a veterinary surgeon for the benefit of its members, to attend to their respective horses and cattle, perform operations, excepting castration, and attend to all illnesses whatsoever.

3. The rates of subscription shall be as follows:—Within a radius of 5 miles of Balaklava Post Office—from 1 to 5 head, £1 1s. per annum; from 5 to 10 head, £2 2s. per annum. Over 5 miles and up to 20 miles from post office the rate will be £3 3s. up to 30 head of stock. These rates to include horses and cattle the *bona-fide* property of a member. All over 30 head to be charged for at the rate of 6d. per head per annum. Mileage each way, 3d. per mile extra.

4. All subscriptions shall be due and payable on or before the 30th of April in each year. Any member whose subscription shall remain unpaid by that date may be suspended by the committee until such subscription is paid, and in the interim shall not be entitled to any benefits accruing under these rules.

5. The management shall be vested in a committee of eleven members (who shall elect a chairman from their number). The committee elected shall retire annually, but shall be eligible for re-election.

6. The committee shall meet as required by chairman and secretary. Five to form a quorum.

7. The committee shall cause to be kept fair and accurate minutes of its proceedings, including statements of all receipts and payments, and the minutes of each meeting shall be read and confirmed at the meeting following.

8. The committee shall lay before the annual meeting a report and statement of all receipts and expenditure during the year.

9. The secretary shall attend all committee and general meetings, and keep accurate minutes thereof, and conduct the correspondence of the lodge. He shall pay all moneys received by him into the lodge banking account as soon as the same shall amount to £10.

10. One auditor shall be appointed at the annual meeting for the ensuing year. He shall, prior to the annual meeting, examine all books and vouchers, and certify as to the correctness or otherwise of the balance-sheet.

11. The annual meeting of the said members of the lodge shall be held during the month of March each year, when the committee shall present their report and balance-sheet, and election of officers (if necessary) and any other business may be brought forward.

12. The veterinary surgeon shall enter into an agreement to serve the lodge, and three months' notice must be given by either side before same can be terminated.

13. Fourteen days' notice shall be given to each member for all general meetings, 12 to constitute a quorum. If, at the expiration of one hour from the time appointed for holding such meeting there shall be no quorum present, the meeting

shall lapse, and the committee shall convene a special general meeting to be held within 30 days of the date first fixed.

14. A special general meeting may be convened by the committee, or by petition to the committee, signed by any 12 members of the lodge, notice thereof being given in the same way for the annual meeting, such notice also to state the business for which such meeting is being called. No other business than that set forth on the notice paper shall be taken into consideration at any special meeting. Any vacancy may be filled at such meeting called for the purpose.

15. Any person residing outside the radius of the lodge may become a member of such lodge on payment of subscription, as provided by rule 3, over 20 miles, mileage 1s. per mile, but the committee shall have power to refuse any person membership without assigning any reason for so doing.

16. The veterinary surgeon shall be entitled to attend private cases, so long as same do not interfere with the attendance upon members.

17. Should the veterinary surgeon be at one member's place, and another member call for him, it will be the duty of the veterinary surgeon to attend as soon as possible.

18. Medicines required shall be supplied by the veterinary surgeon at cost price, and shall be paid for within one month of purchase.

19. Should a member have horses or cattle requiring frequent treatment he may take same to the veterinary surgeon's residence, who shall attend to same there; but the member must pay all cost of feed and stabling, etc.

20. Should the veterinary surgeon leave the district for either business, holiday or illness, he should, if possible, supply a substitute in equal ability to himself, but the committee may grant him three days' leave of absence without so doing.

21. All salaries, accounts, &c., over £1 shall be paid by cheque, duly signed by one member of the committee and secretary.

22. Any member or the veterinary surgeon of this lodge coming within these rules may be held thereby to consent to be bound by them, and shall not be entitled to appeal to any court by reason of anything done under these provisions.

23. The committee of this lodge shall be indemnified from the funds of same against the cost of any legal proceedings that may be instituted against them in consequence of the performance of their duties.

PAPERS READ AT CONFERENCES.

YORKE PENINSULA BRANCHES, KADINA, 6th MARCH.

HORSE DIPPING.

[S. PONTIFEX, Paskeville.]

Whilst the word dipping may be somewhat anomalous as applied to horses, it doubless explains the operation sufficiently. It is quite safe to totally immerse sheep—one minute being considered the correct time for a swim through the dip, on account of the wool retaining a fair amount of the fluid; but horses require 20 minutes, and if the dip is deep enough to cover the animal, serious complications may arise. Also the dip is very expensive to construct.

I speak with first-hand knowledge of this subject. Our horse dip has been in operation at Paskeville for some time, and since its inception my horses have not missed their annual bath.

I advocate Cooper's Milk Oil Fluid, procurable in 5gall. drums, and if the directions on the tin are correctly carried out, good results are obtained. The advantages of dipping horses annually should be obvious to all. No great time ago it was quite uncommon to see horses rubbing against any available structure; but since skin parasites have spread throughout the country, stall rails are pushed down, mangers knocked over and polluted, and post and rail fences around the stables are almost impossible to keep in repair. Dip once a year as a preventive, rather than wait until the horses get very badly affected, when it would require two dippings at intervals of two or three weeks to be effective. Once the team is free from lice, a marked difference will be noticed. Horses appear and do much better. The tuft of hair so much admired on the legs of a Clydesdale will grow to its normal size and shape. After feeding, the horses rest quietly, instead of continually stamping their feet and rubbing, some continuing until the legs are quite raw. Dipping obviates the necessity for continually mending the fence of the horse paddock; when horses are shut in a paddock devoid of timber, the fences suffer to a great extent.

If the fluid is deep enough to cover what is generally known as the chain mark on a horse, that appears to be quite an effective depth. Having to construct the dip of stone or concrete underground, it will be readily understood that the fluid is mostly very cold; but at this depth no ill effects have been known. It is a warm weather job, and then the horses dry quickly after the dip has been bucketed up and the body of the horse thoroughly washed, the mane and tail in particular. It is not a good practice to dip horses in an overheated state; they should have time to cool down before entering, and should be kept steadily under control until reaching home.

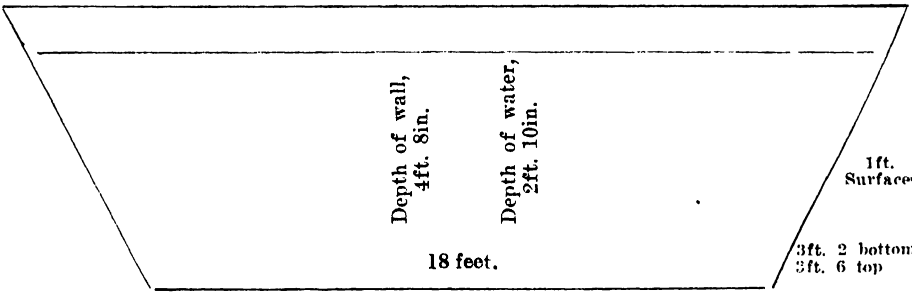
Our dip is long enough to take four horses at a time, and as the legs are always most affected, the fourth horse stands up to his knees in the shallow entrance, likewise the first horse in the sloping outlet, and the two middle ones in the deepest part.

With sufficient help, 12 horses an hour can be put through, and each horse is given its prescribed time. The inlet and outlet have corrugations in the concrete, and should be a gentle slope to minimise slipping, because when valuable horses are going through, reasonable care should be taken. All stock are dipped at owner's risk and a notice to that effect should be exhibited. Some people consider it a dangerous operation; but the horses take it kindly enough, especially if there is more than one horse in the dip at a time.

To facilitate entering, they are blindfolded with a piece of old canvas or some dark material that they cannot see through, being pushed up under the noseband and forehead band of the winkers; once in the dip, this is better removed.

[*Papers Read at Conferences.*]

All farmers are advised to keep their horses in a clean and healthy condition by dipping them in a reliable compound for that purpose at least once a year.



This dip could be improved by making it 9in. to 1ft. deeper. At present it is not quite deep enough.

There can be five or six draught horses standing in the dip at once; when a horse has been washed all over in the deep part of the dip, move him on up the slope, because the legs are the worst trouble. The time for dipping is from October to April, or just before hay harvest and as soon as the harvest is over. Keep the horses in the dip from 15 to 20 minutes, and if very bad, dip again on the ninth day. Use Cooper's Liquid Dip, 1 gall. of dip to every 120galls. of water.

When the Paskeville dip was built in 1932 164 horses were dipped, in 1933-34 159, and so far this season 58.

PIG RAISING.

[S. CHYNOWETH, Boor's Plains.]

The two essentials for success in pig farming are breeding and feeding. The pigs must be of even type and correct shape, and they must be given such food as will make them capable of producing the kind of bacon that the consumer desires. The breeding of pigs of the type in demand is the most important factor, and means the difference between profit and loss. At present the buyer of bacon pigs is looking for a pig with a long, deep middle, light shoulders, and good hams, first in importance being the middle. The hair and skin give a fair indication of the firmness and quality of the flesh. The pig with coarse hair and wrinkly skin will probably yield coarse, dark flesh. Hairless skin usually denotes too much lard. A pig should show fine bone, coarse bone indicates coarseness throughout. An animal with heavy, thick shoulders should be avoided. The shoulder must be fine, joining on to the side smoothly, and must be free from lumpiness. The top line should run smoothly from ears to tail, with a slight arch; the side deep, with a level underline, thick at flank. The pig should not taper from shoulders to hams. It should be as wide as and preferably wider there than at the shoulder. White pigs are preferred.

The breed recognised all over the world as the best bacon producer is the Large White. The fact that the Large White has been accepted as the ideal bacon pig does not mean that all Large Whites are good. Careful and continued culling and selection are needed, and the culling should be drastic. Those showing short bodies, signs of wrinkly skin, coarse heavy bone, coarse hair, heavy shoulders, and heavy jowls should be culled. There are two methods of keeping pigs—in the sty and in the open air. For the past decade the Department of Agriculture has advocated the latter method. Running pigs on pasture has proved more economical than keeping them in sties. Not only is there a saving in labour, the pigs are healthier, and less subject to infestation by worms, and there are fewer losses after farrowing.

[*Papers Read at Conferences.*]

In sties—and especially dirty sties—there are losses, frequently from 20 to 50 per cent. of the young pigs die after farrowing, and a considerable percentage after weaning.

In trials carried out over a period of years, the average litter per sow with open air methods was over 9, and the average number reared was over 8, the loss being approximately 1 per cent., and the percentage of loss after weaning less than 1 per cent. For the open air method of keeping pigs it is necessary to have proper paddocks. A convenient size for the farrowing shelters, which can be made of wood and iron, is the roof type, 8ft. x 8ft. x 5ft. high; a floor is unnecessary except under very wet conditions. Two rails are placed 3ft. apart and 9in. from the ground, to prevent the young pigs from being crushed. The shelter is open in front, but as a sow always turns her head to the open when farrowing, the young ones are born under shelter. These structures can be moved readily by two men. Shelters in the fattening paddocks should be about 12ft. x 6ft. x 4ft. at the back and 5ft. in front. The use of automatic feeders is recommended; there is a decided saving of labour, while the pushing and jostling that occur at the troughs, with a consequent waste of feed, are reduced to a minimum. Again, if pigs can feed whenever they wish, they eat slowly, the food is more thoroughly digested than is the case when it is bolted, and the weak pigs get as much as the stronger ones.

Shelter sheds for the dry sows should be the same as in the fattening pens, and the paddocks should be provided with water troughs, amply shaded.

After being served, the sows remain in the paddock adjoining the boar paddock for three weeks; if in pig, they are moved to the larger paddocks reserved for dry sows. If the pasture in these paddocks is good, very little grain feeding will be required until within a month of farrowing, when they are shifted into the paddock for forward sows. A week before farrowing they are brought into the farrowing paddocks.

In both these paddocks the sows are fed a balanced ration, consisting of crushed grain and a little meat meal. The amount of feed will depend on the condition of the sows. Breeding sows should not be fat, neither should they be in low condition. If run on pasture they will remain in good store condition and keep healthy. The sows remain in the farrowing paddocks for eight weeks after farrowing. During this time the sow requires an average of 1lb. of grain mixture for each pig in the litter, plus an extra 3lbs.; thus a sow with a litter of 10 pigs would require 13lbs. of grain mixture per day. When three weeks old, the young pigs should be provided with a feeding trough in a creep and fed a mixture of gristed grain and 12 per cent. meat meal. At eight weeks—when the young pigs are ready for weaning—the sow and litter are moved to the fattening paddocks, the sows being removed two days later to the paddock adjoining that of the boars to await service.

All little pigs should be "wormed" as soon as they are weaned. There are several methods of getting rid of worms, but I recommend Nema worm capsules, as they kill round worms, hook worms, and stomach worms. They are easily administered by using the capsule forceps and mouth spreader. While in the fattening paddock, any short, dumpy pigs should be culled and sold as porkers, for they will not be saleable as baconers.

Each sow should be earmarked for identification purposes, and a record kept of her progeny. The useful life of a sow extends to six years, and usually after that age it is advisable to dispose of her as a "back-fatter."

FEEDING.

Skim milk and buttermilk are of equal feeding value. Care should always be taken to see that the buttermilk has not been adulterated by water used in washing the butter; drainage from the testing room must be especially avoided. There is a belief prevalent among some farmers that if milk is to produce the best bacon it should

be allowed to sour and thicken before being fed. There is no ground for this belief, and one reason why it should not be acted upon is that milk which has been put in dirty casks to thicken may cause the death of young pigs. Sweet milk is safer and produces first-class pork and bacon when fed with grain. In feeding milk to get the best results, sufficient grain should be added to provide the carbo-hydrates required to balance the ration.

Where feed is fed in a trough, the grain—which should be crushed—should be added to the skim milk at the following rates:—

For young pigs in creep—

At 1 month—2lbs. grain to 1gall. milk.
At 6 weeks—2½lbs. grain to 1gall. milk.
At 8 weeks—3lbs. grain to 1gall. milk.
At 10 weeks—3½lbs. grain to 1gall. milk.
At 12 weeks—4lbs. grain to 1gall. milk.
At 14 weeks—4½lbs. grain to 1gall. milk.
At 16 weeks—5lbs. grain to 1gall. milk.

The broadening of the ration as the pig gets older means a greater supply of carbohydrates. Where the automatic feeder is in use the pig should get a drink of milk twice daily; in addition, there should always be clean drinking water available.

Barley comes first among the grains as a food for producing first-class pork or bacon, and in conjunction with skim milk, forms an ideal food. Oats, on account of the large percentage of hull, which is indigestible by the pig, are not advised for pigs under the age of 12 weeks. They, however, produce good bacon or pork. Wheat as a food gives fair results. Feeding trials carried out with wheat and barley mixed and wheat alone showed that pigs made quicker gains on wheat and barley. When killed and dressed and allowed to set, the pigs fed on the wheat and barley mixture showed a firmer fat than did those fed on wheat alone.

Pollard is perhaps the byproduct most used by pig farmers, being so finely ground it is especially suitable for young pigs; but when a pig is fattened on pollard alone, the flesh is soft, therefore other grain should be introduced and fed in conjunction. Suitable quantities are set out hereunder:—

At 10 weeks—7 parts pollard, 3 parts barley.
At 12 weeks—6 parts pollard, 4 parts barley.
At 14 weeks—5 parts pollard, 5 parts barley.
At 16 weeks—4 parts pollard, 6 parts barley.

Bran is usually fed as a laxative, not as a fattening food, and is given to brood sows a few days before and after farrowing, to prevent constipation. From 1lb. to 2lbs. daily will be sufficient.

Meat meal is a protein rich food, containing from 50 to 60 per cent. of that constituent, and is used when no milk is available to add to grains to balance the ration, and may be fed in the following quantities according to the age of the pig:—

For young pigs in creep—12lbs. meat meal to 100lbs. grain.
At 8 weeks—10lbs. meat meal to 100lbs. grain.
At 12 weeks—8lbs. meat meal to 100lbs. grain.
At 16 weeks—6lbs. meat meal to 100lbs. grain.

And finish off at this amount.

Pigs are quick-growing animals with a comparatively small stomach capacity, consequently those kept in sties and fed in troughs should be given at least three feeds daily. When fed only twice, they become exceedingly hungry and may perhaps gorge themselves; diarrhoea aften follows, sometimes with fatal results. Pigs must not be allowed to become ravenous. They should be given at each feeding as much as they will eat in half an hour. Keep plenty of clean drinking water before the pigs at all times.

[*Papers Read at Conferences.*]

Where sows are kept in sties, they should never be fed on grain and water only. If milk or pasture is not available, meat meal fed at the rate of 6 parts to 100 of grain, or bone flour 1 part to 100 of grain, will suffice. Open-air farrowing is preferred, where possible; this will necesitate the use of movable farrowing shelters in small paddocks.

Little pigs should be kept out in the light and open air as soon as possible. They will look for roughage when about three weeks old, and a creep should be provided for them. Young pigs should not be allowed to become ''staggy''. To guard against this, castrate them at a month old. If possible, fatten in small lots, never more than *20 pigs together;* when kept in large mobs they require a longer time to fatten.

Never place sties or sleeping quarters in gullies or on the side of banks where there may be draughts; always provide a shelter which will shield them from the wind, cold, and rain. Shade in summer is essential; a wallow will give good results. It need not be very deep—about 16in. will suffice, and it should contain 9in. or 10in. of water. It should be protected from the sun by a roof—one of straw will do. A small quantity of crude oil may be added with advantage to the water.

The most economical way of supplying mineral matter is by charcoal and ashes. The animals may be kept free from vermin by using crude oil. When a pig attains the weight required by the curer, and is in good condition, it should be marketed, even though the market is dull. It is a mistake to wait for prices to rise; a pig may lessen in value, for there is no sale for overfat bacon. The sow should earn as much as the cow on the farm.

There are possibilities for the pig industry in South Australia, but those possibilities will not be attained until a policy of grading pigs and grading bacon is adopted. Payment according to the grade of a pig will ensure the farmer receiving the highest price for animals of the best quality, while the grading and marketing of bacon will ensure consumers getting exactly the sort of bacon they desire. The boar should have plenty of exercise and be fed well, but not too fat. I prefer feeding barley or oats in the morning and a sheaf of wheaten hay at night.

METHODS OF SEED SELECTION RECOMMENDED FOR THE IMPROVEMENT OF WHEAT VARIETIES.

[L. Mc. Carter, Boor's Plains.]

This paper is written with a desire to bring before the notice of wheatgrowers the necessity of encouraging them in the growth of improved strains of varieties, that they may in time become sufficiently interested to take part in this business themselves. Much of the higher experimental work of the Agricultural Department's officers will then appeal to and interest them, and its importance will encourage them to support and encourage scientific investigation generally. However modest the farmer's original work of seed improvement, a good purpose is served, and it inevitably acts as a lever to raise agriculturists to a still higher plane, both socially and politically, and is an important economic factor in the Commonwealth's progress.

The creation of new varieties of wheat is of absorbing interest to the majority of farmers, though as a rule, they have no conception of the rigorous tests each seedling wheat has to pass through before it reaches their farms. So few new crosses measure up to the standards required of a new variety, that unless a farmer has a special inclination for this work, without interfering with his business, he should leave it alone and confine his undivided attention to the improvement of standard varieties by selection. This is a work all farmers should give every consideration.

The principal methods adopted for improving the quality and yielding power of a variety by selection are—

(1) Pedigree selection.
(2) Mass selection.

[*Papers Read at Conferences.*]

PEDIGREE SELECTION.

In pedigree selection individual plants of a variety are dealt with and consideration given to their yields and prepotent qualities through a season of growth until harvested. After harvesting the grain is tested for flour strength.

Naturally the first consideration that enters the mind of the seed farmer is to choose for his operations promising yielding varieties having other desirable qualities, such as practical harvesting properties. As a nucleus from which to select, a farmer should always purchase a quantity of pedigree grain from a reliable grower.

Just as the development of fine breeds of livestock is due to the keen perception of the stud breeders when selecting right types of animals to breed from and eliminating the less desirable, so will keen perception and selection account for the development of productive strains of high quality wheats. The environal conditions would influence the selector in this choice of selecting strains of a variety. Rust resistance, early maturity, a less shattering proclivity of the grain in the ear, a higher gluten content, a stronger flourmaking grain, greater drought resistance, and such qualities give a wide field for enthusiastic activities, since all bear on that important essential, the production of a profitable commercial wheat.

For pedigree selection, the grains of picked plants are sown singly in well prepared soil, from 6in. to 8in. apart in the rows, in order that the characters of every individual plant may be studied. At harvest time what are considered the most typical plants, perhaps a dozen, are selected and kept separate. Equal quantities of grain from each selected plant are then sown in separate rows, preferably as single seed plots, in order to better estimate the trueness in characters of the individual plants and to discard the strains showing imperfections.

The average farmer will not have the time at his disposal, nor the inclination, to enter deeply into pedigree breeding, unless it is his intention to make the production of pure pedigree seed for sale his primary object. Every wheatgrower, however, should be interested in improving wheat varieties by mass selection and thorough grading of the seed.

Owing to the seed being drilled in, and possibly several seeds germinating at the same spot, it is impossible for the farmer to select the best plants. For this reason he must depend on the selection of the best typical ears. To do this he must fix in his mind the type of ear he intends to establish, and select through years to it, otherwise he would never arrive. Naturally the most prolific ears will be those with the greatest number of spikelets, containing from three to five grains across—that is, three to five grains to the spikelet. An average of 12 rows of spikelets on either side of the rachis will prove sufficient.

To minimise errors due to possible soil variations, a narrow rectangular plot is more desirable than any other, and the long side should be at right angles to the furrows of the previous working.

The average farmer is most likely to content himself with one plot, the longer the better; but it should be not less than one-fiftieth of an acre in area, and this would require approximately several pounds of seed for an even drilling. A plot 124½ft. by 7ft., sown with an ordinary 12ft. drill, would serve for all practical purposes, being approximately one-fiftieth of an acre. Where several plots are undertaken, they should be spaced widely enough to allow of proper harvesting.

MASS SELECTION.

Mass selection relies on the selection of the best ears of the crop, threshing them together, and by a process of continuous mass selection to arrive at a similar end to pedigree selection. Before sowing, the seed of the selected ears should be thoroughly hand picked.

Each season the process of mass selection should be continued to keep the strain pure and to improve its other good qualities.

[*Papers Read at Conferences.*]

A spirit of mutual help should be fostered in each district by the Agricultural Societies, so that a common interest may be created in producing the best strains of particular varieties most suitable for a particular district.

It must be understood that the process of mass selection does not induce new characters in a variety; it simply develops the inherent qualities, and conditions are made available to bring out what is best in them. It is owing to these fluctuating variations in a variety that seed selecton is so desirable and necessary to develop a strain suiting the environal conditions of each particular district.

Change of seed is rarely necessary if soil and environal conditions are favourable to the variety and seed selection is practised.

It should not be thought that seed selection is a substitute for cultivation, so that where the best results are expected, seed selection as well as thorough cultivation and good management generally should be practised. It has been proved in a number of cases that where the same varieties have been grown from 20 to 25 years without change of seed, that they are to-day better than the originals. Unless seed selection is practised, it will be found that many of the plants in time exhibit loss of stamina, which is also reflected in their liabilities to the attacks of disease and physiological irregularities.

THE VALUE OF READING TO THE MAN ON THE LAND.

[H. QUEALE, Boor's Plains Branch.]

Reading ranks with travel and intercourse with one's fellow men as a means of acquiring knowledge, and for the rank of file of farmers is the most accessible. The average farmer is blessed with a fair amount of commonsense, and has his own ideas about matters pertaining to his daily life. Left unexpressed, they are of small account. But passed on to his fellow men, the ideas become vitalised and of greater importance. Even the wrong idea is best expressed, because one is given the chance to help and correct his fellow man. Of infinitely greater importance is the good idea when it is passed on.

Many men cannot always evolve an expression from a thought. He is not good at telling the other fellow, with any marked degree of lucidity, what he has in mind. This applies in a peculiar manner to the man on the land, because he lives, to a point, unto himself. Resulting from this quasi-lone life is an embarrassment at hearing his own voice, with the consequent difficulty of expression. Herein lies the value of reading. The man who reads and takes notice of what he reads, unconsciously absorbs words, terms, phrases, and paraphrases, and modes of expression. These are stored away in his subconscious mind, and at the most unexpected times, very often, these expressions flash across his mind and help him out of a difficulty. He acquires an ease of manner and a freedom of speech from his reading which, without travel and intercourse, would be denied him. With a little reference to a good dictionary he will also acquire correct pronunciation and enunciation of the language of the day.

In his daily life he has the practical experience of his work, and if he couples this with studying suitable books he is undoubtedly the gainer. The bogey word "theory" would certainly lose a vast amount of valueless meaning to the conservative-thinking farmer, and he may become a Bureau member and a reader of the *Journal of Agriculture,* the value of which is very great.

To accumulate knowledge and obtain ideas of current topics the constant use of the daily paper is unsurpassed. Reading widens one's outlook and extends the vision to realms of thought and feeling otherwise unattainable. Australia, by reason of its great distance from other countries, is apt to foster ideas of insularity. Although and aerial progress have minimised distance, the man on the land, by his still labours under many disadvantages. Travel is too expensive to be in- extensively.

[*Papers Read at Conferences.*]

The desire for and value of co-operative thought and action have been evidenced times without number. The danger of thinking and acting alone threatens to become political retrogression and industrial stagnation. The value of reading to the man on the land cannot be too greatly stressed. For, as he reads, so he thinks; and as he thinks, so does he act. The value of acting upon the result of co-operative thought brings it own reward.

As a pleasure and a hobby, the book lover finds nothing so entrancing or enchanting as a good book. R. L. Stevenson's lines, "What are my books? My friends, my church, my tavern, and my only wealth," readily come to one's mind. To-day the value of recreation to the man on the land has a definite place. It is a time of serious thought and grim struggle. Unless he spends his leisure hours—few enough though they be—in pleasant ways, his mind will not be refreshed when he again takes up his daily duties.

The choice of literature is of very great importance. There are many dangers as well as benefits to be had from reading. It is well worth a man's while studying carefully the works of the day, before accepting all and sundry alike, and when Australia has a better informed farmer, who has the ability to put his "case," then, and then only, will she have a rural population who can defend the man on the land and lend a dignity to his calling.

Reading is one of the surest, safest, and most accessible means of acquiring a sense of expression, a knowledge of matters requiring understanding, and a real and lasting pleasure to the man on the land.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held at the Blackwood Experimental Orchard on 27th February, there being present Messrs. A. J. Cooke (Chairman), H. N. Wicks, P. J. Baily, R. H. Martin, S. Shepherd, F. Coleman, A. J. A. Koch, A. G. Strickland (Deputy Chief Horticultural Instructor), R. Fowler (Manager Blackwood Orchard), and H. C. Pritchard (Secretary). Apologies were received from Professor A. J. Perkins, Dr. A. E. V. Richardson, Messrs. J. B. Murdoch, J. W. Sandford, and A. M. Dawkins.

Leave of Absence.—The Secretary reported that the Minister had approved of five months leave of absence for Mr. Jeffrey.

Life Members.—Messrs. H. G. Pym and R. S. Talbot, of the Blackheath Branch, were approved as Life Members of the Agricultural Bureau.

New Branch.—Approval was given for the formation of a Branch of the Agricultural Bureau at Maltee (Women's), with the following as foundation members:—Mesdames L. M. Martin, J. Bassham, C. Ferguson, H. J. and C. T. Schwarz, A. Edson, and S. Bawden, Misses L. and A. Bassham, L. Ferguson, L. and S. Schwarz.

New Members.—The following names were added to the rolls of existing Branches:—Balhannah—B. E. Nitschke, T. E. Edwards, G. T. Edwards; Balhannah Women's—Mrs. F. Leane; Block E—C. F. Sowden; Boor's Plains Women's—Miss L. Lamshed; Coonalpyn—E. Fox, J. Fox, Charles C. George, C. L. George, P. Haydon, J. Haydon, R. V. Potter, C. Todd, sen., Cyril Todd, Charles Todd, jun., S. Todd, F. Todd; Kybybolite—A. W. Feuerheerdt, H. S. Naylor, H. G. Spencer; Maltee—N. D. McConchy; Mount Compass—L. W. Weinert; Mount Gambier—Harold Clark, Ralph Clark; Mundalla—Ivan Dinning; Myponga—J. A. Schmeiss; Pinnaroo Women's—Miss Ruth Pearce; Renmark—H. Vorweck, F. Hunt; Tweedvale—P. Kerber, V. Gurr, W. Erdmann, C. Pfeiffer; Wilmington—L. F. Modystach; Wirrilla Women's—Mrs. H. V. Kirk.

Present No. of members, 6,818; present No. of Branches, 339.

Sulphate of Ammonia.—At the January meeting the MacGillivray Branch asked the Board to endeavour to have the tariff reduced on sulphate of ammonia. The rates of duty are:—British preferential (free), general (22½ *ad valorem*). For each £1 by which the equivalent in Australian currency of £100 sterling is less than £125 at date of exportation, an additional duty of .6 per cent. *ad valorem*. It is exempt from Commonwealth primage duty and sales tax. The Secretary was instructed to advise the Branch of the rates of duty.

Records of the Blackwood Orchard.—The Secretary reported that Mr. Quinn had supplied portion of his report and the copy was in the hands of the Government Printer for publication. Members expressed appreciation of the fact that this work was at last being undertaken.

Veterinary Instructors.—The Secretary reported that in accordance with the Board's instructions, the correspondence relating to this question was circulated among Branches and replies have been received from Koolunga and Penola appreciating the Board's part in endeavouring to secure instructors for country districts.

General items were taken in committee.

OFFICIAL SINGLE TEST EGG-LAYING COMPETITION, 1934-35.

CONDUCTED AT PARAFIELD POULTRY STATION.

ONLY FIRST GRADE EGGS RECORDED.

EXPERIMENTAL FEEDING TESTS CONDUCTED AT PARAFIELD POULTRY STATION.

[By C. F. ANDERSON, Poultry Expert.]

A series of feeding tests are being conducted at Parafield Poultry Station with a view to ascertaining if suitable foods which are obtainable on the majority of our farms can be satisfactorily fed to poultry. The tests are each of 50 White Leghorn pullets, and commenced on April 1st, 1933.

The feeding is as follows:—

No. 1 *Test.*—Morning—Wet mash composed of 1 part crushed barley, 2 parts wholemeal (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 2 *Test.*—Dry mash composed of same proportions as No. 1 Test.
Midday—Greenfeed. Evening—Wheat.

No. 3 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts pollard (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 4 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts wholemeal (by weight), ½ lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 5 *Test.*—Morning—1½ozs. wheat per bird.
Evening—1½ozs. wheat per bird. Greenfeed in season.

The following are the numbers of eggs laid by each pen from April 1st, 1933, to February 28th, 1935.

Definite conclusions, however, cannot be given at this juncture with regard to the various methods of feeding. It is necessary for the tests to complete the 24 months before any satisfactory opinions can be formed.

	No. Eggs Laid April 1st, 1933, to Jan. 31st, 1935.	No. Eggs Laid Month of Feb., 1935.	Total Eggs Laid April 1st, 1933, to Feb. 28th, 1935.

DAIRY AND FARM PRODUCE MARKETS.

A. W. SANDFORD & Co. reported on March 1st, 1935, as follows:—

BUTTER.—Conditions in dairying during February were very difficult as, owing to the hot dry weather prevailing, it was hard for farmers to maintain the quality of their produce, and on the other hand, although the stock in most districts was hand fed, supplies showed a further decline. In some areas along the Murray, where irrigation was possible, supplies were maintained because of the cows being fed with green maize and lucerne. Values in London moved forward earlier in the month but have since receded somewhat and at date of report ruled from 80s. to 81s. per cwt. There was no change made in local prices, being:—Choicest creamery fresh butter, in bulk, 1s. 4½d. per lb.; prints and delivery extra; store butter, 6d. to 8d., according to quality; separator lines from 9d. to 1s. 1d. per lb. for choicest. These prices are subject to equalisation levies.

CHEESE.—The South-Eastern factories forwarded usual weekly consignments, which met with good demand from local and Westralian buyers, so that the floors were kept nicely cleared. Exporting still continues, but within the next week or two the final consignment will have been sent, as production is now quickly declining. Rates are:—Large and medium, from 8½d. per lb.; loaf from 9d. per lb., store door, delivery extra; semi-matured and matured, 9½d. to 10½d. per lb.

EGGS.—Supplies are now shortening, which is usual at this time of the year although the quantities marketed during recent weeks were less than for the corresponding period last year. However, this may be partly accounted for by seasonal conditions. Values have improved and at date of report were:—Ordinary country eggs, fair average quality, 6½d. per dozen net; long distance rail or shipping eggs lower; selected new laid clean eggs, 1⅞ozs. and over, 8½d. to 9d. per dozen net.

BACON.—As is usual in the summer time, consumption of bacon shrinks, but this was offset by the greater turnover in bacon factory small goods and cooked hams. Market continued steady at:—Best quality sides, 9½d. to 9¾d. per lb.; middles, 10½d. to 11d.; heavy middles, 9d. to 9½d.; rolls, 8½d. to 9d.; hams, 1s. 1d. to 1s. 2d.; cooked hams, 1s. 3d. to 1s. 4d. per lb.

ALMONDS.—The new season's crop is now being marketed in increasing quantities and it is pleasing to record that there is an improved inquiry from interstate and local buyers. Large quantities, however, are not yet being placed on the market as growers, in many instances, are allowing the nuts to dry out thoroughly before consigning. Rates ruling at present are:—Softshells and Brandis, 7½d. to 8d. per lb.; hardshells, 4½d. per lb.; kernels, 1s. 9d. to 1s. 10d. per lb.

HONEY.—Sales of this commodity continue dull although supplies of the new season's honey were, generally speaking, of nice quality. The demand was not sufficient to absorb all lots offering and considerable quantities are still held in stock by the distributing merchants. Rates are:—Prime quality clear extracted, 2½d. to 3d. per lb.; lower grades 1d. to 2d. per lb.

BEESWAX.—Was in better supply during the month and sales generally were sufficient to clear all lots offering at:—1s. 4d. to 1s. 4½d. per lb., according to quality. Discoloured lots lower.

LIVE POULTRY.—Sales are held every Tuesday, Thursday and Friday and our Sale Rooms are the best equipped in the State. Our auctions have been well attended by large numbers of buyers and the catalogues submitted met with ready quittance. The strongest demand as usual was experienced for prime quality, heavyweight, well-breasted birds but there were considerable quantities of old season's white Leghorn hens submitted and for these values were low as this type of poultry is not very suitable for table purposes. We advise consigning. Crates loaned free on application. The following are prices realised:—Prime roosters, 4s. 1d. to 5s. 1d.; nice conditioned cockerels, 3s. to 4s.; fair conditioned cockerels, 2s. 3d. to 2s. 10d.; chickens lower; heavyweight hens, 2s. 3d. to 2s. 11d.; medium hens, 1s. 6d. to 2s. 11d.; light hens, 1s. to 1s. 4d.; couple of pens of weedy sorts lower. Prime young Muscovy drakes, 3s. 6d. to 4s. 3d.; young Muscovy ducks, 2s. 3d. to 2s. 10d.; ordinary ducks, 1s. 2d. to 2s.; ducklings lower. Geese, 2s. 9d. to 3s. 9d.; goslings lower. Turkeys, good to prime condition, 8½d. to 10d. per lb. live weight; turkeys, fair condition, 6½d. to 8d. per lb. live weight; turkeys, poor and crooked-breasted lower. Pigeons, 2d. to 3d. each.

POTATOES.—New season's, 10s. per cwt.

ONIONS.—New season's, 9s. per cwt.

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.

Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

SOUTH-EASTERN DISTRICT.

PROBLEMS CONFRONTING THE DAIRY INDUSTRY IN THE SOUTH-EAST.

Paper read by Mr. W. H. Downes, H.D.D. (District Dairy Instructor), at a meeting of the Mount Gambier Branch of the Agricultural Bureau.]

Improved Quality Milk and Cream Essential for Future Progress.

With the general expansion and tremendous increase in dairying, both in this and other districts we have reached a stage in the industry to-day, almost without parallel in history, where the extent of production has so rapidly overtaken the rate of consumption The extent of this growth may be gauged by the fact that during the past 9 years, New Zealand has just doubled her production of dairy commodities, Australia by at least 60 per cent., and in fact, there has been a general increase of considerable magnitude right throughout the world. The result of this is that there is a fairly large surplus to dispose of, through the avenue of export, and unfortunately the difficulty of placing some of the produce has been accentuated by the fact that its quality has not been consistently good. Many of our previous markets overseas—principally on the Continent—are now closed, and we have to depend almost solely on the London market. In the past this market has proved a valuable outlet, capable of absorbing enormous quantities of both cheese and butter; production has increased at such an astonishing rate throughout the Dominions, however, that its capacity in this respect has been so sorely taxed, that the saturation point has already been reached. With an abundant supply of dairy produce available, it naturally follows that buyers can be far more discriminating than they ever were before; consequently any defects in the quality are quickly noticed, and this class of commodity is readily rejected. The most probable conclusion to be drawn from these facts is that the selling potentialities of dairy produce will be chiefly gauged for some time to come on the basis of quality.

Recent Local Improvements.

Producers are probably well aware of the steps recently taken by local factories; the bulk of which are cheese factories; in ensuring a better quality raw material, and all dairymen who co-operated in this direction are to be commended for their assistance and support. As a result, the grading of export cheese this season has shown a marked improvement over any previous year, yet while this is true, there is still a considerable quantity of inferior quality cheese going away. While occasionally there may be a fault in the manufacture, given good quality material in the first place, the majority of district managers can turn out a good article. To support this opinion, comments by the graders from time to time indicate that the quality of raw material is one of the chief drawbacks, or that most of the defects noticed in the flavour of cheese are due more often to the processing of some tainted milk, rather than to errors of manufacture. The stricter grading of milk has received attention by all managers, but while they have been firm regarding the rejection of any milk possessing undesirable bacterial taints, strong feed flavours, or high acid, there is a certain type of milk which is objectionable, yet which is not always so easy to detect on the receiving platform. This refers to milk of "borderline" quality, one of the most difficult to define because of its uncertain character, *i.e.*, it is hardly bad enough to reject entirely, but is not the best for cheesemaking purposes. In many cases this milk may have received a late, though heavy, inoculation of germ life, which when first delivered had hardly had sufficient time to develop. Given favourable temperatures associated with the cheesemaking process, their development may be extremely rapid, and the consequent deterioration in quality will prove both puzzling and worrying to the cheesemaker.

Methods Which Should Ensure a Cleaner, Better Quality Milk Supply.

As a general rule, little trouble is experienced with the quality of milk during the colder months of the year, but it is quite another story with the advent of warmer weather. Unfortunately, it is not compulsory to cool milk in South Australia, for though this treatment was provided for in the Dairy Industry Act, the clause was deleted soon after the Act became law. Most other States where dairying is practised to any extent make this a compulsory measure, and, may it be said, greatly to their advantage. While no one cares about compulsion, and would much prefer voluntary tactics, the practice would never become general unless strict enforcement was made possible.

The Value of Cooling.

If efficient cooling of milk was faithfully carried out by all suppliers, fully 50 per cent. of the present troubles would automatically disappear. To illustrate how greatly the keeping qualities of milk may be enhanced by cooling, a recent experiment could be quoted. During a warm spell some milk of reasonably good quality was divided into two equal portions. One half was cooled immediately after milking to a temperature of 70 degrees F., while the other received no treatment, and was merely allowed to cool down naturally as well as it could under the circumstances. The result was that the cooled or treated milk remained sweet for 80 hours, while the portion which was untreated became sour in the course of 25 hours. Such a definite contrast should surely commend the process of cooling to the dairymen of this district, and would probably be the means of saving much of the milk which is usually lost at this time of the year. Besides checking excessive acid and other bacterial development, cooling has the added advantage that it assists in reducing objectionable fodder taints which may be present in milk as a result of feeding cows on rank flavoured food. The mere act of cooling and exposure to the air during the process enables many feed gases to escape, but greater assistance will be given if the milk is regularly stirred at frequent intervals. Cooling, to be properly efficient, will need to be something better than merely standing the cans of milk in a tub or trough of water. Better results will be secured even by this method if the water in which the cans are standing is constantly changed. There is, of course, a far better way of cooling milk when one of the modern water-cooled milk coolers is utilised. The milk flows over the outer metal surface of the cooler, which is internally cooled by a continuous stream of cold running water. The midget types, suitable for a small dairy, receive their water supply from a water bag, but the larger ones, requiring a bigger flow of water, are usually connected directly to a water tap. The cost of a cooler is not so very great when the wonderful improvement achieved in quality by its use is taken into consideration, and with ordinary care a cooler should last a long time.

Yard Contamination.

The cleanliness of the surroundings where milk is kept, and the effect on its purity and keeping quality, is a much more important factor than many producers imagine. Otherwise, the more or less general practice of at present allowing milk to remain all night on a stand in the vicinity of the milking yard would not be permitted to continue. There is, firstly, the danger that the milk may absorb certain yard odours of objectionable nature through direct exposure to them, and, secondly, windy nights will favour direct bacterial contamination through dust, &c., filtering into the open cans. In this way quality may be quite seriously affected on occasions, no matter how clean or careful other procedures may be. It is unfortunate, though nevertheless true, that some of the very worst forms of organisms are transmitted to the milk in this manner, frequently resulting in untold damage to the quality of cheese manufactured from it.

The Effect of High Acid.

Although the South-East enjoys a fairly temperate climate, at certain periods of the year the acidity of some of the milk received at factories is much too high to entertain any hope of making high quality cheese from it. Acidity in milk or cream refers to the lactic acid which develops in it as a result of a bacterial fermentation, in which the milk sugar or lactose becomes converted into two separate products, namely, lactic acid and CO_2. In some cases—particularly where no additional bi-products are released during the fermentation—it could be described as a clean fermentation. There are, unfortunately, a great many objectionable types of organisms which, besides lactic acid producing, form many other bi-products, including gases, which are naturally injurious to flavour, and makes them most undesirable. For this reason, any milk containing a high percentage of acid is usually considered as doubtful, and always open to suspicion.

The degree or percentage of acid in milk can be readily ascertained by a quick titration test. This test involves the use of two solutions: the first, an alkali, which is usually a deci-normal solution of sodium hydrate; the second, a chemical indicator, known as phenolphthalein. The first solution is used to neutralise the acid in a carefully measured volume of milk (9 c.cs.), to which 3 drops of the indicator have already been added. The development of a faint pink tint in the milk denotes when neutralisation has taken place. The percentage of acid in the milk is determined by the amount of alkali necessary to produce this delicate shade of pink, and the higher the acid the greater the quantity of alkali required.

Most cheesemakers experience difficulty in making cheese of even fair quality from vat milk exceeding 0.2 per cent. of acid. Even allowing for the fact that the bulk of the milk received has an initial acidity of 0.15 to 0.17, no individual can of milk should be received for cheesemaking purposes which tests 0.3 or over, and even this seems to be a trifle too high.

WHEY CARTING IMPROVEMENTS.

There is no doubt that the local cheese factories have effected a wonderful improvement in milk quality by asking their suppliers to refrain from carting whey home in the cans ordinarily used for milk delivery. While this measure may have appeared rather tedious and inconvenient to several of the larger suppliers, it is pleasing to record that they have accepted it. Results have shown that it has been well worth while, if one is permitted to form this conclusion from the improvement in the standard of grading. In addition, the washing and steaming of milk cans in vogue at some factories should prove a boon to suppliers who have not got the same facilities at home to do this work.

This matter has also made a considerable difference to the value of the produce, and no doubt will commend itself to other factories when time and finance permit of suitable can washing arrangements being installed. The fact is that with present selling conditions on a greatly overloaded market, we cannot afford to neglect any opportunity which presents itself for the improvement of our product. If we do, the more progressive enterprising manufacturer must assuredly gain by capturing the bulk of the trade, at our loss and ultimate disadvantage. These remarks refer principally to matters associated with milk and cheese manufacture by reason of the fact that this industry is more strongly represented here than that of buttermaking. In a fairly wide sense, however, many of the points apply equally as well to cream and to butter.

It is regrettable that the development of an over-keen competition for cream supplies between the various factories has created an awkward position, which does not always permit of the best grading tactics being faithfully carried out in every case from factory to factory. This perhaps does not apply so much to the South-East as it does to other parts of the State, where butter factories and cream depots are more numerous. The result of such a position is obviously very unsatisfactory, for besides being very misleading from the suppliers' point of view, it is uneconomic and commercially unsound. Proof of this may be gleaned from the fact that the grading of South Australian butter during the season has been anything but satisfactory, and it appears high time that the whole scheme was revised and tightened up. During the warmest weather we have experienced it has proved a very difficult matter to obtain anything like a fair percentage of good choice cream, despite what factory returns might lead us to believe.

The commonest fault noticed in cream is that of staleness. Next to this comes "unclean" taint, followed by strong, feedy flavour; then "metallic" and "tallowy" flavours. The first-mentioned fault—that of staleness—is due to the fact that the cream is held too long by the supplier before being delivered to the factory. In some cases small supplies and transport difficulties are factors which militate against prompt delivery of cream, but the reasons quoted, though probably quite sound and excusable under the circumstances, are not in every instance responsible for the great bulk of stale cream arriving at our factories and depots. With some suppliers I know that a false belief exists that factories cannot churn fresh cream, or possibly that the older the cream becomes the more the test improves. Both these arguments are quite unsound, but whichever the reason, the sooner suppliers can be impressed with the necessity for a fresh cream supply, the better for each of them individually, and the industry as a whole. Unclean taint is another trouble which becomes predominant in cream at about this time of the year. While some of the fault might be attributed to the greater activity of undesirable organic growth under more favourable conditions of temperature, some blame at least is due to the rush of harvest work, resulting in the separator only being washed once a day. When the bowl of a separator is used in an unclean condition, the amount of contamination is surprisingly high, and to anyone who is unacquainted with this fact, I would suggest that they examine it for themselves by pulling the bowl asunder. Once they have done this they would doubtless be convinced of the damage they are inflicting on the quality of their cream, and would not feel disposed to continue with this practice.

UPPER NORTH DISTRICT.

(PETERBOROUGH AND NORTHWARD.)

WEPOWIE (Average annual rainfall, 12.46in.).

September 10th.—Attendance: 11.

Mr. J. Jasper read an instructive paper, "Care of the Harvester." A good discussion followed.

Eleven members attended the meeting on October 1st, when Mr. E. L. Orchard (District Agricultural Instructor) delivered an address.

WEPOWIE.

February 11th.—Attendance: 8.

HARVEST REPORTS.—Mr. J. Burns reported: Ranee, on stubble 14bush., on fallow 17bush.; Nabawa and Felix, 15bush., Waratah, 12bush. Mr. J. Crocker: Ranee 4H, 18bush., Nabawa, 15bush. (these varieties were sown dry, and yielded 12bush. and 11bush. respectively), Sultan, 10bush. Ranee, he stated, shook freely, and Nabawa lodged badly. Mr. T. Orrock: Ranee 4H, on ley land fallow, 15bush., on stubble fallow, 18bush., Felix, 18bush., Dundee 15bush., Ghurka and Nabawa, 12bush., with a farm average of 16bush. Mr. W. Roocke: Turvey, Kerley's Early, Ranee 4H, Sword, Nabawa, and Sultan gave a fallow average of 14½bush., stubble sown wheats, 12bush. Mr. H. Noske: Ranee, 12bush., after being very badly shaken, Nabawa, which lodged, 9bush., Joffre, attacked by hoppers, 9bush. Mr. E. Roocke: A 14bush. average over a large area, covering stubble and fallow, Ranee, 20bush., Free Gallipoli, 12bush. and 18bush., Waratah and Sultan, 15bush. and 10bush., Ranee 4H and Ranee, 16bush. and 15bush., Nabawa, Sword and Waratah, 15bush., Sultan and Ranee, on stubble, 10bush. (Secretary, E. Roocke.)

MIDDLE NORTH DISTRICT.

(PETERBOROUGH TO FARRELL'S FLAT.)

BEETALOO VALLEY (Average annual rainfall, 23.50in.).

February 18th.—Attendance: 11.

HARVEST REPORTS.—Members' reports on the 1934-5 harvest indicated very favourable returns. Many varieties of wheat received a severe setback early in the season, but responded to the excellent finish. Currawa averaged 27bush. to 30bush., and Ranee 30bush. Other varieties returned fair yields, but severe storms reduced their yields very considerably. Barley returned approximately 10 bags per acre. Mr. Halse reported having sown 1 bag of seed (Victorian) oats, from which he reaped 31 bags. The wool clip was light, and lambing percentages low, owing to lack of feed. Citrus crops are fair, with other fruits good. (Secretary, B. Giddings.)

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

BLACK SPRINGS.

February 14th.—Attendance: 9.

HARVEST REPORTS.—On the average, yields of cereals during the past harvest were reported as having been quite satisfactory. In some cases excellent averages were recorded, although heavy losses were caused by wind and grasshoppers. Gallipoli was the most popular wheat. (Secretary: K. Dunn.)

SUTHERLANDS (Average annual rainfall, 10.88in.).

November 1st.—Attendance, 14.

OUR BIRDS OF PREY.—In the course of an address on this subject Mr. E. Boehm referred to the hawks, owls, &c., that were observed in the Sutherlands district; and

exhibited stuffed skins from his collection. He pointed out that a good deal of confusion existed concerning the various birds of prey, the valuable birds often being mistaken for those that were destructive. Mention was made of the hawks that destroyed grasshoppers and other noxious insects, and it was shown that by preying on weak specimens of other birds the hawks helped Nature to maintain her balance. The nocturnal birds of prey took mice and rats and also large numbers of injurious insects. Hawks which should be protected by the farmer included the Nankeen Kestrel, Brown Hawk, Grey Falcon, Sparrow Hawk, Spotted Harrier, Black-shouldered Kite, Little Eagle, and Whistling Eagle. Those which did some damage and should be kept under control were the Little Falcon, Common Goshawk, and Wedge Tailed Eagle. The nocturnal birds which deserved protection were the various kinds of Owls, Nightjars and Frogmouth.

A previous meeting was held on October 4th when reports of the delegates who attended Congress were received and discussed. (Secretary, E. Schiller.)

TRURO (Average annual rainfall, 19.95in.).
November 19th.—Attendance, 12.

SHED CONSTRUCTION.—Paper read by Mr. L. Miller: "Although the construction of up-to-date farm buildings usually requires the services of a tradesman, quite a number of useful buildings can be erected by the average farmer, providing a little forethought and judgment are used. Every farmer who takes a pride in his horses will see they are provided with protection from the weather. I fully realize the difficulties that confront a settler taking up an unimproved property. Usually a few fork posts and rails are quickly erected, covered with straw, with perhaps mallee shorts or straw around the back and ends, but where practicable, a stable should be built of stone walls, with a gable iron roof facing the north, with an open front, built in size according to circumstances, and preferably on sloping ground to allow for drainage. A good, roomy manger, constructed of timber and flat galvanized iron, is most economical and efficient. This should be erected for each horse, so that every animal gets its share of the feed without interference. A separate compartment or loose box at the end of the building is always useful. A stable should be enclosed with a strong post and rail and wire-netting fence, extending from each end for several yards, from 4ft. to 6ft. high. This will make a poultry-proof enclosure and a building strong, durable, and fireproof. Where a chaffing plant is erected, this should be done immediately at the rear of the stable or at the most convenient possible place. The next building of consideration is providing weather protection for the implements. This can be done neatly and cheaply with three rows of good strong fork posts to carry the beams placed 3ft. in the ground; the centre row should be 3ft. to 4ft. higher than the outside. Rails wired from the centre beam to outside beams and covered with a thick layer of straw will keep the place dry in the winter and cool in summer; ends and back closed with corrugated galvanized iron will complete an excellent implement shed, and one that can be converted into a shearing-shed when the occasion arises. It may also be used as a protection for vehicles.

A barn for the conservation of corn is also important; one of timber and galvanized iron would prove the cheapest, with a board floor or gravel and cement, and where possible, erected on sloping ground with a door at the back and front, so that the back door is level with the ground and the front door about 4ft. from the ground, which will prove convenient for unloading and loading. Shelter or housing of cows: The proposed Dairy Act provides all the information regarding an up-to-date dairy yard, and anyone contemplating the erection of same would be well advised to build on those lines.

In connection with cover for poultry, this can be done quite effectively when it is only a case of providing shelter at night with either a timber and iron or iron and straw building, but it must be cosy and free from draughts. Where poultry is continually housed, up-to-date pens should be built to get the maximum results. Plans can be obtained from the Department of Agriculture.

The pig is content to seek shelter in a straw stack, but in the case of a farrowing sow, a properly fitted pen should be provided for best results; there are many good examples in our district.

On no account bunch too many buildings together, yet they should not be separated too widely; each construction should be distinct and outstanding, although it is quite obvious that very few farmers actually have the privilege of wholly improving their farms, as many go on to improved places, and what was good enough for the other fellow is good enough for them. Others are content to carry on where their forefathers left off, and there is hardly one farmer in a hundred who has his farm buildings just as he would desire them. Every farmer should do his best in erecting good farm buildings, for apart from being convenient and pleasing to the eye, they often more than repay the outlay involved if the property is sold, and will frequently realise pounds more per acre on account of being well improved. Good farm buildings in most cases reveal a prosperous farmer and a high producing farm." (Secretary, L. Davis.)

SUTHERLANDS (Average annual rainfall, 10.84in.).
February 7th.—Attendance: 29.

FAT LAMB RAISING.—Mr. W. Schiller read the following paper:—"The production of fat lambs for the export trade is now a factor in the primary industries of the State, and is destined to play a large part in the future progress of South Australia. It is therefore up to farmers to improve the standard of their fat lambs in order to meet the requirements of the overseas buyer. Do not think that the buyer will take whatever type of lamb is offered to him. If the fat lamb trade is to be developed producers must offer the lamb for which the buyer can find a ready sale. The overseas market demands a light-weight lamb, dressing 32lbs. to 36lbs., for which the buyer is prepared to pay a higher price, even if the quality is not quite so good as that of the heavyweight lamb. Naturally the aim of the breeder will be to produce the most profitable lamb under the conditions which obtain in his district.

THE MOTHER.

The ideal mother of the export lamb is either the Longwool-Merino crossbred ewe or the Corriedale. They are more prolific and less liable to parturition troubles than the Merino in lamb to British rams. The lambs mature quickly; the ewes have a decided tendency to produce twin lambs, and can be mated to carry lambs as 2-tooths. When too old for breeding they can be readily sold to the butcher. The only disadvantage is that they do not grow a fleece equal in quality to that of the Merino. It must be admitted that they are bad fencers, and in this district difficult to obtain. Where Merino ewes are to be mated they should be large, plain-bodied animals, from 5 to 6 years old. These animals will produce bigger lambs, and a better percentage. They make good mothers, and are less liable to lambing troubles than 4-tooth maiden ewes. The Merino is essentially the sheep of the country, and the ewes can be obtained in unlimited numbers. It is possible in special cases for farmers to breed their own crossbred ewes, but on a small farm this is not a profitable undertaking. Where the ultimate objective is the raising of fat lambs, it would render unavoidable the simultaneous presence on the farm of small groups of sheep of various grades which, on a small area, would result in confusion and loss. For the beginner, a line of station-bred cast for age ewes is the most suitable. They have generally withstood several cullings, and as a rule make a very even line, whose fleeces are more to be desired than an uneven or nondescript line. Their natural timidity can be overcome by careful and gentle handling.

THE SIRE.

The utmost importance attaches to the appropriate choice of the sire, particularly so when ewes are Merinos. There are three special characteristics which the sire must be expected to impress upon his progeny—early maturity, good bodily conformation, and high quality flesh. The sire must also come from a breed possessing a high degree of prepotency. From the standpoint of quality of meat, the Merino leaves much to be desired. It is long, narrow, flat ribbed, high in the withers, very irregular in top and bottom outline, with poorly developed legs and coarse bone. If Merino ewes are to produce lambs with the desired type of carcass, then there is no better sire than the Southdown. In this district the Dorset Horn is more favoured. The lambs from this cross are well suited to the local market, and owing to their rapid development, command

● FULL MOON.

high prices when fat lambs are scarce. The lamb from the Shropshire ram is of irregular conformation, and the lambs have a tendency to wool blindness. The Suffolk produces a very good lamb, but the carcass is not so shapely. The Corriedale ewe is a valuable mother, but the ram is not suitable for fat lambs. The English Leicester must be considered as a ram for fat lambs, but the flesh has a tendency to tallowiness. The size of the fat lamb flock will naturally depend on the amount of pasture available. Overstocking must be strictly avoided, but at the same time understocking will prove a losing proposition. Hand-feeding during the late autumn and early winter will pay the fat lamb raiser handsomely, a good ration for the ewes being 1lb. of oats and 3lbs. of chaff per ewe per day.

GENERAL MANAGEMENT OF THE FLOCK.

Do not limit the number of rams, and British-bred rams will not work if alone. Three rams to 100 ewes is a good percentage. Any ram after he reaches full-mouth cannot be relied upon. Ram lambs from 6 months old will work quite effectively, but this will certainly check their development. Join the rams not shorter than a fortnight after dipping, and leave them with the ewe for 8 to 10 weeks. The ewes should be in good forward condition, and maintained at such right through the gestation period. The best time to start mating is some time in December, so that lambs will drop from about the end of April until the middle of June.

As lambing approaches, the ewes should be put into sheltered paddocks and visited at least twice each day to render any assistance that might be necessary. After lambing, remove the dry ewes from the flock, and give the lambs and ewes the best pastures available. Much benefit will be obtained if a frequent change of paddock is made. Tailing should be done when the lambs are about 2 weeks old. If the lambs are to be marketed when they carry that bloom which is so desirous to the buyers, then it is most important that they have access to a plentiful supply of green fodder right through their lives. When the time comes to market the lambs, on no account handle them by the leg or wool; this causes bruises, and renders the carcass unfit for export. Catch each lamb behind the forelegs and the brisket. When trucking never poke them with sticks." (Secretary, E. Schiller.)

YORKE PENINSULA DISTRICT.

PASKEVILLE.

February 12th.—Attendance: 11.

HARVEST REPORTS.—It was generally agreed that returns were favourable, especially in view of the late seeding and the unfavourable weather that was experienced prior to August. Ranee ranked as the highest yielder, and Burra gained in popularity this year, but several members reported that it shook rather badly. Other varieties that did well were Glueclub, Ford, Waratah and Nabawa. The barley sample was superior to that for the past few seasons, with yields light to moderate. (Secretary, J. Prouse.)

WESTERN DISTRICT.

MOUNT HOPE.

November 20th.—Attendance, 8.

THE CARE OF SHEEP.—Mr. G. Vigar read the following paper:—"Sheep are the most important industry in this district, and they should be handled in a commonsense way. First get your country fenced securely. Have the land securely fenced with a six-wire fence, and if possible water in every paddock. Sheep should not have to travel more than a mile and a half for a drink. The Merino is the most suitable breed for this district; they give a good yield of wool, are also useful for mutton, and quiet to handle. Give them attention all the year round; they should be inspected at least twice a week, and see that the water and feed are always present in abundance, and a look-out kept for blowflies. There is often a heavy loss of sheep through fly. Crutch during March or April, and clean the wool off the eyes; a number of hoggets will die during the year if this is not done, through not being able to see where the feed is, also running into every bush they come to. The best time to shear in this district is during September and early in October. I prefer the blades for shearing, as they do not cut as close as the machines. Care should be taken in getting up a clip, even if it is only a few bales. Make two grades of wool: all the brighter and stronger wool to be marked as AA and the duller and weak wool be marked A. The fleece should be skirted, all the raggy ends removed, and sandy backs taken out. Oddments should be marked; pieces, stains, bellies, table locks as the case may be, and the bales branded and numbered, and a correct statement forwarded to the wool broker. After shearing the sheep should be dipped, using a reliable brand of dip. During shearing cull the flock; first cast for age; mark for sale or killing all broken-mouthed ewes and full-mouthed wethers, and if enough lambs to warrant it, mark any poor quality younger sheep. The best time for lambing is during June. There should then be some green grass about to ensure the ewes having milk for the lambs. Mark the lambs when they are from a month to six weeks old. In order to secure an abundant supply of feed for sheep, top-dress the paddocks with about 60lbs. of super per year. When this is done the Clover soon shows up and takes the place of Barley Grass and Silver Grass. All the country about this district would carry a sheep to the acre if it were top-dressed with 60lbs. of 48 per cent. super per year. This would mean that at a cost of about 3s. per acre the carrying capacity of farms could be doubled. We have a regular and reliable winter rainfall in this district, and the super makes the grass grow during the winter months." (Secretary, J. Vigar.)

ROBERTS AND VERRAN.

November 15th.—Attendance, 16.

FAT LAMBS.—The meeting took the form of an inter-branch visit from the Taragoro Bureau. Mr. J. Crooks read the following paper:—"First obtain suitable ewes, and as Merinos are practically the only breed available, it is necessary to obtain the type. The ewe should be short in the neck and legs, broad in the back, with well sprung ribs, deep in the sides, and plain-bodied. For the sire, I would choose a Southdown or Ryeland. The Southdown is short-legged, short-bodied, and very sturdy of build; the Ryeland is taller, but similar in character, and both types should be ideal for producing the lamb required for the fat lamb trade. One feature of the Ryeland lamb is that it retains its bloom much better than most breeds. The ewes should be in good condition at the time of mating, and kept so, right through the gestation period. Six weeks before they are due to lamb all ewes should be crutched and the wool trimmed away from the udder. Immediately the ewes begin to lamb they should be turned into a paddock set aside for the purpose; a lamb born of a well-nourished and cared-for ewe has an excellent foundation and a good start in life. Have sufficient feed in paddocks, and also for hand-feeding if necessary. If fat lamb raising is to be turned into a profitable business it is necessary to topdress pastures, and to sow feed in paddocks for the ewes and lambs, preferably with barley, oats, and wheat, so that the ewes and lambs can be changed frequently from paddock to paddock to ensure frequent and succulent changes in pasture, which is very necessary to young growing lambs. If one relies on natural grasses for feed, success of a limited nature only can be expected. If fat lamb raising is to be made profitable it requires care, attention, and forethought as to pasture and the needs of the prospective client, for you must be prepared to sell him what he requires and not what you think he should take. His trade is governed by his consumers, and in turn must react accordingly. The time for fat lambs to drop is largely a matter for the individual to judge, as lambs born on greenfeed are far better lambs at birth and make far better growth than those born on dry feed. In conclusion, have the ewes in good condition, have a sufficient number of rams, and when yarding for trucking, handle the lambs carefully. This is where trouble with most rejects starts. Rough handling means badly bruised lambs. Last but by no means least, grow good feed and plenty of it and make some attempt at topdressing natural pastures."

Discussing the paper, Mr. A. Edwards considered if plenty of good green feed was available any breed would grow good lambs and fatten quickly. Mr. A. Cowley said certain types of sheep produced a better type of lamb than another, therefore it was essential to have the right type of ram for fat lamb raising, also to have good young strong ewes for success. Mr. Winters thought Border Leicesters a dual purpose breed, producing a good lamb, and if there were any rejects they could be kept, as the wool did not deteriorate as it did with some English breeds. Mr. C. Marters said it was necessary to have the right type of rams and ewes for success in lamb raising. Feed was also essential; he advised sowing feed as well as natural pastures. Mr. H. Smith said if certain classes of sheep were allowed to become crossed with different types, their wool would not weigh so heavy. He advised members to make sure that this did not occur, and said crossbred lambs were necessary for fat lamb raising, but would not allow any to mature. Pure Merino ewes should be used in this locality. Fencing should be worked out systematically. All fences should be put up permanently, thus saving time and labour. Water was as essential as capital. If no water mains were close he advised scooping for dams. Generally speaking, capital was the biggest handicap.

Developing a New Farm.—Paper read by Mr. E. James:—"Anyone taking up a new block should have, if possible, sufficient capital to purchase a plant suitable to the rough work to which it will be subject during the process of clearing. Choose a site for homestead and outbuildings as near the centre of block as possible, which keeps the farmer within reasonable distance of future paddocks. In making the first clearing, clear a definite shaped paddock, starting at the house, so that permanent fences can be erected as clearing progresses. The implements most suitable are a good disc plough, disc drill and harrows, and for harvest a stripper and power winnower. In this district —which is of the low mallee type—the disc plough successfully ploughs the land and deals with sticks and shoots, and the stripper will reap successfully on any class of land. It is lighter to pull than a harvester. In clearing, roll in spring and burn the following year. If a good, clean burn has resulted, it is quite safe to crop that year, but if through bad weather or thin scrub a bad burn results, fallow instead of crop. Fallow all new land if possible and sow early wheats. The firerake is probably the cheapest implement of the lot, but it is one of the most important in developing the block. Introduce sheep as soon as there is land available; they are a most valuable sideline; they provide meat for the home, proceeds of the wool clip, and the land is improved for wheat-growing." Discussing the paper, Mr. A. Cowley did not agree that the central position was the best for a homestead. There were many things to be taken into consideration, such as water mains; if no water, the most suitable place for dams; also the outlet from the farm to the town or main roads, and fences. After considering these things one could proceed with the laying out of the homestead. He favoured placing the homestead near the main road, especially if a water main was available. Make a rough sketch of all buildings, fencing, &c., and put up permanent structures if possible. He favoured clearing along one boundary first, gradually working away from the homestead. Mr. Crooks (Taragoro) thought the writer's choice of implements good. He favoured clearing 400 acres the first year, 200 sown to wheat and 200 fallowed. He would clear along a main road first. The site for the homestead depended on the water position. Sheep were essential as soon as possible. Mr. Barber said spring time was the wrong time to roll scrub; winter was best. The young shoots got a start before burning, thus giving a second check. He favoured a house in a central position; it saved time travelling backwards and forwards. He thought a dam too close to the house a nuisance. Mr. Whittaker (Taragoro) considered water was as essential as capital. One was no use without the other. He would put his homestead "on a water main" if possible. There was no advantage in building in a central position unless the water could be laid on. Mr. Ramsey said he would make his homestead near a road, especially if water was available. Mr. T. Winters favoured building a homestead as near to a water main as was convenient. He would leave a belt of scrub round a homestead for protection, and build permanent structures where possible. By doing so one soon had something which was an asset. Protect all machinery by building sheds—brush or straw if nothing else was available. Machinery could not be over-cared for. It was expensive to buy and demanded care if one is to succeed. Every farmer should make his farm attractive by planting trees along fences, especially the main entrance. Through the medium of the Bureau farmers had every advantage, and by working with a system and careful observance, one should be able to carry through. Records were essential, book-keeping necessary, and a diary most useful and easy to keep written up. Mr. C. Masters said the position of the homestead depended on the water problem. A saving in capital could be made by working off another block, gradually starting instead of going straight on to a new block. Build a stable and implement sheds as soon as possible. Mr. Smith thought a central position for the homestead was essential. He said water could be laid to the homestead, but it was not an easy matter to move the homestead when once established. He favoured clearing small portions of scrub at a time, and rolling scrub early in winter. Stake fences would serve until permanent ones could be put up. Disc implements were essential. (Secretary, C. Masters.)

EASTERN DISTRICT.

LONE GUM AND MONASH.

At the February meeting the president (Mr. W. R. Henwood) was in the chair. Messrs. N. Fotheringham (Manager of the Berri Experimental Orchard) and F. R. Arndt (District Horticultural Instructor) took advantage of the opportunity of bringing under the notice of members the grave danger which was threatening from a further visitation of grasshoppers. It was decided that the committee should take the matter up and formulate some scheme to assist in checking the grasshopper menace.

Messrs. K. B. Hocking and H. March gave short addresses on the subject of the classification of dried fruits, and related some of their experiences in the grades and general chracteristics of the fruit seen by them in various districts.

Our Fruit in England.—Mr. J. O'Callaghan, who has recently returned from a trip to England, commented very strongly on some of the poor samples of fruit seen by him in the sale-rooms. In his remarks regarding citrus, Mr. O'Callaghan commented very favourably on a shipment of Australian oranges seen and tasted by him. There was no doubt as to the quality, but he could not help contrasting the general get-up for the public between our fruit and some he had seen from South Africa, which, although undoubtedly inferior fruit to ours, exhibited in an attractive manner under glass and the glare of coloured lights, and with a neat black band around the fruit, sold exceptionally well.

SOUTH AND HILLS DISTRICT.

BLACKWOOD (Average annual rainfall, 27in. to 29in.).

There was a large attendance of visitors, including the Hon. A. P. Blesing, M.L.C. (Minister of Agriculture), Messrs. L. S. Smith (Secretary to the Minister), Mr. G. Quinn (Chief Horticultural Instructor), Mr. A. G. Strickland, M.Sc. (Deputy Chief Horticultural Instructor), Mr. E. Leishman (District Instructor), Mr. F. C. Richards (Assistant Secretary Agricultural Bureau), and members of Hills Branches of the Agricultural Bureau, at the Blackwood Orchard on 1st February, when the local Bureau held its annual field day. The Manager of the Orchard (Mr. R. Fowler) conducted the visitors through the Orchard, and explained the various experiments that are being carried out. Mr. Strickland also took the opportunity of discussing with growers the regulations that will be in operation during the forthcoming fruit export season.

CHERRY GARDENS (Average annual rainfall, 35.03in.).

19th January.—Attendance: 15.

GARDENING.—The following paper was read by a junior member of the Branch, Master R. Elliott, and outlines lessons in gardening as taught at the Scott's Creek School:—"We have 11 experimental plots at the school, and it was from work on these plots that I am learning how much more interesting and successful it is to do the work as shown by our teacher. Each plot is exactly the same area, so that it is possible to estimate how much fertilizer is required at the rate of so much per acre. To prevent the goodness from one plot creeping into the other, it is necessary to have a barrier; to do this, paths are made 2ft. wide. On account of the nature of the ground, the hoe helps to keep the moisture in the ground, where it is most easily obtained by the plants, and in this way maximum results are secured from the manure. Before planting the ground is dug deeply. Each pupil has one plot, girls as well as boys. The plots are all numbered, and in each is planted eight different kinds of vegetables, so arranged so that if potatoes are planted in No. 1 plot, No. 1 row, No. 1 row in No. 2 plot would be lettuce. No. 1 plot is planted as follows:—No. 1 row, potatoes; No. 2 row, onions; No. 3, peas; No. 4, cabbage; No. 5, lettuce; No. 6, carrots; No. 7, silver beet; No. 8, potatoes. No. 1 row in No. 2 plot is lettuce; No. 2 row, carrots; No. 3, silver beet: No. 4, potatoes; No. 5, onions; No. 6, peas; No. 7, cabbage; No. 8, potatoes. The other nine are planted in the same manner as No. 2 plot, but with dif-

ferent manures. No. 1 plot has no manure and no rotation. No. 2 plot no manure, but rotation; No. 3, superphosphate and lime, rotation; No. 4, sulphate of potash. The results are about equal. Fairly good. No. 5, nitrate of soda; No. 6, super, sulphate of potash, and nitrate of soda; No. 7, sulphate of ammonia. These three plots are slightly better than the last four plots. No. 8, stable manure. The improvement on this plot against the others can easily be seen. No. 9, green manure. This plot is about equal to No. 8, but the moisture is greater than the other fertilizers or manures, and compared with the manures of the first eight plots, this is the best. No. 10, stable manure and combined fertilisers; No. 11, combined fertilizer, lime, and stable manure. We put 4cwts. of fertilizer per acre on the plots with the exception of No. 8, which has 20 tons per acre. These two last plots stand out as excellent, and are the best we have. In all the plots excepting No. 1 we have rotations, *i.e.*, the last row in the plot this year is moved to the first next year; which means that all the other rows move towards the bottom, at the rate of one row per year. Carrots and onions do well on No. 1 plot, which has no rotation, but cabbages and lettuce and the rest of the plants do much better in the rotation plots than those in the no rotation plots. If ever I take up gardening, I will remember that these experimental plots have taught me that to grow good vegetables, fertilisers and keeping the ground well worked are necessary to grow good crops.'' (Secretary, A. Stone.)

Hills Branches Field Day, Blackwood Orchard, 1st February, 1935.

HOPE FOREST.

February 4th.—Attendance: 14.

Mr. Bevan occupied the chair, and the meeting was devoted to a discussion on subjects of local interest.

The Annual Field Day of the Branch was held at the residence of Mr. Wollaston on February 16th. Mr. Wollaston gave a demonstration of the handling and working of bees. (Secretary, E. Muldoon.)

AUBURN (Average annual rainfall, 23.98in.).
January 25th.—Attendance, 16.

TOWN VERSUS COUNTRY LIFE.—Mrs. Blatchford occupied the chair at the January meeting which took the form of a debate on the above subject. Mesdames Giles, Schmerl and Burfield spoke in support of the advantages of country life. In the course of their remarks these speakers contended that there was more freedom in the country and that the children were healthier and happier. Good fellowship was more in evidence in the country, home life was worthy of the name, and living was cheaper with plenty of meat, butter, milk, cream, eggs, fruit, and vegetables. There was not the hustle and bustle of the city and residents in rural districts were able to lead a more peaceful life. Mesdames Stephen and Kench and Miss Dennison argued in favour of town life. They claimed that in the city, the homes were equipped with many conveniences and labour-saving devices, beautiful gardens could be laid out and attended to without any fear of having to give up the work because of a shortage of water. Facilities for the purchase of home necessities were undoubtedly better and cheaper, the children could be given the best education and there were more organizations for women to belong to and take part in public affairs. With these advantages the city dweller had infinitely more time for recreation and pleasure. A vote taken at the conclusion of the addresses decided in favour of the advantages of country life. (Secretary, Miss L. Dennison.)

BELALIE (Average annual rainfall, 17.71in.).
October 2nd.—Attendance, 40.

BABY'S RIGHTS.—Paper read by Mrs. J. Davies.—"Let me preface my paper by a quotation from Socrates, 'In every work, the beginning is the most important part, especially in dealing with anything young and tender.' The extreme importance of care and system in the rearing of babies is becoming universally recognised; modern mothers are applying themselves more and more to the theory of the upbringing of children in contrast to earlier days, when haphazard methods were used, with a consequent far

greater infantile mortality rate than is the case under present-day methods of care and treatment. The days when baby was fed when he was hungry, slept with his mother, or very often between mother and father are over. Every baby who makes his bow to this world has his rights as has every citizen of the great British Empire.

Pre-natal Care.—Give baby every chance by keeping mother healthy before his birth. She should lead a normal healthy life, walking briskly (not sauntering) at least two miles every day in all weather, thus ensuring fresh air and sunshine and keeping her muscles toned up. She should not lead a life of semi-invalidism, at the same time avoiding over-exertion.

Feeding.—Breast fed is the best fed. No system of bottle feeding can ever give to the mother and child the advantages which both derive from suckling; nothing can rival milk drawn direct from the breast into the baby's stomach, pure, fresh living blood, warm and uncontaminated by germs. If it is impossible to breast feed baby, no pains must be spared to provide the best substitute suited to his own individual needs.

Regularity.—Bring up baby by the clock. He should have regular hours for sleeping, bath, exercise, regularity of action of bowels, and above all regular feeding times with nothing between meals but boiled water and fruit juice. Do not hesitate to wake him if asleep when meal time comes round and do not feed him during the night. A baby will soon become a 'real little clock.'

Fruit Juice.—Give baby orange juice which has been carefully strained, beginning with half teaspoon midday between meals after he is one month old. Prunes stewed without sugar and carefully strained may be given at an early age and are very valuable as laxative.

Fresh Air.—Let baby have plenty of sunlight and plenty of fresh air day and night. Never cover his mouth with anything, not even with muslin. The more baby is out in the open air the more he will thrive. Let him sleep in a room by himself whenever possible, or at least away from his mother's bed in a corner of the room away from direct draughts, but where the air can circulate freely.

Cleanliness.—Immaculate cleanliness in everything, especially with regard to food and utensils, which should be regularly sterilised and kept apart under fly-proof gauze.

Comfortable Clothing.—Clothing should be light, porous, and warm, free from irritating properties, sufficiently loose to allow perfect freedom of limbs and free play for expansion of chest and abdomen, but not so loose as to ruck into folds. Beware of constricting tapes and belts. A binder should be discarded as soon as the cord is healed.

Bathing.—Bathe baby quickly in a cosy corner—no dawdling or playing. Dry him thoroughly, especially about all folds of skin.

Do not give baby a dummy. It is utterly unnecessary. It deforms the jaws, teeth, and palate, and causes saliva to dribble, thus interfering with digestion. Further, it is a leading cause of adenoids. A baby needs abundance of sleep. Proper mothering and handling of a baby are essential for the best growth and development. Every baby should have his mothering time every day. Weaning should commence at from nine to 12 months. Up until then, milk has supplied all his needs, but the time has come when he must learn to assimilate solid foods. At six months he can be given a chicken bone to gnaw to teach him to chew and also exercise his gums. During the 10th and 11th months, baby should be learning to eat, rather than eating solid food. Make all changes very gradually. He may be given a dry crust to nibble at. Prepare these crusts by cutting day-old fingers of bread and drying in oven with door ajar until crisp and lightly brown. Store in airtight tin. After awhile, scrape with butter; these are better than prepared rusks as they are not sweetened. Oaten or barley jelly, prepared by boiling oatmeal or barley for at least two hours and then straining through a fine strainer, makes an admirable 'first solid.' A day's supply can be prepared each morning. Vegetables, baked apple, &c., should all be rubbed through a strainer at first until baby has become thoroughly used to them. Give a raw, ripe apple as part of meal, but do not leave baby alone in case of choking until he has thoroughly mastered the art of mastication. Teach the child to chew by giving solid food, such as crust or bone, at the beginning of meal when he is hungry.'' (Secretary, Mrs. E. Orchard.)

McLAREN FLAT.

December 6th.—Attendance, 21.

Cake Competition.—A Sponge Cake Competition was held under the auspices of the Branch, and the following are the recipes of the winning entries:—*Plain Flour Section—First Prize,* Mrs. Bert Elliott: 3 eggs, ¾ cup sugar, pinch salt, 1 large cup plain flour, ½ teaspoon c. soda, 1 teaspoon c. tartar, ¼ cup hot water; beat eggs 10 minutes, then add sugar and beat 10 minutes. Add flour and rising and finally hot water; bake in a moderate oven 10 to 15 minutes. *Second Prize,* Miss F. Nicolle: 4

eggs, 1 cup plain flour, ¾ cup sugar, 1 teaspoon c. tartar, ½ teaspoon c. soda, 2 tablespoons cold water; beat eggs and sugar well, add other dry ingredients which have been sifted 3 times, then add water and beat lightly; bake 20 minutes. *Cornflour Section—First Prize,* Miss P. Green: 4 eggs, ¾ cup each sugar and cornflour, 1½ teaspoons c. tartar, ¾ teaspoon c. soda; beat eggs and sugar for 20 minutes, then add flour and rising; cook in moderate oven for 20 minutes. *Second Prize,* Mrs. Bick. Elliott: ½ cup sugar, 3 eggs, 1 tablespoon flour, 2 tablespoons cornflour, ½ teaspoon c. soda, and 1 teaspoon c. tartar. (Secretary, Miss I. Nicolle.)

MONARTO SOUTH (Average annual rainfall, 14in. to 15in.).

November 17th.—Attendance, 12.

WASHING WOOLLIES AND SILKS.—Paper read by Miss E. Hein:—"To wash silks so that they retain their freshness and colour, make a lather of the very best soap and water. Any chemical will remove the lustre and discolour silks, so add nothing else to the washing water. A garment of undyed silk that has become very soiled may be steeped for a little while in a weak solution of borax and water. To cleanse the silks, knead and squeeze them in soap and water, but avoid hard rubbing. Soiled parts should be rubbed on the palm of the hand with a little extra soap. Rinse the silks in two or three waters of the same temperature as the washing water, and into the last rinsing water add a few drops of methylated spirits. This gives the silk a nice gloss. As a general rule, roll silks to dry in a towel after squeezing out as much water as possible, and iron them while still damp. The washing and ironing of any silk should be accomplished in as short a time as possible. Japanese silk, crepe-de-chene, washing satin, and all soft thin silks, iron while wet. Fuji may be partly dried before ironing, and tussore silk should be dried thoroughly and ironed on the right side. Crepe-de-chene and any other silks with a raised pattern should be ironed on the wrong side. There are five reasons why woollies shrink—rinsing and washing waters of uneven temperature; woollens are left lying about wet; if not stretched into shape before being hung out; if water is too hot and cheap soap powders are used. Wash woollens in two or three lathers of good soap and warm water, then rinse quickly in several waters of the same temperature. Squeeze the woollens in a towel to get rid of as much water as possible before hanging out. It is essential that they dry quickly, so put them in a shady, cool place, where they will get a cool stiff breeze. When they are almost dry, press them on

the wrong side, with a cloth between the iron and garment; then air. When the baby's knitted, crocheted, or Shetland wool shawl has been washed, dry it on a sheet on the floor, or a lawn, with the points of the lace border pinned on the sheet. If the shawl is a very heavy one, it may be thrown over the line, but remember to change the position frequently. To wash blankets mix together 2 large teaspoons of borax and 1 pint of soft water. Put them in a tub of water. When the soap is dissolved, shake the blankets and put them into the tub and leave there overnight. Next day squeeze and knead the blankets, then rinse in several waters. Hang to dry without squeezing. Put the blankets in a windy place, where there is a moderate sun. See that the stripes are hanging perpendicularly to the ground, so that if the colours do run, they will not run into the plain parts of the blankets. Shake each blanket frequently. Some women use cloudy ammonia when washing blankets. It is an excellent solvent for dirt, but blankets are really still so clean when they are put into the wash that there is no necessity for using it. It cannot improve the blanket and certainly will do a lot of harm unless used in the proportions of 1 tablespoon of cloudy ammonia to 1 bucket of water. Ammonia means death to colours.'' (Secretary, Mrs. F. Liebelt.)

January 19th.—Attendance: 20.

Mrs. H. White presided at the January meeting, which took the form of a Biscuit Competition. Eight entries were judged by Mesdames Hartmann and Altmann, who made the following awards:—First prize, Mrs. A. Schubert; second prize, Mrs. F. Liebelt. (Secretary, Mrs. F. Liebelt.)

MORCHARD (Annual average rainfall, 13.59in.)

November 27th.—Attendance, 37.

Rice: the Food of the People.—Mrs. C. Schulz (Hon. Sec.) read the following paper:—Rice is the staple diet of half the people of the world and one of the highest grades of rice is grown in Australia. It is important that food for human consumption should be produced under hygienic conditions, and this is true of the rice grown and milled in Australia. Whilst no article of diet can claim to possess all the properties of an ideal ration, rice embodies them to a greater degree than any other meat, cereal or vegetable. It is so easily digested that doctors recommend it as the best food for children. It can be used in a host of ways for soups, stews, savouries, biscuits, cakes, etc., and it is very beneficial for invalids. The following recipes have been tested and their worth proved. *Rice Water*: 3ozs. rice, 1oz. raisins, 1 quart water and salt. Wash the rice three times and place in a stew pan with 1 quart of water and the raisins; boil gently for ½ an hour, strain through a sieve and drink when cold. *Rice Gruel*: 2 teaspoons rice, ½ pint milk, 1 teaspoon sugar, salt, cinnamon, brandy or sherry. Wash the rice and add boiling milk; simmer for 15 minutes stirring all the time. Add sugar, salt and a pinch of cinnamon or 1 tablespoon of sherry or brandy. *Invalid's Drink*: 3ozs. rice, 1oz. sugar, 1 tablespoon or raspberry or other flavouring, salt. Wash rice, boil in 3 pints of water until reduced to 1 quart. Strain, sweeten, and flavour with essence. *To Boil Rice*: 1 large cup of rice, 1 teaspoon salt, juice of ½ a large lemon in a saucepan containing 2 or 3 quarts of boiling water. Wash the rice in 6 waters; put salt and lemon juice in boiling water, then add rice. Boil fast for 20 minutes or until a grain tested between the fingers feels soft. Strain through colander, allow cold water to run over rice for a minute or so then place the rice in a colander over a saucepan containing boiling water. Keep water boiling and cover rice which will be ready for use in about 15 minutes. Always use lemon juice. *Sultana Cake*: ½lb. each butter, flour (plain), sultanas, sugar and ground rice, 1 teaspoon baking powder, 3 eggs and a little milk. Beat butter and sugar to a cream, mix powder in flour and add gradually fruit. Beat eggs thoroughly, add milk, beat all 5 minutes. Bake in moderate oven 2 hours. *Rice Biscuits*: ½lb. each flour, sugar, ground rice and butter, 1 teaspoon baking powder, 2 eggs and salt. Rub butter into flour, sugar, ground rice and baking powder; add eggs. Roll thin and cut with cutter. *Short Cakes*: 5ozs. butter, 6ozs. castor sugar, 4 eggs, 4ozs. flour, pinch of salt, 2ozs. rice flour, ½ teaspoon baking powder. Cream butter and sugar, add eggs one at a time, beating in well. Sift in the flour, rice, flour, salt and baking powder. Stir lightly until well mixed. Put in patty pans and bake in a moderate oven about 10 minutes. These cakes keep very well. *Rice Cheese Cakes*: Raspberry jam, pastry, 2ozs. butter, 4ozs. sugar and ground rice, 2 eggs, lemon peel and salt. Line patty tins with paste, put into each 1 teaspoon of raspberry jam and cover with curd made after the following directions—melt butter, beat with it the sugar, ground rice, lemon peel and eggs. Bake about 10 minutes. *Spice Cake*: 2 eggs, ½lb. plain flour, ¼lb. rice flour, 1 teaspoon each ground cinnamon and ground allspice, salt, ½ cup milk, 4ozs. butter, 5ozs. brown sugar, 1 tablespoon golden syrup, 1 level teaspoon carb.

soda dissolved in dessertspoon boiling water. Sift flour, rice flour, allspice, cinnamon, and spice. Cream butter and sugar, add eggs one at a time and beat in well. Add milk, then syrup, soda, and boiling water mixed. Add flour, etc., and mix lightly. Bake in a moderate oven 35 to 45 minutes. *Tasmanian Raspberry Buns*: 1 cup rice flour, 1½ cups flour, 1 teaspoon baking powder, ¼lb. each butter and sugar, raspberry jam, 1 egg, milk, and salt. Sift flour, rice flour, and baking powder. Rub butter into flour and sugar and mix into a fairly dry paste with the yolk of the egg and a little milk. Divide into small balls and roll each one out flat. Put ½ teaspoon raspberry jam on each round and close over the bun. Brush with white of egg and bake on a greased tray in a rather quick oven from 10 to 12 minutes. The buns will crack as they bake and show the jam. *Christmas Cake*: 6ozs. each brown sugar and butter, 8ozs. S.R. flour, ½lb. seeded raisins and sultanas, 4ozs. rice flour, ¼lb. each cherries and almonds, 3 eggs, salt. Beat butter and sugar to cream add eggs well beaten, then alternately sifted flour and fruit. Pour into prepared tins which must be lined with 2 thicknesses of brown paper and one of white. Bake 2 to 2½ hours in a moderately hot oven. *Rice Rocks*: 2 eggs, ¾ cup of sugar, 1 cup sultanas and peel, 1 level teaspoon soda, ¼lb. butter, ½lb. ground rice, 6ozs. flour, 1½ teaspoon cream of tartar, milk and salt. Cream butter and sugar, add eggs, then dry ingredients and fruit. Mix with milk. Drop spoonfuls on a cold tray and bake.

NELSHABY (Average annual rainfall, 17in.).

January 17th.—Attendance: 14.

VEGETABLE DYEING.—Mrs. Pearce read the following paper:—"Vegetable dyeing can be very interesting if one has the material at hand with which to experiment, but this district has not much from which to choose. Brown colours, ranging from nigger to the palest shades of fawn, can be obtained from the green husks of walnuts. The brown skins of onions, when boiled, will produce a rich yellow. Boxthorn berries also yield a vivid yellow. Wattle bark can be used to produce many shades of grey; other dies can be made from lichens, St. John's wort, quondong, and other wild shrubs. For the amateur, chemical dyeing is most satisfactory if a reliable dye is used. There are two methods by which dying can be done—by boiling the material in the dye bath, or rinsing in cold water dye. The former method is necessary if woollens or other heavy materials are to be dyed, or if a dark shade is required. To prepare the dye bath:—Dissolve the dye with boiling water in a small basin, and strain through a cloth so that it will be free from any residue. Put the solution into a vessel large enough to contain the material, which must be thoroughly immersed in the fluid, and yet leave ample room for stirring. The latter must be done continually to prevent spotting. Do not use an iron vessel, or it will leave stains on the material. Any material that is to be dyed should first have any grease marks removed, and be washed in the usual way, then put in a bath whilst still wet. Commence with the bath almost cold; the colour goes into the fabric more evenly at a low temperature, and does not spot or streak. Then raise the temperature gradually to boiling point, and simmer until the desired shade is acquired. If very dark shades are wanted, then the material must be left in the bath until the liquid is cold. Lift out the article when the desired shade is reached, and rinse thoroughly in clean, cold water, using warm water for woollens. Hang on the line dripping wet, and as free from folds as possible. Unless dying the material its original shade, it is advisable to remove the old dye, and this is particularly necessary when it is desired to dye the article a paler shade than the original. Some silks are difficult to dye, but fair results can be obtained if they are lightly soaped before putting in the bath. Old white bedspreads can be dyed, and make very attractive sofa covers or curtains; the brocaded designs look very nice when coloured. Faded stockings can be made to look like new if a little dye is added to the last rinsing water. Rugs and carpets can be brightened by first beating them clean with warm water and soap. While the carpet is still moist, brush in the hot dye solution with a scrubbing brush, going over it twice to get an even shade. With a little practice, shade dying can be done, and is especially suitable for curtains. For light and delicate shades, cold water tinting is preferable to the boiling method. It is advisable to dissolve the dye, strain through a cloth, then bottle and cork tightly for future use. By adding a few drops of the dye to the last rinsing water one may obtain good results. Dying is invaluable for renewing articles which would otherwise be discarded." (Secretary, Miss T. Franks.)

YURGO.

December 12th.

The December meeting was held at the residence of Mrs. E. Easton, when a paper, "Sport for Women," was contributed by Mrs. N. Easton.

POTATOES AND THEIR USES.—A paper on this subject was read by Miss J. Kelly at the January meeting:—"The potato lends itself to the preparation of many wholesome dishes. It is cheap and nourishing, and a valuable standby when green vegetables are scarce. The potato, in addition to its high starch content, contains two of the known vitamins. If the full vitamin and mineral content is to be obtained, they should never be peeled before cooking. *Baked Brown Jackets.*—The most elaborate dish cannot be more delicious than a perfectly cooked potato baked in its jacket. Select large, plump tubers of even size, and scrub them with a stiff brush; prick them all over, and, if liked, they can be soaked in cold water for half an hour. Bake in the oven for 1½ to 2 hours, according to size and the heat of the oven. Test with a skewer; the skin will be brown and slightly loose and the inside floury and crumbly. They may be peeled and mashed in the usual way, but if split open and spread with butter and lightly sprinkled with pepper and salt are very tasty. Tubers cooked in hot embers are even more delicious, and are relished by young and old alike. The inventive cook can improve many a dish with the aid of the baked brown jacket. The usual method is to scoop out the floury interior and mix it with a variety of ingredients. The mixture is then put back into the brown shell and heated and browned again in the oven. *Fillings.*—Mash together the floury potatoes, chopped parsley, and a little finely chopped bacon or ham, with salt and pepper to taste. Fill the cases; sprinkle the tops with bread crumbs and a dab of butter or bacon fat. Bake about 20 minutes. (2) The floury potatoes, grated cheese, a dash of cayenne, mustard, salt, and a little butter. Sprinkle the top with grated cheese before baking. (3) The floury potatoes, finely chopped nuts, a little butter, the yolk of an egg, pepper, salt, and a spoonful of milk or cream. *Boiled Potatoes.*—If the potatoes must be peeled before cooking, do it carefully, and either steam or cook them in just enough boiling water to prevent burning. By the time they are done the water has boiled away, leaving the potatoes full of good elements. If the practice of boiling in a lot of water is preferred, after draining, put the saucepan back on the stove without the lid, and shake until the potatoes are dry and crumbly. Mashed potatoes are lighter and much more fluffy if done in this way. *Potato Chips.*—These are very easily prepared, and can be managed without any special equipment. All that is required is a deep frying pan or a widemouthed, heavy saucepan. Heat sufficient clarified dripping to cover the chips. While it is heating peel the potatoes and cut them into strips about 3in. long and about ¼in. square. Rub in a clean cloth to absorb surplus moisture, and as soon as a faint blue smoke rises from the fat drop in the chips and cook for 4 or 5 minutes. Lift with a large fork or egg slice, and when the fat ceases spluttering and appears smoking hot return them to the pan and cook for 5 to 10 minutes, or until a golden brown colour. Drain on clean, crumpled paper, sprinkle with pepper and salt, and serve at once with a grill or fried fish. A frying basket is convenient for lifting out the chips and putting them back into the hot fat. Potatoes can also be used in cold salads. Boil and let cool, then peel. Recipe.—Line a bowl with lettuce leaves; then place alternate layers of par-boiled onions, green peas, and grated carrot, and serve with mayonnaise.

FRUIT AND ITS USES.

[*Paper read by* MRS. A. CURTIS *at a recent meeting of the Wirrabara Branch.*]

The word fruit as spoken in everyday speech is a misnomer, or partially so, because the words fruit and vegetable are used to imply different things, whereas the dictionary and encyclopaedia term both as fruits. When the female organs of a flower are fertilised the most important result of the process is the production of a seed, but usually the ovule from which the seed develops is not the only part of the flower to be affected; the seed vessel or ovary which is frequently stimulated to fresh growth and modification and even the part of the stalk receptacle on which are inserted the organs of the flower may be caused to take on a new appearance or structure. The total result of all three processes is a fruit. This conception of the fruit causes us to include under the term objects like the tomato and marrow, more generally regarded as vegetables, or like the grain or corn, usually termed a seed.

Fruits are classified in the first place according as they open at maturity to liberate the contained seeds or not. Those which open are variously termed capsule, such as the legume or silique. A capsule is a dry, many-seeded seed vessel, such as the Foxglove, the legume a seed vessel of two valves like the Pea or Bean.

Silique, the long pod or seed vessel of such cruciferous plants as Wallflowers or Mustard, the two latter being in the term pod. The distinction rests on the number of vessels in the fruit and the manner in which the latter open. Fruits which do not open may be either dry or juicy. The dry fruits are termed Nuts, different types being recognised. But certain dry fruits, although they do not open to liberate their seed, break up into distinct parts; such are the fruits of the Carrot family and the Marrow.

The juicy fruits are of very various structure. In the berry, the whole wall of the seed vessel is fleshy, such as the Gooseberry, Orange,-Tomato. In stone fruits, known as the Drupe, which means a stone fruit, such as the Cherry or Plum—a fruit in which the outer part is fleshy, while the inner forms a stone with a kernel. In the Apple and Pear, the fleshy part is the receptacle enclosing the root of the fruit, while in the Strawberry the fleshy part is again the swollen receptacle, this time bearing numerous small fruitlets on its surface.

The Fig is an example of an aggregate fruit, developing not from a single flower, but from an inflorescence. In some cases, a fruit is formed subsequent to fertilization, but without seeds, such as Sultanas, Raisins, and Bananas, while in the Fig and Seedless Apples, no fertilization takes place. Of great interest are the adaptions shown by fruit for securing dispersal of the seeds. Fruits which open frequently do so with considerable violence and scatter the seed. Examples are the Whin and Broom, the pods of which may be heard exploding on a warm summer day.

Frequently the fruit is provided with wings, by means of which it is kept floating in the air, and may drift to a considerable distance, such as the Ash, Elm and Maple, while in the Dandelion and Thistle family the fruit is provided with a tuft of hair, which serves the same purpose. The Burrs have hooked hairs which hang on to passing animals. Finally there are those fruits classed as fleshy fruits which form the food of birds and other animals, the seed passes unscathed through the animal and is deposited at a spot distant from its parent.

The uses of fruit will be dealt with in the following order:—Fresh fruits, dried fruits, preserved fruits, jams and jellies, then sauces, and pickles.

The best possible use of fruit is just as Nature provides it. There is nothing more appetizing, enjoyable, and wholesome than to pick ripe fruit, fresh from the tree, and eat it. Fruit that is reasonably fresh should be in every home, not only one day a week, but all day and every day. Far too many homes consider fruit a luxury, but the same homes probably provide quite a number of shillings per week for the family to spend on sweets. If that same amount was spent on fruit, the family would be much better off, both monetarily and physically.

Parents should encourage children from earliest infancy to spend their pennies on fruit instead of so many sweets. Children need plenty of sugar, but all fruit contains sugar as well as vitamins and minerals which are so essential to health. Fruit in any form—that is wholesome fruit—dried fruits, preserves, jams, &c., are far better than no fruit at all.

DRIED FRUIT.

Most kinds of fruit can be dried, and in this form, fruit can be stored from times of plenty until there comes a time when fruit is not so plentiful. Fruit that is well dried is the nearest akin to fresh fruit, it still contains the fruitose, vitamins and minerals; perhaps in a lesser degree than fresh fruit; but children will never become fruit hungry who have a box of dried fruit to dip into. Dried fruits need thorough mastication, and the hearty chewing is good for the development of teeth and jaws. In homes of modest circumstances, to purchase dried fruit would be beyond their means, but in the fruit season the market is often glutted and fruit becomes very cheap, then is the chance to dry fruit cheaply. After all, the only necessity for doing it is plenty of bright sunshine. A handy tray for small lots of fruit can be made out of 2 yards of bird netting, nailed on to two long, strong but light pieces of wood, with a short crosspiece either end. This can be placed on 2 boxes in a position where it gets the benefit of the sun all day and is easily covered or carried under shelter at night.

Currants are placed on the tray just as they come from the vine, place a tarpaulin or sheet under the tray to catch them as they dry. Grapes need to be plunged into a hot lye of caustic soda; about 2 level tablespoons to 4galls. water, take out and plunge into cold water, then spread on tray. This same treatment is used for prunes and plums. Apricots, peaches, and pears are fumigated with sulphur, but for home use, if they are just cut and spread out in the sun with a little care and attention they can be dried quite nicely, they will go dark and not have such a nice appearance but are none the less wholesome for that. Last season I used quite a lot of fallen apples for drying, just cutting out the cores and any bruised pieces, not peeling them and they are quite a success. The feel of fresh stewing apples seems coarse and unpalatable, but on the dried apples it is not noticeable.

Figs are another fruit that are quite a success, just cut and spread in the sun, they are beautiful for use in cakes and mince fruits. In cooking any dried fruits it is best to use as little sugar as possible, sweet apples and pears can be cooked without the addition of sugar. Apricots and plums that are very sour can be improved by thoroughly boiling in water to which has been added 1 teaspoon of carb. soda, pour this off and add fresh water and sugar and they do not need nearly so much sugar.

Preserved Fruit.

I prefer preserving to jam making, because it takes less sugar, and the fruit does not have to be heated to such a high degree and therefore must be more wholesome as well as more economical. I use a Fowler outfit, following the instructions to the word, if not to the letter. The length of time given for cooking is not long enough, it leaves the fruit too firm, but the instructions are for the best appearances, and if treated longer it rises in the bottles.

For our own use, I do not peel quite a lot of the fruit. Pears are merely cut in halves, bottled with the stems and cores and the russet brown patches on the skin leave nothing to be desired in appearance and have a beautiful flavour. The skin is not coarse, and there is very little waste from the core. Modern methods of cooking are inclined to err too much on the fineness of foodstuffs, discharging roughage that would often be beneficial.

This method also saves many weary hours of peeling. The early varieties of peaches also do very nicely without peeling. Referring to the light kinds of peaches; Fowlers do not recommend preserving these. as they are much softer than the yellow peaches, and are inclined to make the syrup milky, but when possible I include white peaches in my collection.

Jams and Jellies.

This is another form of preserving fruit, but it needs more sugar to make good jam than to make good preserves, therefore, it is not so economical, nor is jam as wholesome a form of storing fruit, as that of preserving, because in the latter the fruit is not heated to such a high temperature nor maintained at it for such a long period, and therefore, contains more of its natural minerals, &c. Nevertheless, jam carefully made can be, and is very wholesome food. Fruit for jam should be sound and firm and of even ripeness it is best to sort the fruit, putting aside that which is too hard, using the ripest first, but it should not be too ripe; over ripe fruit does not make the best jam. Wash the fruit and drain carefully and prepare in the accustomed manner according to what ever kind of fruit is being used, weigh and put into jam pan or copper, and before putting on the fire, pulp the fruit thoroughly, using a heavy jam stick or well-washed hand, place on fire and bring to boil. Boil until skins and fibre are tender, or if pressed with the back of a spoon against the jam stick the fruit will mash after about 1 hour's boiling. Now add sugar and bring to boil again as quickly as possible, stirring constantly to prevent burning. Test occasionally and when the right consistency, in about 1 hour, bottle as soon as it has gone off the boil, and seal immediately. Bottles or jars should be scrupulously clean and warmed in the oven to avoid cracking when the hot jam is poured into them.

The amount of sugar varies according to the variety of fruit. I seldom use more than ¾lb. sugar to the lb. Apricots, Peaches and Sweet Plums, ¾ sugar to 1lb. fruit;

Dark Sour Plums, from 14ozs. to 1lb. sugar to 1lb. fruit; Pears 10ozs. sugar to 1lb. of fruit; Figs, ¾lb. to 14ozs.. sugar to 1lb. of fruit; Quinces or any other fruit that needs the addition of water, ¾lb. sugar to every lb. of fruit, ¾lb. sugar to every pint of water added. Do not waste time peeling quinces, the peel boils perfectly and also adds to the jelling of the jam.

It is a waste of time to try and wash quinces, for cleaning off the fluff, tie a large duster firmly around the right thigh when in a seated posture, and rub the quinces on this. Quarter and core (the core makes the jam jell better), cover with water and boil until well pulped, then add sugar and boil until the desired colour. Figs are the one fruit that I do not wash. If necessary, wipe with a damp cloth and be sure they are not picked after a shower of rain, they need to be perfectly dry as there seems to be less likelihood of fermentation.

TESTING.

The methods of testing are many and varied, judging by the advice given in many periodicals and papers, and so far as country women are concerned, the only difference is one method may outdo the other. A small portion of jam must be cooled to see if it will jell satisfactorily, but to get cool quickly before the jam on the fire has boiled too long is the outback woman's problem with the thermometer in the kitchen soaring over the 100 degrees. For many, the water bag must suffice, some may have a cool safe, others a cool spring, the more fortunate may have an ice chest, but use whatever means are available. Get a saucer as cold as possible, place a teaspoonful of the hot jam on this, stand it in a cool place, in the draught of a southerly window, or float it on the water in a waterbag. When it is thoroughly cooled, it should have developed a skin, if the saucer is tilted sharply the skin should wrinkle, the stiffer the skin and the more distinct the wrinkle the better the jam will set. This last season I have made into jam just over 4lbs. short of 4cwts. of fruit and so far there is not a sign of any fermentation.

The main essential for a good setting in jams and jellies is the pectin contained in most fruits, some much more than others, and the greater the proportion of pectin, the more sugar needed to get a good jell. Lemons and some varieties of Plums contain a higher percentage of pectin, while in some of the sweeter fruits, such as Pears and Strawberries there is very little pectin. In the Lemon it is not the flesh or the skin, but rather the pith that contains the most pectin. The fruit juice should be tested for pectin, before adding the sugar, then add the sugar according to the test. If lacking in pectin, use less sugar than usual. If a fair amount of pectin, then add the usual amount of sugar. If rich in pectin then use more sugar, up to 1¼lb. to 1lb. of fruit. Fruit a little on the firm side usually contains more pectin. The method for testing is as follows:—Pulp the fruit thoroughly and boil well, dip a teaspoonful of the juice into a glass, add 3 teaspoons of methylated spirits, shake together and if the juice congeals into a firm lump and holds together this is a high pectin test, if the juice forms two or three lumps this is a fair percentage and if there are quite a number of small lumps, this shows a poor pectin test.

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences—1935.

Dairying, at Mount Barker, Thursday, May 9th (P. Wise, Secretary).

River Murray, at Moorook, Thursday, June 20th (S. Perkins, Secretary).

Upper North, at Booleroo Centre, Wednesday, July 17th (Wepowie Branch, E. C. Roocke, Secretary, Booleroo Centre).

Hills, at Lenswood, Thursday, August 22nd (B. F. Lawrance, Secretary).

Murray Lands (East), at Alawoona, Thursday, October 3rd (A. J. Pengilly, Secretary).

Fruit (Non-irrigated), at Lyndoch, Tuesday, November 5th (J. S. Hammat, Secretary, Williamstown).

Each Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda of the Conference in their respective districts.

Oats on Weedy Stubble Land.

The Supervisor of Experimental Work (Mr. R. C. Scott, R.D.A.), who was asked by a member of the Hartley Agricultural Bureau if a crop of oats would give a profitable return when sown on a very weedy paddock which grew a wheat crop the previous year, says the success of a crop of oats planted on a weedy wheat stubble depends entirely upon the seeding conditions. Oats are just as liable as wheat to be crowded out by vigorous weeds, and therefore unless these weeds can be destroyed before planting the oats the crop is not likely to be satisfactory. On the other hand, should early rains be recorded, as has been the case this season, resulting in the germination of the weed seeds, and subsequent destruction of the plants by tillage, a good stand of oats can be anticipated. However, should the rains be delayed until it is time to seed the oat crop, the planting of weedy land is not recommended.

Concrete Floor for a Chaffhouse.

In the course of a reply to a correspondent at Lameroo, who asked how to put down a concrete floor in a chaffhouse, Mr. T. A. Macadam (Lecturer in Building Construction at the School of Mines) says:—

Clear away all debris from the area proposed to be covered with concrete and see that the soil is firm and dry. Ram if necessary. The floor area should then be divided into sections approximately 4ft. x 5ft. wide, and no longer than 10ft. in the other direction, that is to say, each section will be approximately 10ft. x 5ft. The various sections can be separated by strips of wood fixed to pegs driven into the ground. The strips of wood should be firmly held in position so that the strength of ramming the concrete can be withstood. If the soil is firm where the concrete is going to be laid there should be no necessity for reinforcing rods. If, on the other hand, there are several pockets of soft soil, it would be advisable to place ⅜in. rods at 6in. centres each way, the rods being laid 1in. from the underside of the concrete floor.

The concrete is mixed in the following proportions:—Four parts of metal (¾ screenings), 2 parts of sand (river or pit), 1 part cement. Mix the materials thoroughly in their dry state on a clean hard surface, then add sufficient water to moisten them and see that the minimum of water is used. Thoroughly mix after water is added until the mix is moistened evenly. Place the concrete in alternate sections, and ram well into position. Trowel the surface of the concrete, and if a smooth finish is desired, dust smooth cement on the top when the concrete has partially set.

Keep concrete damp for at least 10 days. Before filling the intermediate sections place a piece of tarred paper against the edges of completed sections, to form a joint between the new and completed work. The joint will prevent all contraction and expansion between the adjoining sections. Four inches thick should be sufficient for the floor if the soil under floor is good.

Publications Received.

The Library of the Department of Agriculture acknowledges the receipt of Bulletin No. 83, "Experiments on Inbreeding of Poultry." Price 1s.

Bulletin No. 88, "Brown Rot Diseases of Fruit Trees." Price 1s. 6d. These Bulletins are published by the Ministry of Agriculture, England.

Circular announcing the Second International Congress of Rural Engineering, which will be held under the patronage of the Spanish Government at Madrid from 26th September, to 3rd October, 1935. Further details can be had on application to the Secretary: Mr. E. Aranda Heredia, 10, Amandes Vives, Madrid (12), Spain.

"Journal of the Institute of Agricultural Science," published by the Australian Institute of Agricultural Science. Secretary, A. J. Vasly, B.Sc., Werribee, Victoria. Membership of the Institute is open to University Graduates. Subscription, £1 1s. per

HORTICULTURAL INQUIRIES.

[Replies supplied by A. G. STRICKLAND, M.Sc., Deputy Chief Horticultural Instructor.]

Apple Tree with Split Trunk.

Lameroo asks, "How to treat a 15-year-old apple tree, the trunk of which is badly split?" *Reply.*—The best means of dealing with the trouble is by putting a bolt through the split portion. Before drawing the split together by means of a bolt, the exposed wood and inner bark should be trimmed to a fresh living surface so that when the two surfaces are made to meet, there will be an opportunity for them to heal together. After drawing the two portions of the trunk together, anoint the exterior of the treated part with grafting wax, or a bituminous compound, such as "Colas." If the latter is used, care should be taken to prevent the material running down between the two joined trunk portions, as in such case, the knitting of the two sections may be prevented.

Dropping of Young Citrus Fruits.

The same correspondent reports an orange tree, the fruits of which drop off when small.

Reply.—The shedding of superfluous young fruits is a natural process with most kinds of fruit trees, as such trees often produce far more fruits than the tree is capable of bringing to maturity, or are necessary for the maturation of a commercial crop. It is presumed that this query has reference to that excessive shedding of young fruits which sometimes leads to reduced yields.

A number of factors influence the abnormal shedding of fruits at the stage mentioned, but usually the occurrence is due to adverse climatic conditions which bring about water deficits or to nutritional deficiencies under certain climatic conditions with low humidity and high temperatures; the water loss through leaves may be greater than the amount which the roots are able to supply, even though the soil be thoroughly moist. Under such circumstances a weakening of the attachment between the tree and its young fruits may occur, with consequent excessive shedding.

From the nutritional standpoint the most common contributing factor to excessive fruit dropping is lack of available soil nitrogen during and subsequent to fruit setting. There is, in fact, some evidence that when the effects of heavy water loss and nitrogen deficiency go hand in hand shedding increases.

Where excessive dropping occurs it is advisable to use a nitrogenous fertiliser such as sulphate of ammonia just prior to blooming, and to see that the soil at no time lacks water. The incorporation of organic matter under green crops will result in improved water holding capacity and to some extent overcome any undue water deficiency.

VETERINARY INQUIRIES.

[Replies supplied by Veterinary Officers of the Stock and Brands Department.]

"South-East Conference".—Have experiments conducted by the Department of Agriculture conclusively proved that it pays to give sheep mineral licks other than salt in farming areas where superphosphate is used for cropping and top dressing?

Reply.—From 1929 to 1931 an experiment was conducted at Dismal Swamp in the South-East by the Division of Animal Nutrition, to determine the extent of benefit which supervened on offering various phosphatic licks to sheep grazing on an area where the soils are low in phosphorous, and to contrast this with the growth and wool production of similar sheep grazing on immediately adjoining country which had been topdressed wth superphosphate.

The results showed that the animals consuming the phosphatic licks experienced little or no benefit and that neither their wool production nor growth rate was significantly increased above that of identical animals running on the same areas and receiving only a supplement of salt. On the other hand, the animals that were run on the top-dressed pasture showed much more marked increase of growth rate and productivity. This improvement was concluded to be due to the improvement in the protein content of the pastures brought about as the result of top-dressing.

While (as Mr. Marston, Acting Chief of Division of Animal Nutrition), points out it is impossible to generalize from the results of one experiment, it would from this experiment appear that the phosphorous requirements of sheep are comparatively low, that they are not benefited by access to phosphatic licks, and that it is much better to apply the phosphate to the soils and thus bring about an improved supply of protein in their feed which is the more necessary thing to ensure satisfactory growth and wool production.

"Lameroo" asks, (1) *treatment for pig that is continuously rubbing itself, and* (2) *how to treat warts on a cow's teats?*

Replies.—(1) The trouble is probably dietetic. Wash the pig all over thoroughly, using a good soap and warm water in which has been dissolved a little washing soda; then dry as thoroughly as possible. Give the animal a dose of 2ozs. of Epsom salts (either as drench or well diluted in milk or thin swill) followed by 10 grain doses of photographer's Hypo mixed in the food daily for a few days. If possible allow a daily run out on green feed. (2) Any warts that are pedunculated may be snipped off at the base with a pair of sharp scissors, and the bleeding cut surface then cauterized with a pencil or stick of caustic. If the warts are flat and cannot be dealt with in this way, they should be treated by first scrubbing well with a weak solution of washing soda to remove all surface scale, &c., and to soften them. If not numerous they can then be cauterized carefully with a caustic pencil, but if too numerous for this treatment to be adopted, rub a little castor oil into them for a few days after each milking.

"Lameroo" reports 2-year old filly with offensive smelling discharge from the nostril.

Reply.—The indications are those of putrid decomposition taking place either in some portion of the nasal passage itself, or in one or another of the structures of the head closely assocated with it, for instance, the bone at the back of the nasal passage or the sinus of the head connected with that passage may be infected. In the latter case, this might be due to a decaying upper molar tooth on that side of the mouth. The case is really one for examination by a properly qualified veterinary surgeon, who could determine the necessary treatment as the result of his examination. All you can do in the way of "home treatment" is to give repeated inhalations of steam medicated with eucalyptus or turpentine. This is best carried out by using a nosebag into which a

couple of double handfuls of bran are put. Some boiling water which has been medicated with a teaspoon of eucalyptus or turpentine is then poured on to the bran to wet it thoroughly and a piece of folded sacking or cloth is placed on top of the wet hot bran to prevent the horse's nostrils from coming into contact with it. The nosebag is then adjusted over the horse's nose.

Secretary, Bugle Agricultural Bureau, reports filly with growth on upper eyelid.

Reply.—It is presumed that the growth is from the skin-side (not inside the eyelid) and if so will be a greyish coloured wart-like mass. This can be removed by tying a piece of strong thin cord or string tightly at the base of the growth and then cutting through on the growth side of the ligature with a sharp knife. If there is any haemorrhage, it can be controlled by applying a hot iron lightly to the bleeding surface, or by using a caustic pencil (silver nitrate). It would be better to leave the removal until the autumn when the weather is cooler.

Secretary, Agricultural Bureau, Kyancutta reports death of foals—off feed, severe scours, heavy breathing, and high temperature.

Reply.—The symptoms exhibited and the result of post mortem examination definitely indicate that the trouble is associated with digestive derangement. In my opinion the cause of bowel derangement is due to the food supplied containing too much indigestible matter.

Local conditions during the past season have been abnormal and possibly, owing to the grasshopper invasion, the livestock have had to subsist on food which has been spoiled or had much of the nourishment in it removed. Also the danger from taking in sand cannot be overlooked.

The analysis of food taken from the stomach would be of no advantage as any growth of bacteria made from it would be too mixed to make possible any diagnosis as to a specific bacterial cause. In addition, the symptoms exhibited are not suggestive of a poison being the cause.

Treatment.—Owing to seasonal conditions and probably the financial state of owners, it is most difficult to give practical advice that can be carried out.

In the first place young stock require good nutritious food, such as good quality hay chaff, fed with concentrates such as bran and oats (preferably crushed). Hay cut late with grain well formed in the heads is on the indigestible side and there is also the danger of the young animal becoming "foundered." Cocky chaff is too irritant and would cause scouring, and bran, though a good food, needs to be given with other concentrates such as oats and linseed.

Medicinal Treatment.—Can only be effective in stopping the catarrh set up in the bowels if given early, and should be in the form of an oil drench, such as:—Take castor oil and olive oil, 2 to 3 ozs. of each, for foals 3 to 5 months old, or raw linseed oil, 6ozs.

At the same time, all rough food should be stopped and for three or four days until scouring ceases, the animal should be given milk and eggs or flour gruel. Then place on a diet of good quality hay chaff with crushed oats and bran and keep off grazing on sandy ground.

Secretary, Agricultural Bureau, Ramco, reports heifer giving milk before she was in calf.

Reply.—This is not uncommon and the cause is not understood, though it is thought to be due to the absorption of a substance (ahormone) sereted by one of the ductless glands of the body such as the ovaries. In some cases, other cattle sucking the teats will cause a milk flow.

CORRECTION.

On page 916 of the March issue, under "Veterinary Inquiries"—"Parasitism in Sheep"—the fourth line should read: Water 6 GALLONS and NOT 1 GALLON.

KYBYBOLITE EXPERIMENTAL FARM

REPORT ON FARM CROPS, 1934-35.

[By L. J. Cook, R.D.A., Manager.]

Since the extension of pasture development work on the Farm, the cultivation of farm crops has been much reduced, and approximately only an area of 120 acres annually, of the 1,000-acre farm, has been put under cultivation of recent seasons. These crops have been grown principally to augment the feed of livestock, in producing grains for pigs, and hays and concentrates for the dairy herd.

An area of each type of cereal has been grown each year so as to provide a sequence of comparative yields since the commencement of records in 1910, but we have been unable to continue tests of varieties and treatments.

It is perhaps of considerable interest and importance to compare what effect the growth of subterranean clover and top-dressed pastures has had on subsequent crop growths. Consequently in Table 1 the mean yields of crops since 1926, when the effects of pasture improvement began, are shown comparatively with the mean yields since 1910, and of those of the immediate season:—

TABLE 1.—*Crop Returns for Season 1934-35 Compared with Mean Yields.*

Crop.	Period.	Mean Yield.	Mean Yield, 1926-34.	Average Yield, 1934.
		Bush. lbs.	Bush. lbs.	Bush. lbs.
Wheat	1910-34	14 38	14 45	24 28
Oats	1910-34	20 7	23 9	35 18
Barley	1910-34	14 29	25 49	35 28
Rye	1914-34	7 5	10 51	13 34
Peas	1921-34	11 23	9 13	10 44
		T. C. L.	T. C. L.	T. C. L.
Cereal Hay	1910-34	1 7 57	1 16 45	2 14 54
Ensilage	1920-34	4 12 96	5 8 8	5 1 91
Meadow Hay	—	—	1 11 60	1 2 88

From this table it is significant that all types of crops except one (peas) have yielded greater average returns during the immediate past nine seasons, and this is largely attributable to the improved physical condition and fertility of our soils, brought about by the growth of improved pastures. Certain individual results have been outstanding in this regard, and the main increases have been from Spring-sown cereals for grain and Autumn-sown cereal hay. Knowledge has been gleaned that treatments, methods, and varieties need to be altered as the soils are improved, and work in testing these matters is needed in the near future.

On referring to the final column of Table 1, the yields for 1934 show that a very good cropping season was experienced, in fact it has been the most productive in the history of the Farm. The returns of wheat, oats, barley, and cereal hay being quite 50 per cent. greater than the mean yields of recent years. The yields of grass ensilage and meadow hay were not as heavy as usual, due to the fact that, although the Spring rains were really good, they were a little late in falling, and consequently the clovers were unable to make the usual very heavy growth immediately before maturity.

The following table sets out the rainfall received at the Farm since 1910:—

October ..	1·80	1·92	2·27	0·52	4·47	1·50	2·55	0·47	1·58	1·05	3·36	1·90
November	1·55	1·51	0·68	2·06	0·99	0·97	0·93	0·38	0·59	3·90	1·87	1·48
December .	1·21	1·10	0·83	1·31	0·17	1·66	2·94	0·06	0·74	0·79	0·46	1·10
Total Rainfall	23·31	21·04	18·60	18·38	22·51	21·62	21·89	18·19	19·85	23·50	17·36	21·55
Total "Useful rain" April-November	19·27	17·71	17·27	14·40	18·46	17·74	17·30	15·46	15·06	20·54	15·93	17·99

The total rainfall for 1934 of 17.36in. is 4in. less than the mean for the past 29 years, and is the lowest total recorded except on three occasions, namely—1914, with 11.94in.; 1919, with 15.60in.; and 1925, with 16.08in. The distribution, however, was good for crop growths. January, February, and March falls were below average, but 3in. fell in April, which provided for good seeding preparation. May rains (8 points) were negligible, recording the driest May experienced, as never before during the life of the Farm had less than 70 points been recorded for this month. June also was very dry, recording only ½in. against an average of over 2½in., and also July, which usually is the wettest month of the season, recorded 1in. below the average. August with 213 points was also ½in. less than usual, but September recorded practically 3in., 33 points above the average. October rains were extremely good with 3.36in., 1½in. above the mean for the month. November also provided better falls than usual, allowing crops to finish well.

Table 3 shows the distribution of the rainfall collected into the various seasons of the year, and the high yields of grain received this year are due largely to the light winter rains, followed by comparatively heavy Spring and early Summer falls:—

CROPS.

119 acres were cultivated during the season, of which 108 acres were sown to cereals for ensilage, hay, or grain, 5 acres to field peas, and 6 acres to turnips.

Turnips.

One field (No. 4D) sown to Mammoth Purple Top turnips in October, 1933, was grazed by sheep during the Winter, but on account of the light and poorly distributed Summer and Autumn rains the crop was a poor one, and provided feed for only 14½ sheep per acre for six weeks during May and June.

A further 2 acres (Field No. 9F) of turnips produced a better crop.

These were used to supplement the feed of the dairy herd during May, and they were pulled daily, and carted to the dairy for slicing. On account of shortage of time and labour weights of these turnips were not taken.

Two fields, Nos. 4C and 9E (6 acres), were sown during the Spring of 1934, and are being reserved for the coming Winter feed.

The following table shows the grazing results of turnip crops grown on the Farm for the past 13 years, and shows an average annual carrying capacity of 2.64 sheep per acre, varying from 4.83 sheep in 1930, the best season for the crop, to 1.43 sheep in 1924, the lowest recorded grazing:—

TABLE 4.—*Feeding Results of Turnip Crops, Kybybolite,* 1921-34.

Season.	Total Rainfall, May 1st-April 30th.	Summer Rainfall, Dec. 1st-April 30th.	Area. Acres.	Total Feed Days.	Sheep per Acre per Annum.

Ensilage Crops.

Of recent years use has been made of the flush Spring growth of pastures to make our ensilage supply, with good success. Mixtures of subterranean clover and grasses, cut from our improved pastures, have made excellent ensilage, which under analysis has compared more than favourably with cereal ensilage as a fodder. This season, on account of the dry winter, we were unable to close many fields from stock until late September, and consequently, although pastures made a very fine response to the Spring rains, they did not produce quite as heavy growth. The silo was filled by utilising pasture growths cut from 12.3 acres, and a mixture of cereal and undergrowth cut from Field No. 4B (5½ acres). 12 acres of pasture were also cut and stacked for ensilage in Field No. 17, but no weights of this could be taken.

Table 5 shows the yields of ensilage cut from various plots and fields:—

TABLE 5.—*Ensilage Yields, Kybybolite*, 1934-35.

No. 4B	Cereal and undergrowth...........	5·52	22 16 0	4 2 68
	Total	17·82	90 14 28	5 1 91

Field No. 11B, which returned the greatest yield, received only light grazing by calves from June until 13th September. Plot P33 consisted of mixed pasture plots, and was not grazed during the Winter. Plot N8 carried a good mixture of subterranean clover and Wimmera rye grass, and was maintained well grazed until late August. Field 16A consisted of subterranean clover and annual grasses, mostly sterile brome, and was lightly grazed all through the Winter and Spring.

Mean, 1926-34.......	20·21	16·91	148·27	801 3 56	5 8 8

The above table shows the annual return of ensilage since 1920, and the yield for this season of 5 tons 1cwt. 90lbs. per acre is approximately 10cwts. better than the average. During the last three seasons, grass and clover ensilage has been made, and the average return from this type has been 6 tons 14cwts. 69lbs. per acre, a considerably higher return than was secured from cereal ensilage in the past.

Cereal Hay Crops.

Field No. 20D, that carried crops of wheat, barley, rye, and maize in 1933 following three years of subterranean clover grazing, was ploughed in April and during the last week of that month Algerian oats were sown at the rate

of 60lbs. seed with 1cwt. 45 per cent. superphosphate per acre. The crop was fed off by sheep during July and August, using 12 sheep per acre for 21 days. A thick crop, rank in places, was produced, and 20.35 acres were cut for hay, yielding 2 tons 14cwts. 54lbs. per acre, which is the highest average received for any season during the 25 years of results. It is almost double the average annual return per acre of 1 ton 7cwts. 57lbs. Other heavy yields were received in 1933 with 2 tons 10cwts. 94lbs., and 1912 with 2 tons 10cwts. 76lbs. The mean annual yield for the past nine seasons has been 1 ton 16cwts. 45lbs., 10cwts. per acre greater than for the previous 16 years.

Meadow Hay.

Approximately 72 acres of pasture were cut and cured this season, yielding 82 tons baled hay, or 1 ton 2cwts. 88lbs. per acre, whilst the mean yield for the past nine seasons has been 1 ton 11cwts. 60lbs. The quality of the hay was very good, but the lightness of yield was due to the late arrival of Spring rains, and the inability to close hay fields from livestock earlier in the Spring.

The next table shows the yields secured from the various plots and fields harvested:—

TABLE 8.—*Meadow Hay Yields, Kybybolite,* 1934.

No. 15A	Sub. Clover and mixed grasses	15·83	11	8	80	0	14	50
	Total	71·95	81	19	79	1	2	88

Plot C1 consisted of pure Wimmera rye grass that was sown on 10th May this year at the rate of 4lbs. seed per acre, following 10 years of subterranean clover and Wimmera rye grass pasture grazing. It was grazed back hard until 15th September, yielding 315 sheep-feed days per acre, or 21 days' feed for 15 sheep per acre. It made rapid and thick growth, and was cut for hay on 19th November, yielding 2 tons 1cwt. 99lbs. per acre.

Plots N7 and N8 have been established with subterranean clover and Wimmera rye grass since 1926, and carried a good sward of pasture. They each provided 9 days' grazing during the Winter months for 10 milking cows per acre until middle of August, and were cut for hay on 12th November. Their return of over 37cwts. per acre was very satisfactory.

Plot C2 consisted of pure *Phalaris tuberosa* sown on 10th May this year at the rate of 4lbs. seed per acre, following 10 years' grazing of subterranean clover and Wimmera rye grass pasture. A good germination was secured, but the grass is not very vigorous in its early life, and consequently only a light grazing of 60 sheep days per acre was secured during mid-September. It made a good Spring growth, and was cut for hay on 19th November, and yielded 1 ton 9cwts. 26lbs. nice quality hay per acre.

Both Plots C1 and C2 received the same treatment, and their comparison shows typical results of first-year growth of the two grasses, Wimmera rye and *Phalaris tuberosa,* the former producing five times as much Winter grazing and 12cwts. more hay per acre.

Plot N4 was similar pasture to N7 and N8, but was grazed later, until 15th October, with the equivalent of 2 sheep per acre all the Winter and early Spring. It was mown for hay on 16th November, yielding 1 ton 3cwts. 64lbs. per acre.

Field No. 17 was of similar pasture established in 1926, and was grazed until 5th October with the milking herd, carrying the equivalent of 2.31 sheep per acre from 1st April. It was cut for hay from 22nd November to 24th, and produced a good quality hay 1 ton 2cwts. 78lbs. per acre.

Plot P17 carried a thick stand of subterranean clover and *Phalaris tuberosa,* which has been established since 1930. It was grazed throughout the Winter months until 11th September, and carried 3.1 sheep per acre for that period. Hay was mown on 14th November, and yielded 1 ton 1cwt. 67lbs. per acre of really good quality meadow hay.

Plot P14 has been established with Wimmera rye grass and subterranean clover since 1929, and has received similar manurial treatment (1cwt. 45 per cent. superphosphate per acre annually) as plot P17. This plot carried 4.35 sheep per acre throughout the Winter months, was also mown on 14th November, and yielded 1 ton 1cwt. 45lbs. per acre, only a few pounds less than the *Phalaris* mixture.

Plot P15 carried a sward of *Phalaris tuberosa* that was sown on 9th May this year, on land that had been under subterranean clover and grass since 1930. A grazing was secured during September and early October equivalent to 1.27 sheep per acre for the Winter. The plot was closed on 10th October and mown for hay on 20th November, yielding 19cwts. 98lbs. per acre.

Field No. 6F was old cultivated land that had been established with subterranean clover since 1930. It was well grazed throughout the Winter until 18th September, and carried 4 sheep per acre for the six months. The pasture consisted of subterranean clover and annual naturalised grasses with a dominance of barley grass. It was mown on 15th November, and yielded 18cwts. 85lbs. of baled hay per acre.

Field No. 15A carries our grass seed trial plots, and the area sown in 1932 with strains of perennial rye grass and *Phalaris tuberosa* was mown on 22nd November. The area had been well grazed during the Winter with 2.02 sheep per acre up till 5th September.

The following table shows the yields of meadow hay secured since 1926 when the harvesting of pastures as hay was commenced at the Farm:—

TABLE 9.—*Meadow Hay Returns, Kybybolite,* 1926-34.

Oat Crops.

Algerian oats were grown in two fields. In No. 20D, particulars of which have been given under cereal hay, an area of 8 acres was left and harvested for grain, yielding 36bush. 23lbs. per acre.

Field No. 15B, which had been out of cultivation since 1923 and has carried ordinary top-dressed pasture, was ploughed by 7th May, cultivated, rolled, and drilled with 60lbs. seed per acre on 23rd May with 1cwt. superphosphate. The crop was fed off during the first fortnight of August, developed well in the Spring, and yielded 35bush. 2lbs. per acre.

The following table shows the returns received from oats since 1910:—

TABLE 10.—*Oat Returns, Kybybolite,* 1910-34.

Year.	Total Rainfall.	"Useful" Rainfall.	Area.	Total Yield.		Yield per Acre.	
	In.	In.	Acres.	Bush.	Lbs.	Bush.	Lbs.
1910-19	20·92	16·75	591·50	11,295	38	19	4
1920-29	20·73	17·50	573·37	11,862	8	20	28
1926	18·60	17·27	57·01	1,198	34	21	1
1927	18·38	14·40	57·41	1,744	30	30	16
1928	22·51	18·46	54·53	1,660	35	30	18
1929	21·62	17·74	40·11	419	10	10	18
1930	21·89	17·30	42·57	980	22	23	1
1931	18·19	15·46	not sown	not sown		not sown	
1932	19·85	15·06	52·54	974	9	18	22
1933	23·50	20·54	43·84	717	9	16	14
1934	17·36	15·93	31·29	1,108	38	35	18
1910-34	20·69	17·07	1,335·11	26,939	4	20	7
1926-34	20·21	16·91	379·30	8,804	27	23	9

The return of 35bush. 18lbs. received this season is the best recorded for the 25 years. In 1912 a return of 33bush. 20lbs. was received, and 30bush. per acre was received in both 1927 and 1928. The mean yield for the full period has been 20bush. 7lbs., but for the last nine years it has been 23bush. 9lbs., or 3bush. per acre better.

Barley Crops.

As seeding conditions during August were good, an extra field was sown to Cape barley. Field No. 15C, similarly to No. 15B, had been uncultivated since 1923. It was ploughed by August 13th, and subsequently cultivated twice, and harrowed three times to clear of weeds and work to suitable tilth. On 24th August it was sown with 75lbs. Shorthead barley and 1cwt. 45 per cent. superphosphate per acre. The crop developed well with only a few rank patches and headed well, yielding 40bush. 27lbs. per acre.

Field No. 20E.—The northern end of this field was grazed well in June, and pasture harrowed in July to break and spread stock droppings. It had been under clover grazing for three previous seasons in the five-course rotation of wheat, oats, and subterranean clover. The soil was ploughed 3in. deep by 27th July, and 10.86 acres were immediately sown with 75lbs. Shorthead barley and 1cwt. 45 per cent. superphosphate per acre. A really good thick stand of crop was secured, which became rather rank in places causing lodging and preventing the complete harvesting of all grain. The satisfactory yield of 36bush. 7lbs. per acre was received.

Field No. 9F carried Shorthead barley this season following a turnip crop which had been carted from the field during June and July. The soil was ploughed shallow on 28th July, and sown with barley on August 2nd. Germination was rather thin, but the crop developed comparatively well, yielding 29bush. 4lbs. per acre.

Field No. 4D also carried a light turnip crop in 1933-34 that was grazed by sheep during June. It was ploughed on 30th July, and sown to barley on 3rd August. Germination was poor, resulting in rather thin weedy crop, that yielded 17bush. 10lbs. per acre.

The following table shows the returns of barley received since 1910:—

TABLE 11.—*Barley Returns, Kybybolite,* 1910-34.

Year.	Total Rainfall.	"Useful" Rainfall.	Area.	Total Yield.	Yield per Acre.
	In.	In.	Acres.	Bush. Lbs.	Bush. Lbs.
1910-19	20·92	16·75	426·79	5,207 9	12 10
1920-29	20·73	17·50	214·13	3,134 39	14 32
1926	18·60	17·27	11·38	363 23	31 47
1927	18·38	14·40	11·15	313 38	28 7
1928	22·51	18·46	13·78	489 46	35 28
1929	21·62	17·74	14·74	117 21	7 48
1930	21·89	17·30	12·41	386 33	31 8
1931	18·19	15·46	11·42	129 40	11 8
1932	19·85	15·06	10·52	241 19	22 47
1933	23·50	20·54	16·41	281 45	17 9
1934	17·36	15·93	33·35	1,186 4	35 28
1910-34	20·69	17·07	725·03	10,567 39	14 29
1926-34	20·21	16·91	135·16	3,510 19	25 49

The average yield for the season of 35bush. 28lbs. is equal to the highest harvested on the Farm, the same average yield being obtained in 1928.

Other good years for barley were 1926 with 31 bush. 47lbs., 1930 with 31bush. 8lbs., and 1912 with 30bush. per acre. This year's return is considerably greater than twice the average yield of 14bush. 29lbs. received for the 25 years, and 10bush. better than the average of 25bush. 49lbs. secured for the past nine seasons.

Wheat Crops.

Only a small area was sown to wheat, on the southern end of Field No. 20E in the five-course rotation following three years of subterranean clover grazing. Thirteen acres were sown with Gallipoli variety on 20th June, on land that was ploughed in April, cultivated and rolled in May, and again cultivated in June before seeding; 80lbs. seed and 1cwt. 45 per cent. superphosphate were drilled per acre; 1½ acres each of Quality and King's White varieties were sown on 31st July on the northern half, which was ploughed immediately before seeding with 90lbs. seed and similar superphosphate dressing.

Tables 12 and 13 show the yields of these three plots and the wheat returns received on the Farm since 1910:—

1926-34	20·21	16·91	269·15	3,971 52	14 45

The average yield of 24bush. 28lbs. secured this year has only been exceeded on one occasion previously, in 1913, when the farm average for wheat was 26bush. 44lbs.

Rye Crop.

As usual an acre of rye was grown for grain production. This was sown in Field No. 20E on 31st July, and returned a yield of 13bush. 34lbs. per acre—4bush. less than wheat, and 23bush. less than barley sown at the same time under similar conditions.

The following table shows the returns received from rye since 1914:—

TABLE 14.—*Rye Returns, Kybybolite*, 1914-34.

Pea Crops.

One small field (No. 4A) was sown to peas this year. The land was ploughed on 19th July, harrowed down, and immediately sown with peas—1.8 acres with 130lbs. White Brunswick, and 3.5 acres with 120lbs. Early Dun variety per acre, both with 1cwt. 45 per cent. superphosphate per acre. The plots made very good growth, especially the Early Duns, but adverse weather conditions at flowering time caused a poor setting of pods. The White Brunswick yielded 12bush. 37lbs., and the Early Duns 9bush. 48lbs. per acre.

Table 15 shows the returns of peas secured since 1921:—

EXPERIMENTS WITH VARIOUS PHOSPHATIC FERTILISERS ON CEREALS, IN CONJUNCTION WITH SUBTERRANEAN CLOVER.

Three fields, Nos. 7A, 7B, and 7C, have been used for testing the citrate and acid-soluble phosphatic fertilisers against the water-soluble phosphate (superphosphate), and cereal crops have been grown every third season in rotation with two years' subterranean clover grazing. The plots are set out according to the phos-

B

phatic content of the fertilisers—each one being tested in equivalence in phosphoric anhydride—with applications of both 90lbs. and 180lbs. respectively of 45 per cent. superphosphate.

It was decided this season to discontinue the growing of the cereal crop, as the breaking of the clover pasture every third season showed to the disadvantage of the latter. The results for six seasons ending 1933-34 are given in Table 16, and shows that the greatest return of grain has been secured from lime and superphosphate fertiliser; with the heavy application of water-soluble phosphate about 2½bush. less per acre. The yields from the citrate and acid-soluble phosphatic fertilisers have been considerably lighter:—

ROTATION OF CROPS EXPERIMENT.

Rotation A.

This five-course rotation of 30-acre fields, consisting of wheat, oats, and three years subterranean clover was commenced in 1923. The following table shows the results received for the past 12 seasons:—

TABLE 17.—*Five-course Rotation of Crops, Kybybolite,* 1923-34.

Subterranean clover maintains itself as the most valuable and productive crop in the above series, and the table shows the consistency of growth obtained from the pasture. From all the clover grazings in the past 10 years this series has a

carrying capacity of 2.57 sheep per acre annually. This means that on the 150-acre block of five fields we are able to carry 231 sheep, as well as cultivate 60 acres and have the stubble feed from the crops to spare.

Rotation C.

The testing of the Norfolk four-course rotation—turnips, barley or oats, peas, and wheat—on 4-acre fields is being continued. The test was commenced in 1919, and the following table shows the returns received during the past 16 seasons:—

TABLE 18.—*Four-course Rotation of Crops, Kybybolite,* 1919-34.

Year.	Peas.	Wheat.		Turnips.	Oats or Barley.

Means	9 41	20 15	1 18 70	3 02	26 29 barley

Of the above crops the yields of all, except peas, are greater than the mean yields of the Farm. We have not of late seasons been able to maintain the supply of lime to these plots, and consequently this no doubt has reduced yields, especially those of pea crops. Sufficient result has been obtained to show that it is scarcely a suitable rotation for the district under present-day conditions.

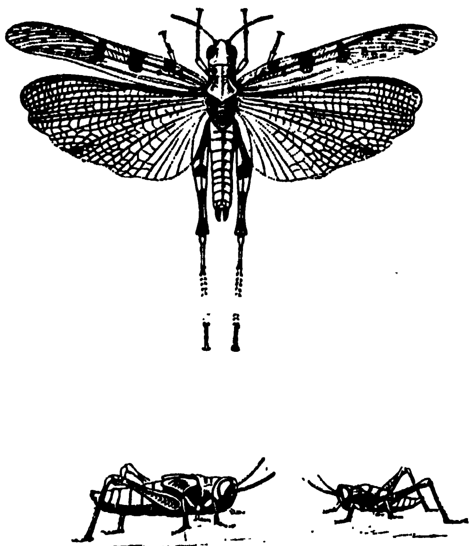
SOME FIELD OBSERVATIONS ON THE GRASSHOPPER PEST, WITH DETAILS OF TRAPPING EXPERIMENTS CONDUCTED AT SNOWTOWN.

[By W. C. JOHNSTON, R.D.A., District Agricultural Instructor, and F. C. C. GROSS, R.D.A., Field Officer.]

INTRODUCTION.

Owing to the widespread nature of the grasshopper pest in the spring of 1934 in many of the wheat growing districts in the State, a Committee was appointed by the Government to investigate the control of the pest. Accordingly, after several reports had come to hand regarding the insects at Snowtown, the Committee visited the locality on a tour of inspection.

After a meeting with members of the Snowtown Council, and at which that body consented to assist with certain labour and other facilities, it



Larger Plain Locust *(Chortoicetes terminifera)*.

[From *N.S.W. Agricultural Gazette.*]

Top—Adult.

Bottom Right—Youngest stage of "hopper."

Bottom Left—Late stage of "hopper," with wing pads well developed.

was decided to conduct trapping experiments by means of zinc sheeting and pits, which were reported to be effective in the control of locusts in Palestine.

The work was deputed to the writers, and the following paper is the result of observations made on the pest during this work, together with other field observations made during the subsequent invasion of the pest throughout the Lower North during the latter months of 1934 and the early part of 1935.

It is not proposed to deal with the subject from a scientific point of view, except to refer to the life history of the insect in so far as its more practical features have some bearing on the subject. Nor is it proposed to make any reference to poisoning; Dr. Davidson, of the Waite Institute, having contributed articles on this aspect of control in this *Journal*.

LIFE HISTORY.

The eggs are laid by the female in holes in the ground, made by means of hard chitinous appendages at the posterior of the abdomen, to a depth of from 2½-3½in., depending chiefly on the type of soil. Governed entirely by meteorological conditions, the eggs commence to hatch in from 3-5 weeks, or they may remain for a considerable length of time if optimium conditions do not prevail.

Upon hatching, the insects are similar to the adult, but of a dirty whitish colour, possessing no indications of wings, and about ⅛in. in length. After they have been in the light for a short time, their colour changes to a brownish grey.

The Winged Insect.

[From *Victorian Journal of Agriculture.*]

Provided food supplies are adequate, the insect passes through three forms before it becomes the winged adult. The first stage occupies about 3 weeks, during which time the skin is cast several times, the insect finally emerging with small rudimentary wing pads. After approximately 10 days, further development becomes visible, and the hopper requires more and more feed. The third stage requires a further 3 weeks, during which time the insect becomes much more active and very voracious. At the end of this time the skin splits and the winged form appears. Thus from hatching to the imago requires approximately 7 weeks.

The average life of the adult form is given as approximately 7 weeks, so that the life of the insect can be put down as being about 3 months.

FLIGHTS.

For some days after reaching the winged stage, the insect does not appear to realise its new means of progression, and it moves along with the less mature hoppers, only taking to the wing when forced to do so. Even such flights are of very short duration, and generally do not exceed a few chains in distance. However, as the insects become older, longer flights are the rule, but in such flights there does not appear to be any definite direction, except so far as influenced by winds.

When considerable numbers of them have reached the winged stage, there appears to be a general exodus from the hatching area. The first of these migratory flights is relatively short, but as the insects become older, the distance covered becomes increasingly great.

When flying they are capable of a speed of 15-20 miles per hour in a moderate breeze. At first, the height of flight does not exceed about 20ft., but when migration is more general, great heights are reached.

The insects do not favour timbered country when they are migrating, and lines of trees appear to act as a check on their line of flight. This feature was very evident on the Clare-Farrell's Flat road in December last, where there was a decided confluence of the fliers at every gap in the line of trees that borders this road. They seem to prefer to travel parallel with the timber, rather than go up and over the height of the trees.

A Swarm of Grasshoppers.

[From *Victorian Journal of Agriculture.*]

Time Flight Takes Place.

This feature is entirely governed by temperature; they were very seldom seen on the wing before about 9 a.m., and very seldom after the sun had lost most of its radiance in the afternoon, generally about 4.30 or 5 o'clock. Should the day temperature fall, or a cool change be experienced, the insects remain until the weather is more congenial to migration. During any forced delay in their migratory flights, the time is spent in feeding and egg laying, and the cool changes experienced during the early part of the year helped in no small measure to allow the very widespread distribution of eggs that subsequently proved to be the case.

Direction of Flight.

When on the hatching area, the direction of flight appears to be totally spasmodic, governed chiefly by the direction of the wind. Exceptions, however, are noted in which the insects fly directly into the wind.

Later, however, there is a very definite migration in a southerly direction. This is varied slightly in accordance with wind. Thus, with a westerly breeze the flight takes a south-easterly course, or with an easterly wind the movement is in a south-westerly direction. Should the wind be directly from the south, there is no further movement until there has been a change. Whether this feature is due to the direction of the wind being contrary to the line of movement, or whether it is due to the low temperature that invariably comes with a wind from this quarter, cannot be definitely ascertained. The writer inclines to the belief that it is chiefly due to the lowered temperatures, and not to any conscious effort on the part of the insects.

EGGLAYING.

The time that elapses from the emergence as a winged insect until it commences laying does not appear to be very definitely known, but observations lead one to express the opinion that this takes place fairly soon after the insect takes to the wing. At Snowtown, eggs were deposited at a very short distance from the hatching area, which tends to indicate that the insect was capable of this function within a week or so of becoming winged.

The process of egglaying is performed by the insect arching its body in order to place the posterior portion of its abdomen at right angles to the soil surface. Then by means of two pairs of chitinous appendages—rather like the claw of a hammer, with each pair of points turned outwards, and over which the insect has muscular control—it digs a hole into the soil for from 2½-3½in. in depth, the abdomen becoming greatly elongated in the process. When the desired depth has been attained a frothy gelatinous substance is exuded, and the eggs are laid in it. The eggs are long, thin, and sausage-shaped, and about $\frac{1}{16}$in. in length. From 30 to 50 are laid in each hole that is made. As the process continues, the hole becomes full of eggs, and at the same time the abdomen becomes contracted, so that by the time all the eggs are deposited, the insect has become normal in shape, and is ready to move on to some other site to lay again, possibly in a week or so.

Generally the egg cones are completed when about half an inch under the surface of the soil, in which case the remainder is filled with the same frothy substance. Its function appears to be to prevent dust and soil becoming tightly packed on the eggs below, thus allowing easy egress of the hatching insect.

It is usually considered that egglaying is confined to hard, well drained land with very little vegetation, and while it is readily conceded that such a site is generally preferred, it has been noted that eggs were laid in many conditions very far from the ideal.

At Snowtown, egg cones were taken from pea stubble that had only been reaped the week before, and later, in many parts of the Lower North, egg laying was observed in heavily grassed land, stubble, and on one occasion fallow, which carried a well prepared mulch, while frequent instances were observed of eggs being deposited in Sudan Grass patches, many of which were in a very loose condition.

HOPPERS.

After hatching, the insects do not move very far from the hatching area for several days, but as feed becomes more scarce, and the insects stronger, they begin to move away from the hatching ground. The rate of spread will be gauged by the abundance or otherwise of food supplies in relation to the number of hoppers that hatch on a given area.

Should greenfeed be plentiful the hoppers will move rather slowly, but if the reverse applies there will be a much more rapid migration, and should the greenfeed be very scarce only those with the greatest vitality will survive.

The question of the survival of the newly hatched hoppers in the summer calls for special comment, for it was frequently observed in the Lower North that even where they hatched in an abundance of greenfeed, such as lucerne patches or fields of Sudan Grass, very few of them survived more than a week or so. In fact, throughout the district, millions of hoppers hatched in January, 1935, but as was expected, they died within a week where the hatching had occurred in grassland on which there was no greenfeed. But the reason of the heavy mortality of the insects where food supplies were abundant offers a feature worthy of investigation. This position was noticed in too many cases to be purely a matter of coincidence.

The Rate of Migration.

This will be governed entirely by the supplies of greenfeed, and should this essential be plentiful, the hoppers will move at a rate of from 1 to 2 chains per day in the earlier part of their migration. Later, however, as more food is required by each individual, the rate of advance increases to 4 or 5 chains per day. During the final stage—before the insect becomes winged, and if food supplies are becoming short—the hoppers will move at a rate of about 4 miles per day in search of food.

Direction of Movement.

It was observed that the hoppers adopted the line of least resistance, thus they would travel down hill, along sheep pads, down the beds of creeks, and across fallows rather than through dry grass, and always with the wind, never against it. This characteristic can be turned to very good account in trapping the pests, and has led to the scheme of sheeting being used in directing them into pits where they can be destroyed.

During the trapping experiments at Snowtown, it was frequently observed that the hoppers could hop 2ft. in height when disturbed, but if left to move in their own way a 1ft. barrier would prevent their forward movement so long as they could not easily crawl over the material.

TRAPPING EXPERIMENTS CONDUCTED AT SNOWTOWN.

The Committee appointed by the Minister of Agriculture to assist and advise the Government in formulating some means to control the grasshopper pest, decided to conduct trapping experiments at Snowtown. It was decided that the method to be adopted would be along the lines of work done in Palestine where, by means of barriers of zinc sheeting, the pest was led into pits so designed that escape was impossible, and where the insects were destroyed.

Material Used.

Zinc sheets of No. 11 gauge 7ft. long by 3ft. wide were cut into 3 strips 1ft. in width. To hold the sheets in an upright position, wooden pegs 9in. long by 1¼in. square, sharpened at one end, were driven into the ground. Picks and shovels were used for sinking the pits.

THE WORK.

The work of experimenting was carried out on three different farms in the Snowtown area, on all of which the hoppers were in a very advanced state of maturity, which meant that their rate of movement was very considerable.

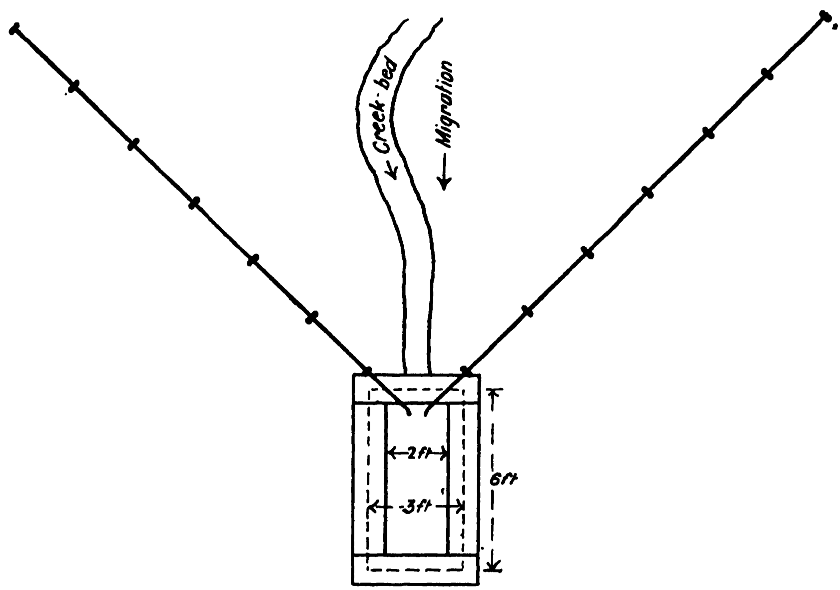
Three different types of traps were tried.

A. Traps in the bed of a creek.

B. A length of trench across the line of the advancing swarm of hoppers.

C. A barrier of zinc sheeting along the line of which were a number of pits.

A.—This type of trap was constructed on the farm of Mr. M. J. Donegan. It consisted of a pit 6ft. long, 3ft. wide, and 3ft. deep. At the ground level, sheets of zinc were so placed that they overhung the edge of the pit, the purpose being to prevent hoppers which entered the trap from escaping. On either side of the entrance to the pit, wings of sheeting were erected to form a barrier which would lead any stray hoppers into the trap.

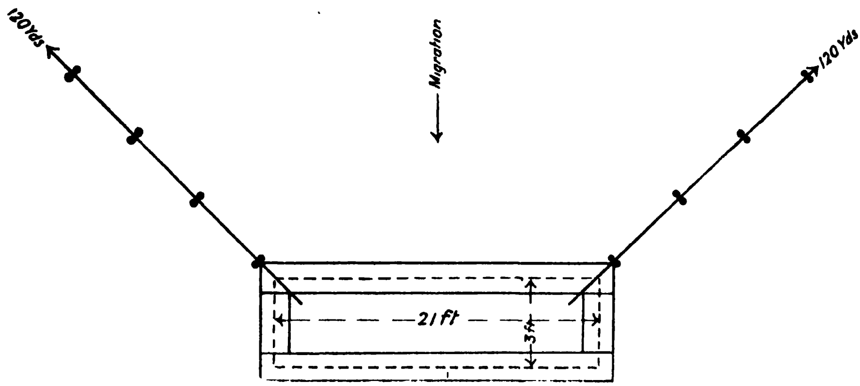


A.—Showing type of trap used on M. J. Donegan's farm in a creek bed.

The trap was successful in regard to the number of hoppers that entered it, but it was not so efficient in preventing their escape, chiefly due to the stoney nature of the soil causing much difficulty. The hoppers could crawl through the interstices of the rock and gravel, and when more material was added, the weight was greater than the zinc would support. However, after some difficulties were overcome, the pit proved successful in trapping the pest. So much so that it is felt that if more time was put into the selection of a less stoney site, or a frame work constructed to support the lining of the pit, this type of trap offers a very useful means of control.

It is suggested that in all cases of pit traps, light frames should be made about the size of the pits, in fact, all pits could be dug to the dimensions of the available frames. This would ensure a better overhang of the zinc lining, and, consequently, greater efficiency of the traps.

B.—In this experiment a trench was dug 21ft. long, 3ft. wide, and 3ft. deep, on the farm of Mr. W. G. Fidge. The trench was in the line of an advancing swarm of hoppers. From each corner facing the hoppers, a barrier of zinc sheeting was erected at an angle of 45deg. for about 120yds. on each side, to lead the insects towards the trench. The lip of the trench had an overhanging ledge of zinc sheeting which was to prevent any escape of the hoppers. Here again much difficulty was experienced in getting sufficient overhang to prevent the escape of the trapped insects, and yet prevent the sheeting from sagging. It was considered that light pins of iron or a framework of wood would greatly increase the efficiency of this type of trap.

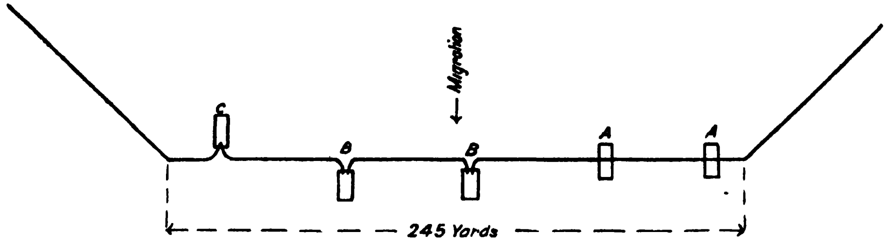


B.—Showing the type of trap used on W. G. Fidge's farm.

Another point that should receive very special attention in the construction of this type of trap is the slope of the walls. It is very important to have them perpendicular, or even better, with a slight overhang. Certainly great care should be taken to prevent any batter whatsoever, for if this should be done it facilitates the escape of the trapped insects.

This type of trap proved to be very effective in catching the hoppers, but its chief disability was the cost of construction.

C.—This experiment was conducted on the farm of Mr. A. M. Robertson. A wall of sheeting was erected 245yds. long, with a slight angle at each end of the barrier. It was placed across the line of advance of a swarm of very mobile hoppers. Along its length, at varying intervals, 5 pits were dug. The size of the pits varied within small limits, in length



C.—A diagrammatic sketch of the trap on A. M. Robertson's farm, showing the three different types, of which A type proved to be the most efficient. Note.—Pits were all standard length of 6ft., but width varied slightly; depth was standard 3ft.

and breadth; but the depth was kept as near the standard of 3ft. as possible. In 2 of the pits the entrance was by means of V-shaped races of sheeting, while in 2 others the sheeting was taken across the middle of the length of the pit. In the final pit, the entrance was made by curving a sheet of zinc into the back of the pit.

Of the different types of pits, the most successful was the one in which the sheeting was taken across the middle. This type also possessed the added advantage that in the event of a change in the direction of the wind it would still be effective as a trap for many of the migrating hoppers.

The size of the individual pits is not of any great consequence, but for economy in digging it was considered preferable to extend the length at the cost of the breadth. Care should be taken to ensure that there is an overhang from top to bottom, as this will greatly assist in the prevention of insects escaping.

PRACTICAL CONSIDERATIONS.

Erection of Sheeting.

In the original suggestions it was thought that the pegs which held the sheeting erect should be placed at distances of 1ft., and staggered each side of the line of sheeting. This method was tried but it was found that a quicker and more effective method was to have 2 pegs driven side by side into the soil. The sheeting was then forced between the pegs. By having 3 sets of such pegs to each sheet a very effective barrier was quickly erected.

In practice, it was found that the work was more quickly done by having the sheets stretched along the line, allowing just sufficient overlap. Then 4 pegs were dropped per sheet, 2 in the middle and 2 at the end, which, of course, was also the beginning of the next sheet. They were then driven into the soil as close together as possible, and the sheeting forced between the 2 pegs. In this way the sheets were found to be much firmer and did not vibrate in the wind to the same extent as with any other method which was tried.

This method of having the pegs in pairs was found to be very economical in erection, effective and speedily dismantled.

Suggestions as to the Pits.

The length of the pits depends upon the length of the sheeting with which the overhanging lip of the trap is to be made. For ease in excavation it will be found preferable to have the pit as long as possible. It will prove more economical to remove the soil from a long, relatively narrow pit, than from a square pit of the same cubic contents. This would be of importance where a number of pits were to be constructed. It is very important to have the walls of the pits overhung from top to bottom, as by so doing it is considerably easier to prevent any hoppers from escaping over the lip of the pit.

It was felt that material assistance would be obtained by having a light wooden frame-work constructed for each pit. In this way the overhanging lip of the trap would be more effectively constructed. This frame would be sunk to its depth into the soil, and the pit then dug with regular sides, all of which would facilitate the work. This framework would also prevent the sagging of the sheeting which was always found to occur in the construction of the traps.

On the experience at Snowtown there does not appear to be any necessity to cover the edge of the trap with soil. Careful observations did not show any hesitation on the part of the hoppers in crossing a bright metal surface. In fact, in all the later—and the most effective traps—the covering of the entrance of the pits with soil was omitted. Also it was found that the soil was very soon removed by the hoppers themselves, as they moved into the trap.

Time of Working.

The habit of the hoppers of not moving at night and during the cooler hours of the day, necessitates that any work which has to be done, in the way of erecting barriers or sinking pits, shall be done during the hours in which the hoppers are stationary. In effect this means that the work has to be done early in the morning or late at night. It was found that should the night be one of warm, sultry conditions, the hoppers will move forward even in the dark, but this is the exception and not the rule. Hence, working hours must be controlled entirely by weather conditions pertaining at the time.

In practice it was found that the work should not proceed later than 9 a.m. and should not be commenced before about 5.30 p.m. In the intervening hours, all work should be completed. This, of course, is controlled by the availability of labour to carry out the necessary work.

ACKNOWLEDGMENTS.

I wish to acknowledge the great assistance received from the Snowtown Council in making available sufficient money to carry out the work of the construction of traps, the transport of material, together with the use of tools, &c. To the Chairman of the Council particular thanks are due for his helpful criticism and suggestions; also to the members of the Council for their kindly interest in the work, and to the Town Clerk for his helpful advice, and the readiness with which he always found men for any work which was in progress.

My thanks are also tendered to the farmers, and especially Messrs. W. G. Fidge, M. J. Donegan, and A. M. Robertson for the readiness with which they co-operated in carrying out the work.

Lastly, but by no means least, I wish to offer my appreciation of the work of the men who did the manual labour, and who were ever ready to turn out, on many occasions at very inconvenient hours.

FARM SHEEP AND WOOL.

[By C. A. GODDARD, R.D.A. (Asst. Wool Instructor, School of Mines).]

(*Continued from page* 937.)

MARKETING AND GRADING WOOL.

Wool is sold by public auction, and like any other product sold in this way is subject to the vagaries of fashions and varying competition. These factors make fluctuations inevitable even when the sale is being conducted by an experienced salesman. These facts are often overlooked by wool-growers, many of whom believe that wool prices for different types are standardised for the sale which is in operation. In any auction bargains are frequently obtained by buyers, and likewise prices which are in excess of market value are sometimes paid.

Competition is the mother of trade, and wool-growers should do all in their power to foster competition by marketing their wool in an orderly manner.

The marketing of wool involves an immense amount of work, gives employment to thousands of men and a tremendous amount of capital has been laid out in buildings and plant. Rules and/or regulations have been framed by the wool-brokers and wool buyers' associations, which are strictly adhered to, and every effort has been made to show the huge Australian clip to the best advantage. In spite of the efforts made by the brokers, many wool clips are offered for sale in a most indifferent manner, due to lack of preparation for sale by growers.

Method of Marketing.

Sale dates are fixed and allocations arranged by the "Wool Council," some months before the selling season is due to open. The wool is offered for sale in the order of arrival into store. All wool as it enters the store is weighed on special scales, which are officially tested every day. The date of entry into store is recorded and the wool is then put into stacks, the position being carefully noted. When the time comes to make up the show floor, the show bales are easily located. When sufficient wool has arrived to fill the allocation for that particular sale it is closed, and later arrivals must wait for future sales.

A rough catalogue is made up, the show floor plotted, and the show bales are then removed from the stacks in the basement by lifts to the floor above, which is specially lighted. Here they are arranged in rows or streets, the bales standing back to back in double rows. Only a percentage of the bales of a classed clip are shown, but every bale of an unclassed clip and of star lots must be set out. The following percentages are exhibited:—

1, 2, or 3 bale lines (Star lots)—every bale is shown.
4 bale lots—2 shown, 1 capped.
5 to 9 bale lots—3 shown, 1 capped.
10 to 14 bale lots—4 shown, 2 capped.
15 to 24 bale lots—5 shown, 3 capped.

When the show floor is completed, the bales are opened and capped, and the wool is pulled ready for valuation. Printed catalogues showing each lot with their description and the number of bales they contain are given to the buyers and they proceed to value any lots that suit their requirements. The wool brokers' experts value every lot and a priced catalogue is prepared, which the auctioneer takes into the selling box with him as a guide when selling.

Valuing Wool.

There are several methods of valuation, some of which are rather intricate, such as the "Tear" method, which consists of judging not only the yield but also the combing results. It is sufficient, however, for the layman to know that wool is

always valued on its clean scoured basis, *i.e.*, the actual wool is valued and not the yolk and foreign matter it contains. Buyers are supplied with "limits," which are prepared from the ruling price for "prepared tops," and the raw wool must be bought in Australia at a price that will enable the top maker to sell at a profit at the ruling quotation. Therefore, all transit and conversion costs must be taken into account. When the limit has been supplied, the buyer valuates accordingly to it. For example, suppose the limit to be 22d. and the yield 45 per cent., then the value in Australia for greasy wool would be 45 per cent. of 22d. or $\frac{45 \times 22}{100}$ = 9.9 or 10d. per lb. The higher the yielding percentage the higher the greasy value. It will be seen from the above that wool valuing is only possible to the trained person. Many wool growers value their wool and set reserves on it. On a rising market this often proves profitable, but should the market weaken, the results would be serious. In a general way it is not advisable for a grower to set reserves, for it is the brokers' aim to get as much as he can, and he can be relied upon to do his best.

Selling Costs.

No doubt, to many the charges appear excessive, but it should be remembered that marketing wool entails an immense amount of work. Highly trained experts must be retained by the selling brokers and the clerical work involved in running a wool sale is tremendous. The regular charges are as follows:—

- Commission—Not over £200, 3 per cent.; £200-£500, 2 per cent.; over £500, 1½ per cent.
- Receiving, warehousing, weighing, sampling, advertising, cataloguing, and repacking sample bales, ¼d., less 10 per cent. per lb. rebate.
- Interlotting bales at 1s. 6d. per bale.
- Fire insurance at 2s. 6d. per cent.
- Bulking mixed bales and bags, ½d. on wools realising more than 2d. per lb., and ¼d. when wools realise 2d. or less per lb.

The sale is held in the city, the buyers attending with their priced catalogues. A wool sale differs from most other auctions, because a tremendous number of lots must be offered in a given time, and as the auctioneer either sells or passes a lot in a few seconds, the bidding is therefore fast and furious, many of the foreign buyers getting very excited, and a wool sale, especially when the bidding is keen, is very amusing.

The sale is not completed until the invoices are made out, the money collected, and finally the account sales in detail are sent to the selling grwers. Where wool is sold to go overseas the show bales must be refilled and sewn up, sent back to the basement, dumped and hooped ready for shipping, and finally carted to the wharves for loading into the ships.

Interlotting.

This consists of lotting together small lines of wool—"star lots"—which are even in type and value, and by so doing make one large lot out of several small ones. This practice was introduced with the twofold object of reducing the size of catalogues and enabling small lots to be sold in the main selling hall. Well done, no doubt it is a benefit to the grower, as the better competition of the main sale is obtained, but badly or carelessly done it is a doubtful blessing.

Bulking.

This means the pooling of the wool from mixed bales and bags into standardised classes, and has proved an unqualified success. Only a few years ago dealers were able to buy huge quantities of wool in bags at their own price,

pool it and resell, and make immense profits. Under the bulking system now in vogue, a farmer can be assured of receiving value for odd fleeces and small quantities of oddments sent to market in bags, and there is not the least doubt that this method of selling wool will extend until all small "star lots" will be bulked or pooled, and the sooner this comes about the better for the farmer and the State.

Grading the Wool.

One of the greatest problems facing the wool industry is to evolve some method of improving the marketing of small farm clips, but no improvements will ever be made until growers themselves realise that by carelessness and ignorance they are losing tens of thousands of pounds annually. When prices are low for all produce, and it is difficult to show a profit, it is urgently necessary for producers to obtain world's parity for their produce. That they are not getting it for wool in the majority of cases is a well-known fact in the trade.

Wool grading does not differ from that of any other produce, *i.e.*, it consists of the separation of the inferior from the superior, and the object is to grade in such a way as will enable buyers to value accurately. They are then in a position to bid up to their full limits, thus improve competition, and obtain better prices for the grower. The work must be done on definite grading principles, otherwise no standardisation can ever be hoped for. The grading principles are:—

1. Length of Staple.
2. Strength of Staple.
3. Quality.
4. Condition.
5. Colour.

When these principles are reviewed individually, it will be seen that when applied they simply divide the clips according to their manufacturing worth.

Length.—This has an important bearing on manufacture, and is the main deciding factor in determining whether wool is a clothing or a combing wool, or if the wool is to be carded or combed. The two processes differ and different machinery is used for each. Therefore, when very short wools are mixed with wools of combing length, neither section of the trade is being catered for.

Strength.—Soundness is an important factor to some manufacturers, while others disregard it. Therefore, to obtain the best competition sound and unsound wools should never be packed together.

Quality.—This refers to the diameter of the wool fibre and has an important bearing on yarn construction; some buyers require only fine wools, while others prefer broad ones. Therefore, quality is introduced to meet buyers' requirements.

Condition.—Wool is valued on the clean scoured basis, and even lines should be made to enable buyers to estimate yield accurately. Condition also has a bearing on freights; some wools will yield as low as 20 per cent., and this would mean that freight would be paid on 100lbs. to ship 20lbs. of wool. It is not an economic business to ship such low yielding wools. Therefore, condition is introduced into grading to separate low yielding wool from the superior ones. In many cases, if the low yielding back wool was not separated, the whole clip would be too heavy to allow export.

Colour.—Good, bright colour usually indicates high yield. Permanent defective colours interfere with dyeing and restrict the uses that wool may be put to, thereby reducing its value.

The grading principles must be applied in a practical way. They are worked collectively. *Length* separates the long from the short; *strength,* the sound from the unsound; *quality,* the fine from the coarse; *condition,* the light from the heavy; and *colour,* the bright from the dingy. Therefore, the superior wools are the longest, soundest, finest, lightest, and brightest wools, while the inferior are the short, unsound, coarse, heavy, and discoloured sorts. With definite principles laid down, it is now possible to proceed with the actual grading.

FLEECE TREATMENT.

The grading of a wool clip starts as soon as the fleece is thrown on the rolling table. Every complete fleece contains wools which vary in value and manufacturing worth, and unless the fleece is accurately and economically treated, the grading of the clip can never be successful. No definite rule can be laid down because fleeces differ, and each fleece must be treated on its merits. The object is to separate the inferior portions from the superior. This does not require technical knowledge, only care. Work around the fleece, removing only the discoloured, short, and hairy wool, and avoid removing clean fleece wool while skirting, as this means degrading a superior wool to a lower class.

The following photograph demonstrates an average skirting:—

Fleece treatment may be summed up as follows:—

1. Spread the fleece evenly on the table tip side up, then, starting at the neck, remove matted jaw pieces and any discoloured uneven wool from the head and neck; next attend to the shoulder points, removing the short discoloured wool only, then

the sweaty ends from the arm pit. Proceed to skirt along the side; very little should be removed here. The thigh and hind legs come next. Here the wool is frequently short and inclined to be hairy and matted, and it is often necessary to remove a fairly large piece from the hind points. Complete the skirting by removing any dags and urine stains from the breech.

2. After the skirting is completed, attend to the back. This work must be very carefully done. It is essential to remove all the earthy, tender wool, but in doing so do not remove sound fleece wool with it.

3. Roll the treated fleece into a neat bundle; the fleece is rolled to put it into a condition convenient for handling. Many growers look upon it as an important function and take all sorts of care to roll up a fleece with all the defects in the middle of the bundle. This is rather like the ostrich which puts its head in a hole and imagines that it is invisible; it is quite impossible to hide defects from the buyers in this way.

4. The farmer should attend to the fleeces himself unless he can afford to employ a reliable man. As a rule the farmer gets in the sheep, shears a bit, presses the wool, and does a host of rouseabout jobs. He leaves the most important work of all, *i.e.*, the wool work, to some inexperienced lad, and then when the wool is sold wonders why it does not fetch a better price.

Grading the Fleeces.

This work must be done on definite lines. The most common mistake is to put all the nice, bright fleeces as firsts and anything dull as seconds; this is done irrespective of length and quality or even soundness, and grading on these lines is quite useless. The grading principles must all be taken into consideration when setting fleece standards. The size of the clip has a most important bearing. It would not be practical to divide a small clip into a lot of classes, and before starting it is a good idea to make an estimate of the number of bales of fleece wool that may reasonably be expected. A good average flock should cut 2½ bales to the hundred. A flock of 300 grown sheep, therefore, should fill 7½ bales. Allow for 1½ bales of backs to be removed, and this leaves 6 bales of fleece wool. A clip of this size, which is the average one on South Australian wheat farms, does not allow of any extensive grading, and the practical method of dealing with it is to make one main line above a "star lot," which is 4 bales or over, and a small "star lot" of mixed fleeces. In a 6 bale clip, if one bale is rejected, the remaining 5, if the clip is of average standard, would be reasonably even in length, strength, quality, condition, and colour.

Another point to consider with a small clip of this description is that there is frequently a variation in ages and sexes. When the clip is large enough to warrant it they should be packed separately, but in a small clip like the one under discussion, it would be wise to disregard ages and sexes, except the few rams' fleeces, which may be packed in bags. The only difficulty in classing a clip on these lines is to know just the right types of fleeces to reject. The farmer woolclasser can, with a little practice, get over this difficulty by learning to analyse each fleece carefully. A staple should be drawn and the length observed. If the clip is a well-grown one, 2½in. could be made the minimum length; on the other hand, if the clip is a short one, this length could not be maintained. The staple is next tested for strength; if it will withstand a reasonable strain it is sound, if it breaks easily it is unsound. The quality is next considered; if the crimps are wide apart, the wool is coarse, if close together, fine. The condition is tested by lifting the fleece; if it is heavy and feels greasy and fatty, it is

heavy condition, if it is bulky, of reasonable weight, and feels dry, then it is light. The rejects are easily decided upon if the analysis is made carefully, and the following descriptions automatically become rejects:—

1. Very short fleeces.
2. Unsound fleeces.
3. Extra heavy dingy or discoloured fleeces.
4. Extra coarse and extra long fleeces.

When any fleece is out-type in length, that is very long, close examination will nearly always reveal the fact that the crimps are wide and that the fleece is strong or coarse. These long fleeces are nearly always light and bright and look most attractive. Nevertheless, they should be rejected, because they do not match with the average fleece type. When the clip is divided on these lines it is advisable to brand the firsts, that is, the bulk of the clip, A. Mo., and the seconds Mo.

The main line A. Mo. would contain 4 or 5 bales of good fleece wool which has been carefully skirted and backed, and is sure to meet with good competition. The small line, 1 or 2 bales branded Mo., will be made up of out-type fleeces, and can only be sold to advantage when sent to the bag pool and bulked. Farmers, when consigning their wool, should make a point of asking to have this done, otherwise it will be bought by a dealer who will make a good profit, which is far better in the farmer's pocket.

Clips of 500-700 Fleeces.

There are many clips of this size, and while the same principles are employed in fleece treatment and the classing of fleeces, the work may be extended to advantage. Instead of making only one main line and a mixed sort, two classes of fleece should be made, which would contain the firsts and seconds of the fine to medium quality, and also one class to take the coarse fleeces, as well as the small mixed sort. The classes would be as follows:—

A. A. Mo.—Consisting of the longest, brightest, sound, fine to medium quality fleeces.

B. Mo.—Consisting of the long coarse fleeces.

A. Mo.—Consisting of sound fleeces, but shorter and heavier and generally less attractive.

Mo.—Consisting of the out-type fleeces, *i.e.*, very short, dingy, extra heavy fleeces.

Clips of 1,000-1,500.

Clips of this size would require still more extensive grading, and as 25 to 30 bales could reasonably be expected when the clip is made up of breeding ewes, a few wethers and hoggets, it would be advisable to class them separately so far as the main classes are concerned, but the low grade fleeces from each might be bulked to make one big line. Make one main line of hoggets and also of wethers, and allow the low grade fleeces from each to go in with those from the ewes. On these lines, the following classes would be made:—

A. A. Ewes.—Consisting of the best of the ewes' wool.

A. Ewes.—Consisting of the second grade ewes' wool.

A. A. Hog.—Consisting of the best of the hogget fleeces.

A. A. Wethers.—The best of the wethers.

A. A. Com.—The coarse fleeces from all ages and sexes.

C. Ewes.—Consisting of all the reject fleeces, that is, very short, heavy, and unsound.

Cross-breds.

The same principles are employed in the grading of cross-bred wool as in Merino, but the sheep are bare on the head and points as compared with Merinos, and a much lighter skirting usually suffices. The wool also shows a greater variation in quality. With large cross-bred clips, careful typing will result in even lines, but with small cross-bred clips there is not sufficient wool to allow this. The fleeces should be carefully but lightly skirted and backed when necessary, and graded as follows:—

A. + BRED.—The bulk line consisting of fine to medium fleeces, sound and light to medium condition, reasonably even in length.

+ BRED.—The small "star lot," consisting of extra coarse, matted, unsound discoloured fleeces. This line should be sent to the bag pool for bulking.

It is always difficult to grade a small cross-bred clip evenly, but reasonably good results may be obtained by rejecting extra short and extra long fleeces, and also any cotted or matted ones.

Mixed Clips.

It is a great mistake to have mixed flocks; however, many farmers have them, and marketing of the clip is difficult. The only practical way to deal with such a clip is to keep the two types strictly separate from the fleeces down to the locks. Shear them separately if possible; if not, keep a bag handy and sweep up the locks after a cross-bred is shorn and put them into it. Do the same with the skirtings and belly wool.

Grading Lambs' Wool.

Length is the chief determining factor in the value of lambs' wool; it is important, therefore, to pack the long, well-grown wool in different packages than the short wool from the young lambs. There is seldom sufficient lamb wool shorn on farms to make bale lots. Nevertheless, it is advisable to grade, because even where it is found necessary to send the small quantity of wool to market in bags, those containing the good wool will eventually be bulked with other wool of the same type until bale lines are made. Send it in mixed and it will all have to be bulked together, because it cannot be satisfactorily separated after being mixed. Lambs' fleeces do not hold together. They cannot, therefore, be spread on a rolling table. The following method should be adopted:—Cover the rolling table with a cloth, pick up the lambs' fleeces after they are shorn with two pieces of board about 9in. wide, two boards from the side of a petrol case will answer the purpose. Place the fleece on the table, then shake it well and the heavy points and belly will fall to the bottom. The long, light wool will be the firsts and the heavy shakings the seconds. When a young lamb is shorn and the fleece is very short, put it all into the seconds. Brand the firsts "A. LAMBS" and the seconds "LAMBS." Never mix Cross-bred and Merino lambs' wool.

The Oddments.

The oddments, *i.e.*, the skirtings, backs, bellies, stained pieces, and locks, are nearly always neglected in a farm clip, yet they represent, without the backs, approximately one-eighth of the clip, or one complete bale, and consequently they are worthy of every consideration. They may be packed separately in bags or in a bale with a cap separating each sort. There is not enough wool to allow of regular classings of the oddments, but there are a few important points to observe.

1. The pieces should be picked over and any urine stains removed.

2. The bellies should be very lightly trimmed and pizzle stains removed from the belly wool of male sheep.

3. The backs are usually in sufficient quantity to be packed separately and they should be branded BKS.

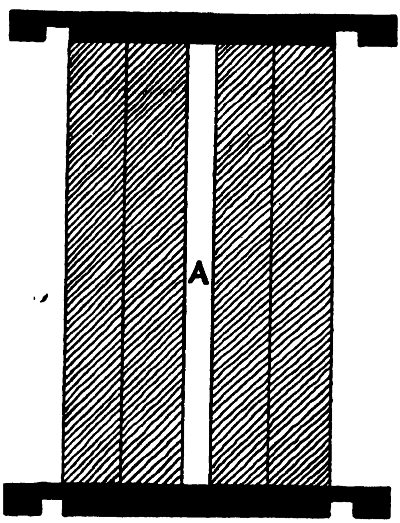
4. Urine stained wool must always be packed separately, even when there is only sufficient to fill a bag. They are branded STN. PCS.

5. Locks should be picked over, dags removed, and any large pieces picked out and put with the pieces.

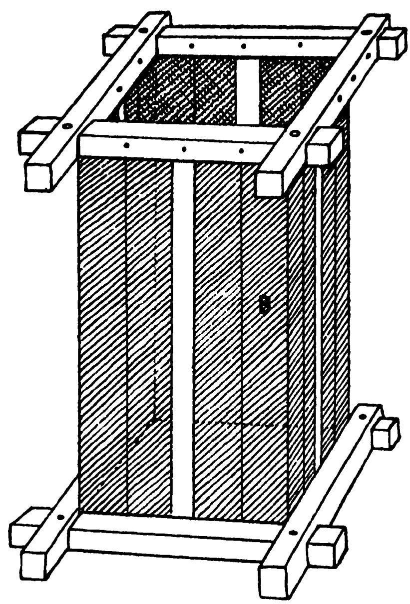
6. Never on any account throw the fleece skirtings under the table to be mixed with the locks. This is a common, but wasteful practice, because it reduces good skirtings to the same price level as locks.

Pressing and Branding Bales.

It is important to send wool to market in neat packages and to do this a press must be used. The method that so many farmers adopt of suspending a a woolpack on four wires from the rafters is not so satisfactory, as neat bales cannot be turned out in this way. A box press can be made at very little expense and is quite effective. The following illustrations and specifications will be a guide when making one.



SECTION OF WOOL PRESS



WOOL PRESS

MATERIAL REQUIRED.

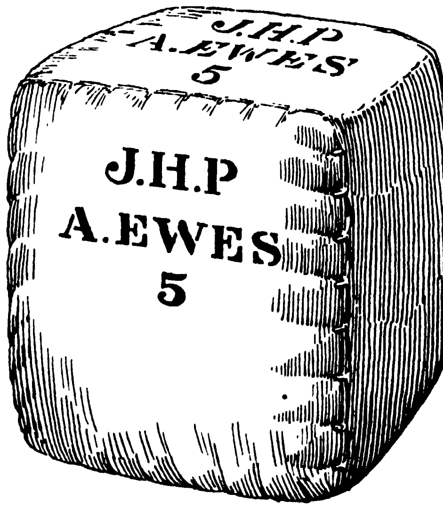
Press 4ft. 6in. high by 2ft. 3½in. wide.

Cross pieces, 3 x 2 softwood, 24ft.

Boards for sides, floor boards, softwood, 75ft.

When filling, place the fleeces in layers of six, and pay special attention to the stamping of the bottom. When finishing off a bale, place at least one layer of fleeces above the sides of the press. Strain the cap over the top with pins

and then sew the front side first. When the front and one side are sewn, if necessary, a fleece may be stuffed in from the side still remaining open; this is done if the top is a little slack.



BRANDING THE BALES.

Bales should be branded neatly on the cap and the front side, with the owner's mark, description, and number. Special care must be taken to brand on the front side, because the bales are placed on the show floor back to back; the front is the only visible side. Stencil plates can be easily cut from the side of a petrol tin, using a ¼in. chisel. Even when cut in stout cardboard, stencil will last long enough to brand the season's bales. The illustration will demonstrate exactly how a bale should be branded.

EXPERIMENTAL FEEDING TESTS CONDUCTED AT PARAFIELD POULTRY STATION.

[By C. F. ANDERSON, Poultry Expert.]

A series of feeding tests are being conducted at Parafield Poultry Station with a view to ascertaining if suitable foods which are obtainable on the majority of our farms can be satisfactorily fed to poultry. The tests are each of 50 White Leghorn pullets, and commenced on April 1st, 1933.

The feeding is as follows:—

No. 1 *Test.*—Morning—Wet mash composed of 1 part crushed barley, 2 parts wholemeal (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 2 *Test.*—Dry mash composed of same proportions as No. 1 Test.
Midday—Greenfeed. Evening—Wheat.

No. 3 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts pollard (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 4 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts wholemeal (by weight), ½ lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 5 *Test.*—Morning—1½ozs. wheat per bird.
Evening—1½ozs. wheat per bird. Greenfeed in season.

The following are the numbers of eggs laid by each pen from April 1st, 1933, to March 31st, 1935.

These tests terminated on 31st March, 1935, and a full report will appear in this *Journal* in due course.

	No. Eggs Laid April 1st, 1933, to Feb. 28th, 1935.	No. Eggs Laid Month of March, 1935.	Total Eggs Laid April 1st, 1933, to March 31st, 1935.
No. 1 test	13,866	346	14,212
No. 2 test	12,757	239	12,996
No. 3 test	12,412	338	12,750
No. 4 test	13,600	254	13,854

THE STATE EXPERIMENT ORCHARD, COROMANDEL VALLEY, NEAR BLACKWOOD, SOUTH AUSTRALIA.

[By GEO. QUINN, Chief Horticultural Instructor.]

(*Continued from page* 987.)

ROOTSTOCKS.

Cherry, Peach, and Pear.

If the fig and the olive trees—which are usually grown from branch cuttings and occasionally from natural stools or offsets arising from the stem of the parent at or immediately below ground level—be omitted, all of the commercial varieties of the 15 different kinds of tree fruits contained in the collections in this orchard are reproduced in nurseries by means of grafting a segment or "scion" of the sort desired on to a suitable rootstock.

Even the most valued of the named sorts of walnuts are, owing to the development of improved technique, now being raised in this manner in commercial numbers in the open nursery beds by a local nurseryman in South Australia.

Expressed in simple terms, any form of plant grafting may be defined as "uniting a scion to a rootstock."

A "scion" may consist of a piece of living bark carrying one live bud only, or it may comprise a living twig on which several dormant buds are present. In technical terms, the grafting operation relative to the former is referred to as "budding," and in respect to the latter as "grafting."

A "rootstock" or "stock," as it is more often termed by nurserymen and fruitgrowers, may consist of a piece of a root, a complete root system, or a rooted plant—whether consisting of a seedling or segment only, but which has already established a separate root system capable of absorbing mineral solutions from the soil.

The functions which a scion is destined to perform in the economy of a fruit tree are—(1) to give rise to a stem and branch system or "head" carrying the foliage and ultimately the flowers and fruits; and (2) through the agency of its green parts to secure carbon from the atmosphere, and to elaborate all necessary tree building and sustaining properties from that element when it is utilised in conjunction with the constituents in the crude solutions received from the soil *via* the root system.

The functions of the rootstock are obviously also of a twofold nature—(1) to develop a root system capable of anchoring the tree firmly into the soil, and (2) to ramify the soil body sufficiently with its absorbing root fibres, and thus secure and transmit through the stem to the foliage an adequate supply of soil moisture in which the required mineral plant food substances are dissolved.

It will be seen, therefore, that in uniting a scion with a stock, two separate entities are brought together, and in view of the reciprocal activities they are called upon to perform, if the union is to be productive of lasting good, a high degree of compatibility between them is essential in this unique form of non-sexual union.

It may be claimed, therefore, that to enable a permanently satisfactory union to take place, the closest botanical relationship must exist between the parent plants from which both the scion and the stock originate. There is no doubt it has been due to the general acceptance of this fact, that nurserymen and horticulturists in all countries have, by common consent, grafted peach on peach, almond on almond, apricot on apricot, plum on plum, and cherry on cherry as standard practice.

Although botanists may class all of the above fruit trees as representing merely different species of the genus *Prunus,* and horticulturists have found that scions and rootstocks of most of them may unite and grow for varying periods of time, yet that intimate symbiotic relationship which is necessary to the maintenance of a successful and prolonged union does not appear to exist between most of them. Occasionally, however, exceptions seem to arise which leads one to the view that this lack of sufficient compatability between all of the varieties of some of these so-called species may not prove to be a fixed and definite characteristic.

There is probably no other phase amongst the many commonly accepted horticultural practices upon which research on scientific lines has been more closely focussed during the past 10 to 15 years than that which centres around the relationship existing between rootstocks and scions.

Most of this research work, both in Great Britain and America, has had reference to rootstocks used in the propagation of apple trees. Latterly, however, some attention has been turned towards the study of the selection and vegetative propagation of rootstocks used in the production of plum, pear, and cherry trees.

Whilst in America and Canada seedling rootstocks have been in general use from the inception of the great apple growing industries of those countries, in Great Britain and the western portions of the European Continent, vegetatively raised apple rootstocks have been largely used in conjunction with seedling stocks of the "crab," and so-called "free" types. These vegetatively produced stocks have been used in what may be termed more specialised forms of apple culture which have prevailed in these older countries where land was restricted and costly, but labour cheap.

In France and Britain, particularly, to suit these limited areas, apple trees have been grown in dwarfed form, as bushes, cordons, and half-standards. When grown as full standards set out in orchard areas, the more vigorous seedling "free" stocks have been used. To meet the demand for trees which assume various sizes, types of apple trees claimed to be possessed of a naturally diminutive stature, the varieties of which have become known by quasi specific names of "Paradise" and "Doucin," have been long used as rootstocks. Certain forms of these had been selected because they also displayed inherent tendencies of free rooting, and thus lent themselves readily to vegetative forms of reproduction—a very necessary point in the commercial propagation of rootstocks.

When Hatton and his co-workers at the East Malling Research Station of the Kent Incorporated Society for Promoting Experiments in Horticulture began to collect these variously named types of apples used for rootstock purposes, they discovered that much confusion existed in respect to the nomenclature as well as to the assumed characteristics of growth attached to these varieties. After much painstaking botanical study and testing had been carried out in the field on all the available sorts, this confusion was finally straightened out and a selection made of the kinds of apples which, under most searching trials, had been demonstrated to possess certain definite rooting characteristics. It is claimed that in Britain, these characteristics of the various rootstock types selected at the East Malling Research Station remained absolutely distinct, whatever the normal strength of growth of the scion variety worked upon them may have been, or the nature of the soil in which they were grown.

These apple rootstocks, which have been tested so thoroughly, have each been vegetatively raised from segments of a selected tree, and are, in consequence, all of a true clonal nature or strain ([1]). They have been

classed by the selectors under the following designations, and each type is claimed to exercise its influence on the growth of the scion varieties worked upon it in the direction respectively set forth hereunder:—

Group (*a*) ..	Very dwarfing	No. VIII.	French Paradise.
		No. IX.	Jaune de Metz Paradise.
Group (*b*) ..	Semi-dwarfing	No. II.	Doucin (English Paradise).
		No. V.	Doucin Ameliore (Improved Doucin).
Group (*c*) ..	Vigorous stock	No. I.	Broadleaf English Paradise.
		No. VI.	Nonsuch (River's Paradise).
Group (*d*) ..	Very vigorous stock ...	No. XII.	Layer raised Free Stocks.
		No. XIII and XVI..	Layer raised Free Stocks.

Although environmental conditions may increase or diminish their health or vitality, or being united to a very vigorous scion variety may also act to a certain degree in the first named direction, yet any morphological characteristics such as a vertical or deep rooting, or a more slender or fibrous or shallow rooting habit is not changed. That the quality conferring immunity or high resistance to the attacks of a certain pest, viz.: Woolly Aphis is not changed by the scion variety, is instanced by the continued use of the Northern Spy apple as a rootstock in Australia.

Providing such clonally raised rootstocks, when being selected from the propagation beds, are carefully graded in respect to such matters as even and healthy development in roots and tops, the chances of achieving great uniformity of growth on the part of any scion variety grafted upon them has been amply demonstrated. Whilst this feature holds many advantages for the commercial fruit-grower, it is now recognised as being absolutely fundamental in importance to the research worker who desires to eliminate all possible variable plant factors such as may arise from the use of rootstocks possessing unknown characteristics.

After beginning to experiment with the Winter Majetin variety—an old Norfolk apple—as early as 1869 at Ballarat, Victoria, it is now about 60 years since Australian Nurserymen systematically began using a type of vegetatively raised clonal rootstock—the Northern Spy—on which to propagate all kinds of apple trees. For several years, the trees were raised by grafting a piece of a root of this American variety on to a shoot of the desired scion variety. As this form of single grafting involved the burying of the base of the shoot of the scion variety under the soil, roots were emitted from it and ultimately discarding the nursing roots of the Northern Spy, the object, which was the elimination of the root inhabiting form of the Woolly Aphis, failed. This method was then superseded by what is known as "double working."

This consisted of grafting a scion of the Northern Spy into a piece of root of its own kind, and on the stem or resulting shoot from this combination, the desired scion variety was budded or grafted several inches above the surface of the ground, or at such a height as to preclude any possibility of the scion variety becoming self-rooted.

This rootstock was adopted in Australia purely because of the immunity it enjoys from the attacks of the subterranean form of the Woolly Aphis or American Blight (*Eriosoma lanigera*, Hausm), which in this country proves extremely injurious to the roots of young apple trees, and more particularly so during their nursery stages. During the past half century, 95 per cent. of the millions of apple trees propagated in Australian nurseries have been raised as described above, either on "double worked"

Northern Spy rootstocks, or simply stem-worked on rooted sprouts from horizontally layered Northern Spy trees. The Northern Spy variety secured early preference for rootstock purposes over Winter Majetin, and other seemingly equally Woolly Aphis resistant varieties which were tried at the time, because, like the selected Paradise strains of Britain, it possessed very free rooting characteristics, and thus proved a good proposition for the immediate furtherance of the nurseryman's objective.

During the last few years, since the apple growing industry of Australia has become widely spread, and reaching out into soils and climatic zones not quite fulfilling all of the requirements of the apple tree, complaints have arisen in some localities against the shallow fibrous rooting characteristic of this rootstock.

As previously indicated, it has not lost its immunity from the attacks of the Woolly Aphis, nor has its capacity to emit abundance of fibrous roots diminished through constant repetitions of vegetative forms of reproduction, but it cannot thrive in shallow or dry soils, nor can its fine roots penetrate the stiff tenacious clay subsoils so commonly found in many of the apple growing districts of the various States.

It would seem, therefore, that whilst the type of rootstock most desired to supplant it must possess deep, strong rooting characteristics, it must still retain the desirable free rooting and aphis resisting qualities of the Northern Spy.

The clonal rootstocks developed at East Malling in Britain for apple, plum, pear, and cherry trees have now been distributed almost throughout the world, and several of the Australian States have procured practically all of the selected series. Through exchanges of scions of other varieties of fruit trees from the Blackwood State Collection, the writer has succeeded in securing from the other State Horticultural Divisions, most of the East Malling types. These are now being vegetatively propagated in the nursery at the Blackwood State Orchard. It is too much to hope that they all will prove equally satisfactory in this climate, as they are claimed to have proved in Britain, but further tests may lead to some of them, at any rate, meeting our requirements more effectively than some of the rootstocks now in use.

Notwithstanding the success achieved by the Chalcid parasite (*Aphelinus mali*) against the branch inhabiting form of the Woolly Aphis, the writer deems that this blight proof quality in the rootstocks used for apple trees is highly valuable, if not absolutely indispensable, in this country with its mild winter and warm spring climate. Genetically, the vegetatively propagated rootstock must possess greater uniformity of composition and habit as compared with the seedlings in common use, and which have usually arisen as the result of the fusion of male and female elements from the flowers of varieties widely differing in such characters. Recognising this fact, the writer, with the assistance of the District Horticultural Instructors, and the cordial co-operation of nurserymen and orchardists, has brought together at the Blackwood State Orchard nursery about half a dozen seemingly varying strains of the Northern Spy apple as found in this State, also some eight types of seedling Myrobalana plums. These are being propagated vegetatively in sufficient numbers for subsequent observation and testing. Any which may display characteristics of an outstanding and desirable nature, may be then worked with scions of known commercial varieties and further tested.

With the exceptions of the Northern Spy apple, and the occasional use of the so-called Angers quince, practically all of the rootstocks used in

Australian nurseries—and in the experiments in the Blackwood State Orchard also—have been raised from seeds of various and often unknown kinds of the different fruit trees.

It cannot be denied, however, that in spite of this latter fact—as Dr. Swarbrick, of the Long Ashton Agricultural and Horticultural Research Station of the University of Bristol, states of the American apple orchards which have been worked on seedling rootstocks (2) that in Australia there are vast numbers of orchards composed of trees of apricot, peach, plum, almond, and citrus fruits of various kinds, which have developed with remarkable uniformity notwithstanding that they have all been raised on seedling rootstocks. This would indicate in respect to the stone fruits, at any rate, that given appropriate conditions and good cultural attention, a high degree of uniformity would seem possible of achievement from seedling rootstocks provided always that equal care and rigidity be applied to the culling out of inferior or weak types of plants from the seedbed onwards throughout the nursery lifetime of the trees in question.

The polyembrionic characteristics of the seeds of members of the citrus family, and as a consequence, the more or less unsuspected use of a great number of asexually developed seedling rootstocks by this means, may yet be found to exercise an important influence in the uniformity of growth noted in these last-named trees.

ROOTSTOCKS.

For Cherry Trees.

In South Australia, the cherry is considered to be the most fastidious of all the stone fruit trees in respect to its adaptability to the varying combinations of soils and climates found throughout most of the fruit-growing areas in the State.

It delights in deep, well drained soils, rich in organic matter. Combined with this, a heavy winter rainfall, a reasonably cool, dry atmosphere during spring and summer, together with shelter from rough, cold, cutting winds are all equally desirable. In this State, these comparatively ideal conditions are found over a limited area only, in the Mount Lofty Ranges. This is situated directly east of the City of Adelaide, and it stretches northwards from Mount Lofty through Uraidla, Norton's Summit, to Cherryville and Montacute, extending eastwards, taking in Basket Range, and adjacent country between.

It is true in other parts of this range where the annual rainfall approximates between 30in. and 35in. fairly good cherries are grown in selected spots. Further north, in sheltered valleys through the hilly country around Angaston and Clare, the Kentish and Morello types of cherry (varieties of *Prunus cerasus*, Linn.) thrive fairly well. In the lower South-Eastern portions of the State, especially in wind-sheltered positions and where the soil is moist and never water-logged in winter, quite good quality sweet cherries (varieties of *Prunus Avium*, Linn.) have been grown. Usually, however, in these South-Eastern localities, the soil is shallow and the trees do not grow to large dimensions, whilst in moist, humid spring seasons, the ripening fruits are liable to be attacked by the brown rot fungus (*Sclerotinia fructicola*).

In the above described most favoured portion of the Mount Lofty Ranges, many varieties of sweet cherries have been successfully grown for a period approximating to three-quarters of a century. It is claimed that there are few parts of the world capable of producing cherries of a bolder and better quality than those grown on some of the very steep hillsides in the narrow sheltered valleys which intersect this portion of the Range. The soils covering the best slopes are of great depth and richness.

Where the hardy pioneer settlers have, with infinite labour, cut their winding roadways around the faces of these slopes, thus descending to the lower levels on a reasonably graduated course, the soil profiles may be studied as readily as the pages of an opened book. Here, in many places, from 2ft. to 3ft. of friable loam overlie a crumbly, deep clay into which is blended a mixture of fragments of soft, shaly slate and quartzite rock—the whole being deeply iron-stained.

This steep land, which annually produces a heavy crop of naturally sown vegetation, embodying clovers, wild vetches, and other legumes amongst its grasses, and more succulent herbage, is, of necessity, hand worked by means of heavy pronged hoes. This tillage is applied in early spring time when the herbage often has to be mown ahead of the workmen who skilfully turn the soil and incorporate the whole of this self-sown crop into the land. This procedure, followed from year to year, has created a rich humified surface soil which holds moisture, but does not suffer by erosion in the same manner after heavy summer rain-storms, as do the less humified surfaces of slopes found in many other parts of these ranges —including Coromandel Valley—where the soil body has been formed from similar types of the original rocks. In some of the old orchards, a wealth of information which has been accumulating over many years, may be found relative to the behaviour of numerous varieties of sweet cherries which have been grafted on various rootstocks and planted irregularly and at random in different aspects along the curving faces of these slopes.

At the time the State Orchard was inaugurated, from a study previously made of the question amongst these cherry orchards, the writer was assured that three distinct species of cherries (*Prunus*) were being used in this State as rootstocks for the popular varieties of sweet cherries.

These consisted of:—

1. The Mazzard, or Black Mazzard, or Bird Cherry of Britain (*Prunus avium*, Linn.).

Recorded in horticultural literature as being originally indigenous to Eastern Europe and extending into the western portions of Asia in the vicinity of the Caspian Sea, and as far as northern India, it is now found wild throughout Western Europe and the British Isles.

This species resembles, and is claimed by botanists to be the original form from which the present sweet cherries ascended. The tree is reported by Hedrick to have established itself in the eastern States of America where it reaches a height of from 30ft. to 40ft. in the woodland glades. (U. P. Hedrick, "Cherries of New York," page 41.) It is stated by that author to be less resistant to cold—as experienced in eastern America—than the sour cherry or the scented cherry, and is very susceptible in the nursery rows to the attacks of a shot-hole fungus (*Cylindrosporium padi*), the suppression of which adds considerably to the cost of raising trees on it as a rootstock. Here, fortunately, these latter characteristics prove of minor importance. It is also claimed that records exist showing that

its use as a rootstock for sweet cherries was understood by the Greeks and Romans upwards of at least a century before the Christian era began. The habit of growth of this tree, together with the colour of its bark, its conspicuous flowers, and bold, dark-green, deeply serrated foliage makes it somewhat difficult to distinguish from many of our cultivated varieties of sweet cherries. The fruits, however, are quite small and black when ripe, and have a rather harsh, astringent flavour—even when dead ripe. The writer has found that a very low percentage of the seeds from locally grown Mazzard fruits are germinable. The rootstocks of this tree used by local nurserymen up till comparatively recent years arose from seeds imported from Europe—chiefly from France. Of later years, it is claimed this seed has also proved to give poor results, and resort has been made to the use of suckers naturally developed from the older plantations growing on seedling Mazzard rootstocks. These are actually root cuttings, or

Mazzard Cherry (*Prunus avium*, Linn.).

[After Hedrick.]

stools arising where roots have been lacerated or broken in the tillage operations. Although originally decried as a stock, sweet cherry trees worked on them may now be seen growing in the orchards alongside others on seedling Mazzard rootstocks, and thus far, doing equally well in every respect.

The old bias, which asserted that the suckering habit would be intensified in the resulting tree, has not, to the writer's observation, been verified. The local cherry growers call these "seedling suckers"—a somewhat involved, yet accurate description.

In Europe, America, or Australia, wherever this rootstock has been worked over to sweet cherry varieties, it is reputed to make an excellent union, and if the conditions of soil and climate are favourable, a very

strong vigorous tree results. This habit of growth is claimed to have postponed the arrival of the fruit bearing period for many years. (The researches of recent years into the varying pollination requirements of the different varieties of sweet cherry trees may be found, however, to have an important bearing on this phase of the matter.) At the same time, when the sweet cherry trees worked upon this stock reach a fruiting age, the quality of the fruit has usually proved superior to that of the same varieties grown on other stocks, and the quantities borne have been greater.

The long period of waiting, however, caused cherry growers in this and in other States and countries to seek other rootstocks deemed more capable of inducing lesser vigour and an earlier cropping habit in the varieties worked upon it.

Mahaleb Cherry (*Prunus Mahaleb*, Linn.).

[After Hedrick.]

2. The Mahaleb, or Scented Cherry (*Prunus Mahaleb*, Linn.).

This species of prunus is also recorded to have been originally a native of eastern Europe and Western Asia, but has spread farther west into Europe, following the course of plant dissemination movements during more recent centuries than the preceding species. It is a slender growing, bushy tree, bearing masses of small, green, smooth, glossy leaves, more comparable in many respects to those of the smaller leaved types of apricot foliage than to that of the other well-known species of cherry.

The fruits which approximate to the size of a garden pea seed quickly pass from green to yellowish red, and finally, when fully ripe, assume a shiny black colour. They are hard, bitterly astringent, and not at all palatable. The bark of the tree has a pale, smooth, brownish colour tone, quite distinct from that of other well-known species of the cherry family. Although recorded in Britain early in the 18th century, as an ornamental

lawn tree only, in France later in that century, its use was advocated by Duhamel du Monceau as a stock for sweet cherries. It was not until early in the 19th century when Loudon, in the "Encyclopaedia of Gardening," first referred to it as "the most effectual dwarfing stock for sweet cherries," that notice was taken of it. Acording to Loudon, the French horticultural writer Dubrueil commended it for use "in soils of a light, sandy, or chalky nature," but Thomas, an American writer, on the other hand, in the "American Fruit Culturist," in 1849 declares that it "possesses the advantage of flourishing in heavy clay land," a statement scarcely supported by our experience at Blackwood State Orchard, as outlined herein. Hedrick in "Cherries of New York," page 32, states, "Wild or cultivated, the Mahaleb is a shallow rooted plant, a fact which must be taken into consideration in its use as a stock."

The writer is unable to indicate when this rootstock was introduced into Australian nurseries, but a few seemingly very old trees may be found under favourable conditions still existing in old-established orchards in the Mount Lofty Ranges in this State, which are claimed by the owners to have been propagated on Mahaleb rootstocks. In the writer's opinion, although unable to find the peculiar foliage of this species, these tree trunks bear the malformation characteristic of the point of union produced by the fusion, or limited degree of fusion, of this rootstock with the sweet cherry varieties.

The Mahaleb nursery stocks used in this State have been raised from seeds imported from French sources. The damaged roots of this species do not, as far as the writer's observations go in this climate at any rate, send up suckers so freely as either the Mazzard or the Kentish species; though in excavations depicted herein, it was found that at Blackwood suppressed suckering evidently existed to some extent from the damaged roots of this stock. Offsets or stools arise freely around the stock immediately below its point of union with the scion variety, and on mature trees these stunted shoots soon produce flowers.

European writers have freely recommended its use as a dwarfing stock for sweet cherries in preference to the Morello or sour cherry, owing to the paucity of its suckering habit. Hatton recommends it should be propagated for stock purposes by using green softwood cuttings off the young growth—presumably rooting them in propagating frames.

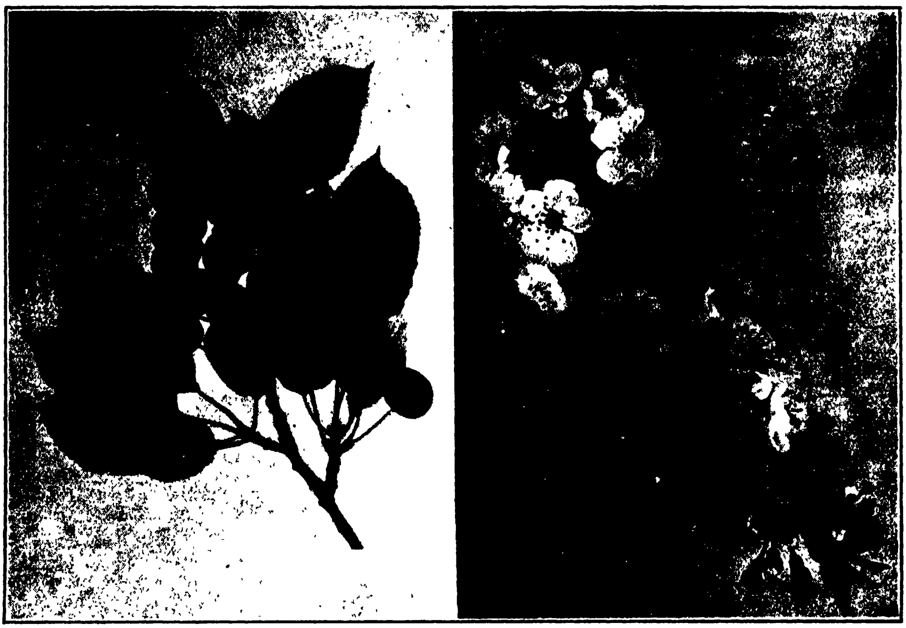
It is stated by Hedrick that the use of this rootstock made great headway in America from 1850 onwards, and at the time of the publication of his illuminating work, "The Cherries of New York," in 1915, he claims that "probably 95 per cent. of the cherries grown in this country are budded on the Mahaleb." The reasons for this may appear somewhat obscure, unless the context is quoted. "There is no question," he states, "but that it is much easier to grow cherry trees on Mahaleb stock in the nursery, than on Mazzard, and usually, a *better looking tree* can be delivered to the fruitgrower on the first-named stock. Seedlings of both stocks are imported from Europe and those of the Mahaleb are usually cheaper."

He further claims that the Mahaleb is less fastidious in respect to soils, climatic, and tillage attentions, and is also less troubled in the nursery by certain common insect pests and fungus diseases. Hedrick proceeds further: "Fruitgrowers on one side hold that the Mazzard is the best stock for all orchard varieties of this fruit, while nurserymen controvert this view, and say that the Mahaleb is at least a fit stock for sweet sorts,

and is the best for the sour cherries, which are very largely grown in America, and moreover, it is now impossible to grow cherry trees on Mazzard roots at prices that fruitgrowers are prepared to pay.'' In the light of local observations, the above quotations are illuminating, revealing as they do the viewpoints of the men who grow cherry trees for sale, and those who grow them for the sale of the fruit they produce. Such variations of opinion are not confined to American cherry growing interests.

3. THE KENTISH, MORELLO, PIE OR SOUR CHERRY (*Prunus cerasus*, Linn.).

The specific form of this cherry is also stated to be indigenous to South-Eastern Europe and South-Western Asia. Two groups have been erected from this species, one representing the bright red fruited form with almost colourless juice in the fruit, as represented by the English Kentish, or Pie cherry, and the other with dark fruits, having coloured juice, known as the Morello or Griotte. The former is the kind which has been used here at times as a dwarfing stock for sweet cherries. The tree has a



Kentish Cherry (*Prunus cerasus*, Linn.).

[After Hedrick.]

comparatively straggling bushy habit, the trunk and branches being smooth, and the bark reddish-brown, lightly tinted with a dull grey colour tone. The branchlets are slender, and as the tree develops, tend to become somewhat horizontal. The blossoms are usually borne on very short stalks on small bud spurs, and the bright red coloured, roundish, oblate-shaped fruits stand out on short stoutish fruit stalks. The flavour is acid, but not unpleasantly so when quite ripe.

This tree is scarcely ever cultivated in the best cherry growing districts of this State, but occupies odd corners and uncultivated spaces where, owing to the facility with which it sends up suckers, thickets form, unless some control is exercised from time to time. Whenever it is taken in hand here, it is almost purely as a dwarfing stock for the more vigorous sweet

cherry varieties. According to Hedrick, in the United States selected varieties of it are extensively grown and highly valued for kitchen purposes.

The labour of overcoming its inveterate habit of suckering, particularly during the earlier years of the growth of the trees worked upon it, has caused its rejection, probably more so than the extreme dwarfing influence it exerts on the scion varieties of sweet cherries.

The general impressions conveyed by the South Australian growers of cherries on the relative merits of these rootstocks and the writer's observations made amongst the cherry orchards in this State may be summarised somewhat on these lines.

The Mazzard rootstock displays a great measure of affinity with practically all of the varieties of cultivated sweet cherries. It forms, almost without exception, the basis of stout, vigorous growing, even stemmed, large trees. This vigour is believed to postpone the formation of fecund flowering spurs and, consequently, causes the trees to continue in an unpro-

[*E. W. Pritchard, Photo.*]

Bigarreau Napoleon on Mazzard rootstock.

ductive condition over a period of years, which inversely varies in length with the quality of the soil and climatic conditions appropriate to the welfare of the cherry tree.

The Mahaleb rootstock, somewhat contrary to the European and American claims, does not in this State, for a good many years, at any rate, appreciably dwarf the growth of the scion variety of sweet cherry worked upon it. It appears, however, that this early vitality begins to wane within probably the first ten years, and the tree soon after settles down to crop quite well. After cropping a few years, the restrictive or non-reciprocal action of the stock begins to become apparent in the swollen nature of the ring along the line of union with the sweet cherry scion. It is also reflected in the erratic dying back of fairly large upper branches in the tree's framework, and sooner or later, according to the environ-

mental conditions, the tree declines, and too frequently dies at an age when, to be profitable to the grower, it should be capable of yielding its largest crops.

The Kentish or Sour Cherry rootstock appears to give a fair start to the sweet cherry scion variety worked upon it, and provided the inherent suckering habit is rigidly suppressed during the first few seasons after planting the trees into the orchard, it continues to make good progress. Not many seasons, however, elapse before evidences of dwarfing become noticeable. and whilst the tree usually retains fair health, it generally comes to a standstill, and the terminals, or leading points of the limbs, die back slightly from time to time. The tree begins to crop in consonance with the above described recession of vigour, but the area of fruit-bearing wood is so limited that in the aggregate, the yield is low compared with

[*E. W. Pritchard, Photo.*]

Early Lyons on Mazzard Rootstock.

that of the same varieties worked on the other two first-named stocks. With closer grouping of the trees in the rows, the increased numbers planted per acre of land might compensate for the deficiency of the individual tree yields.

It was with these impressions before him that the writer planned what has been termed the "Cherry Stock Trials," which were set out in the Blackwood State Orchard in 1910. The object in view was to try to ascertain if the above-mentioned claims relative to the varying influences of these different rootstocks on the behaviour of the scion varieties worked on them could be substantiated when the varieties of the sweet cherries were grown side by side on the same plot of land. Further, being impressed with the uniformity of growth and good health of those trees of all ages stated to be growing on Mazzard rootstocks in the commercial cherry orchards in the Mount Lofty Ranges, the question of finding a solution of the problem of the deferred cropping habit of such trees was

also borne in mind. It was argued by the writer that, if the Kentish rootstock brought about a fruiting habit quickly by checking the too rapid extension of the top of the tree growing directly on it, would not a section or stem piece of Kentish origin superimposed on to the Mazzard rootstock also set up a similar re-action or effect on the vegetative activities of the scion variety finally worked upon the Kentish stem piece? A fourth series, embodying this combination, was therefore included in the trial.

A rectangular plot—including headlands or half-row widths—measuring 293ft. long by 83ft. wide, situated in a fairly sheltered position at the lower and western end of the orchard, was selected for the purpose. The longer sides of this parallelogram run east and west, with a fall westward equal to 29¾in. per chain on the upper or southern side, and 27½in. per

[*E. W. Pritchard, Photo.*]
Early Purple Guigne on Mazzard rootstock.

chain along the lower or northern side. The greater falls in the land are in a northerly direction along the end boundaries, equalling 82½in. per chain on the western end, and 81in. per chain on the eastern end of the rectangle.

The land was subsoiled to a depth varying between 12in. and 16in. The tree positions were arranged in four rows running the full length of the plot, and were distributed on the septuple system at 20ft. from each other. It will be noted that the steeper gradient runs northwards across these rows, and that the general surface of the block is reasonably even and regular on the two sloping faces.

Five of the then principal commercial varieties of sweet cherries were used, viz.:—Bigarreau Napoleon, Early Lyons, Early Purple Guigne, Florence, and St. Margaret's.

The different rootstocks were planted in parallel rows, the Mazzard occupying the top or first, Mahaleb the second, Kentish the third, and those for the combination Kentish on Mazzard being allotted the fourth, or the row lowest down the slope. The rootstocks of Mazzard and Mahaleb

were raised by a local nurseryman (Mr. H. Wicks, Sen.) from seeds imported from France, and those of the Kentish were stools obtained from a cherry grower in the Mount Lofty Ranges. As these cherry stocks were included in a large number obtained for general nursery operations, the most evenly grown plants available of each kind were picked out for this stock trial. They were budded in February, 1910, and to try to save a season, planted in position as dormant buds the following August (1910).

The bud wood of each variety was obtained from a selected tree of each kind in an orchard in the Mount Lofty Ranges. It will be seen, therefore, that apart from any variation which might occur in the seedling rootstocks, the trees were of reasonably uniform composition. Beginning at the eastern end of each row, the same order of planting the scion varieties was followed, viz.:—Three trees each of Bigarreau Napoleon, Early Lyons,

[*E. W. Pritchard, Photo.*]

Florence on Mazzard rootstock.

Early Purple Guigne, Florence, and St. Margaret's were set out in consecutive order. The modern method of randomizing the rootstocks had not then been adopted in the arrangement of horticultural experimental tests, but to try to make the positions as comparable as then deemed desirable, the respective scion varieties on all of the stocks were planted parallel to each other, the only difference being the slight variation in altitude of the rows in which they were placed. As a distance of only 52ft. separated the upper and lower rows, the variations in soil, aspect, and general shelter were reduced to a minimum. This order of planting certainly facilitated the forming of comparisons in respect to the growth, cropping, etc., of the different varieties when growing on the respective rootstocks.

Owing to the western end of this plot broaching upon the margin of a bed of surplus nursery stock, in the second or third year disaster overtook the trees of St. Margaret's variety worked on Kentish rootstocks and two

others of the same variety which were budded on the Kentish on Mazzard combination. This arose from a very sudden and virulent attack of the nocturnal leaf-eating Curculio Beetle (*Otiorrhynchus cribricollis*), which had bred up in destructive numbers amongst the thicket on this more or less neglected nursery plot. These injured trees subsequently died, and those worked up in their places have failed to reach dimensions entitling them to be included in this review. From some obscure cause, one tree of Florence variety worked on Kentish rootstock also died during the early stages of the trial, and the blank space remained unfilled.

A close examination of the soil profiles made in eight positions along the top row, in the centre between the second and third rows, and along the bottom row, indicated that the surface soil—a dark-brown non-humified clay loam—varied in depth between 5in. and 10in., averaging approximately 7½in. Under this, plastic clays varying in colour from a rather bright red to pale yellow, were found in a layer ranging from 13in. to 43in. thick. Amongst these clays, scraps of soft, shaly slate and quartzite

St. Margaret's on Mazzard rootstock.

were freely mixed.. In one spot only, was a soft calcareous marl blended with the lower clay body. In a couple of the test holes a solid slate stratum was located approximately 25in. below the surface. This was in the lower western corner of the plot, where the country rock shelves towards the surface near the bottom of the slope. Most of the other test holes revealed no stone at 40in. to 50in. down. As subsequent excavations more fully verified, the roots of the oldest trees were mostly located below ploughing depth—about 5in.—down to approximately 16in. from the surface. The above description of the soil and subsoil indicates that in its present condition it is not ideal land for growing cherry trees. The surface loam is not only of insufficient depth, but is inadequately supplied with humus.

In very wet winters, the escape of surplus soakage water through the sublayers must be dangerously slow. This is evidenced by the premature decay of certain of the larger and deeper roots, as depicted in the sketches herein, relative to that phase of the subject.

INFLUENCE ON TRUNK AND BRANCH DEVELOPMENTS.

With the exceptions of the early failures of trees of the St. Margaret's and Florence varieties worked on Kentish rootstocks previously referred to, all of the trees in the plot made good progress and maintained a healthy, thriving condition, and began to crop in varying quantities and regularity from 1919 onwards. In November, 1923, when the trees had been planted 13 years, a series of photographs was taken showing the branch development of typical trees of the respective varieties growing on the various stocks. Short range photographs were also taken of the stems of the trees,

[*E. W. Pritchard, Photo.*]

Bigarreau Napoleon on Mahaleb rootstock.

showing the peculiarities of growth evolving from the respective points of union of scions and stocks at that time. These are very clearly indicated in the reproductions accompanying this report. On two of these, an inset shows the same tree stems photographed in 1934—eleven years later. During the same month—November, 1923—measurements were made of the full height and mean spread of each tree. The latter was determined by making several transverse horizontal measurements with a long graduated pole through the broadest part of the branch spread.

In the case of the trees on the Mazzard stocks, this greatest width was found between 9ft. and 10ft. above ground level. The trees on Mahaleb and Kentish rootstocks were gauged at a height between 8ft. and 9ft., and those on the Kentish Mazzard combination at approximately 9ft. above the ground.

Stem measurements were also taken in November, 1923, of the girth or circumference around the rootstock, the point of union of stock and scion, and around the true tree stem approximately 6in. above the point of union. In the case of the combination—Kentish on Mazzard—the girths of the inserted Kentish stem piece, and of its union with the scion variety, were also taken. The average of each of these stem measurements of each of the varieties grown on the respective rootstocks, together with the average of their total heights and mean spreads, are seen in Table A:—

(K = Kentish stem piece. - minus.)

These figures may be interpreted as showing that between 1923 and 1934 these trees generally ceased to make any noticeable progress in so far as height and spread of branches are concerned. It is true they have been very moderately pruned almost annually over the lateral and terminal growths, mainly to keep them at a workable height and spread—cherry harvesting from large, tall trees proves an expensive item. Wherever increased branch developments are indicated, they have been made by a very few trees, which were younger or more backward at the time the 1923 measurements were taken, and these had since grown to a normal stature, or sufficiently to influence the average of the quota of trees of that particular variety growing on certain stocks. The minus figures in reference to Early Purple Guigne worked on Mazzard rootstock was due to an oversight of the failure of some of the dormant buds to grow on two of the trees, and these trees were shaped and grown for several seasons, until the writer, in passing, saw a few typical Mazzard fruits on some of the limbs. When the close resemblance which the foliage of the Mazzard bears to that of some of the cultivated varieties of sweet cherry is taken into consideration, this error on the part of the Officers in charge of the orchard at the time becomes reasonably excusable. These trees were branch budded, and soon produced fine crowns, practically equal to those on the other trees.

The other instances of increased dimensions are seen in the varieties of trees grown on the Kentish Mazzard combination rootstock, which, as previously indicated, being double worked, were not less than a year

[*E. W. Pritchard, Photo.*]
Early Purple Guigne on Mahaleb rootstock.

behind the single worked varieties in the time of being started into final growth in the orchard plot. A study of the stems of the trees in the accompanying illustrations reveals in a much more pronounced manner

than these figures can convey, the peculiar nature or configuration of the developments which consistently arise adjacent to the points of union of certain of the rootstocks with all of the scion varieties used in this trial. This is most noticeable in the cases of the Mahaleb and Kentish—the so-called dwarfing stocks.

[*E. W. Pritchard, Photo.*]

Florence on Mahaleb rootstock.

In the later Table B it will be noted that most of the trees are practically at a standstill as regards branch development, and some have died during the past two or three years. This latter remark particularly applies to those worked on the Mahaleb rootstocks.

A WEEVIL ATTACKING MALLOW (*MALVA PARVIFLORA* L. AND *M. NICAEENSIS* ALL.) IN SOUTH AUSTRALIA.

[By D. C. SWAN, B.Sc., Waite Agricultural Research Institute, University of Adelaide.]

In July, 1933, information was received from Mr. H. J. McConville, of the Metropolitan Abattoirs at Gepp's Cross, that areas of mallow growing in unused stockyards at the Abattoirs had been attacked by an insect to such an extent that the plants had been completely defoliated. The pens were first inspected on the 19th July, 1933. In view of the extensive damage noted and the fact that the family (*Malvaceae*) to which the mallow belongs also contains various cultivated plants, the following notes are given.

Figure 1.—*Malva* plant, showing damage to foliage by *E. sellata*. An undamaged leaf is shown for comparison.

At the time of inspection, in certain pens, pure stands of the weed were completely defoliated; only the standing stems, representing the main axes of the plants remained (Fig. 5). The petioles of the leaves were still attached in many cases, but the leaves were withered from the tips, and the laminae had been eaten away. The stems were also withered at the tips, but remained alive in the lower part. The bark on the upper part of the stems had been removed in many cases, and on the lower parts, where cork-formation had taken place, the damage took the form of irregular scorings. In adjacent mixed associations of *Malva* with other weeds, all stages of injury were noted, isolated plants having leaves with

few holes in them, while in other cases the leaves hung in tatters due to the running together of the rounded feeding holes (Fig. 1). In places where the leaves had been skeletonised extensively, the leaf debris formed a layer beneath the plants. In this material and in the loose soil at the bases of plants not yet defoliated, green grubs of a weevil were sheltering, a dozen or more under each plant. In a few instances, odd larvae were found feeding on sheltered lower leaves in daylight; the normal habit, however, appears to be nocturnal.

Figure 2.—*Ethemaia sellata* **Pasc., larva.**

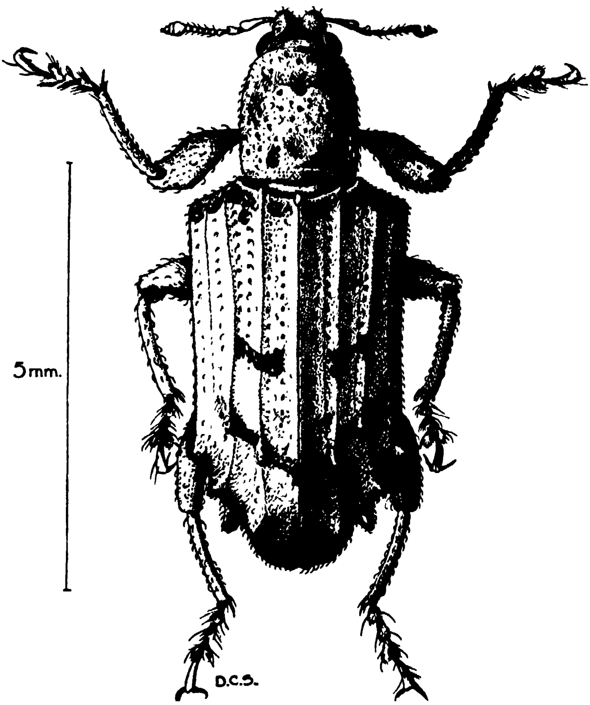

Figure 3.—*Ethemaia sellata* **Pasc. Drawn from a newly emerged specimen, bred in the laboratory.**

In a large patch of the weed which had been defoliated, the soil surface was loose and friable, and digging in the top three inches revealed great numbers of the larvae mostly curled up in cells in the soil prior to pupation. The soil appeared to have been loosened by the larvae in the process of entering it. Approximately one larva per cubic inch could be obtained in such situations. Other weeds in the vicinity showed no signs of attack. Subsequently, this characteristic damage to mallow was noted at a number of localities in South Australia although not to such a marked extent. It is presumed that the insect concerned is widely distributed in the better rainfall areas of the State.

Mature larvae were placed with soil in flower pots, embedded in damp sand, in the laboratory, and by the 14th August, 1933, most of them had pupated. From these, 22 days later, brown-grey weevils developed, which proved to be *Ethemaia sellata* Pascoe (Fam. Curculionidae).*

The habit of feeding on leaves so far from the ground is not usual with weevil larvae. In this instance the larvae were able to climb the plant by means of three pairs of thoracic, and nine pairs of prominent abdominal pro-legs, aided by the terminal region of the abdomen (Fig. 2).

The pupae are translucent green in colour; they move the abdomen actively when disturbed. The adults (Fig. 3) remain quiescent for varying periods up to several days before leaving their earthen pupal cells (Fig. 4).

The affected area of mallows at the Abattoirs was again visited on 22nd September, 1933, and though no adult beetles could be found, a search of the soil revealed many pupae and larvae. Temperatures in the field were lower than those prevailing in the laboratory where the collected larvae were bred out. The main

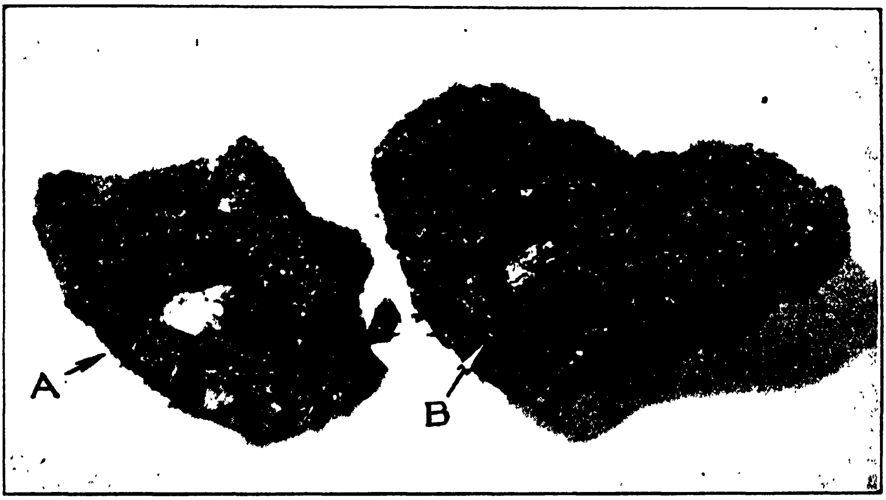

Figure 4.—Pupa (A) and adult (B) of *E. sellata* Pasc. in earthen cells.

point noted was that many mallow plants, apparently almost completely destroyed at the time of the July visit, had now sprouted from dormant buds low down the stem, and a lateral shoot in many cases had become the main axis (Fig. 6). Isolated plants were not so severely attacked as close stands, and this, coupled with the plant's power of regeneration, reduces any significance of the weevil in controlling the abundance of the weed.

Adults of the weevil were commonly met with at another surburban locality (Lockleys) during the winter of 1934. They were found usually on the soil surface beneath mallow plants. In such situations they sham death readily, with legs folded. Two specimens were seen at night (28/9/34) walking on rhubarb leaves, and one was seen feeding on the leaf of a mallow plant. They fell to the ground as soon as disturbed. In the laboratory the adults fed readily on mallow leaves, producing injury similar to that of the larvae. Smooth ovoid eggs, green at first, but later turning black, were laid freely on the leaves and petioles.

Mass injury to *Malva* spp. of the type described in this paper appears to be uncommon; that it may occur sporadically is suggested by one verbal account received. *Ethemaia sellata* appears to be a common feeder on these plants, as its

* Kindly identified by Mr. H. Womersley, Entomologist of the South Australian Museum. The Museum collection contains specimens from all the Australian States. The nomenclature has been confirmed by Sir Guy A. K. Marshall, Director of the Imperial Institute of Entomology, London.

feeding marks are sparingly present on a large proportion of those examined. These plants usually occur as isolated individuals among other weeds, and here the damage is unimportant; only pure stands appear to be liable to severe damage.

Figure 5.—Damage to *Malva* caused by *E. sellata* Pasc. Photo., September, 1933.

Figure 6.—Regrowth of *Malva* damaged by *E. sellata* Pasc. Photo., September, 1933.

Lea (*Journ. Agric. S. Aus.* 1927, xxx., p. 598) noted *E. sellata* as a common weevil, which may attack the bark and buds of fruit trees, shrubs, and vines. The writer has not yet found it to feed on other than malvaceous plants.

STUDIES OF GROWTH AND FRUIT BUD FORMATION No. 5.(1)

OBSERVATIONS DURING TWO SEASONS ON SOUTH AUSTRALIAN APPLES.

[By C. BARNARD, M.Sc., Assistant Botanist, Division of Plant Industry, C.S.I.R., Canberra, and R. FOWLER, Manager Blackwood Experimental Orchard, Department of Agriculture, South Australia.]

[The time of differentiation of the fruit buds of four varieties of apple growing at the Blackwood Experimental Orchard has been determined during two seasons and for one variety during three seasons.

An account of the process of fruit bud formation is given and the development of the fruit buds throughout the season is described.

It has been found that the differentiation of fruit buds occurs slightly earlier during the "on" crop season than during the "off" season and variations in the time of fruit bud formation may also be associated with characteristics of shoot growth. Further, it is shown that under conditions stimulating shoot growth the time of differentiation is delayed, though once differentiation has occurred the rate of development of the fruit buds is accelerated by those conditions which favour vegetative growth.]

A conference of fruitgrowers of the Hills Branches of the South Australian Bureau, held at Balhannah on August 28th, 1930, passed a resolution to the effect "that the Waite Agricultural Research Institute be requested to initiate research into the development of the fruit buds of the apple, with a view to determining as to what period the wood bud changes into the fruit bud." Following a report(2) on the matter by the Chief Horticultural Instructor, the Advisory Board of Agriculture and the Department of Agriculture indorsed the recommendation, whereupon an investigation of the question was commenced by the Waite Agricultural Research Institute. Shortly after the collection of material had started, however, the work was passed over to the C.S.I.R., which was already engaged upon similar studies in other States. The C.S.I.R. therefore made an examination of the material collected during 1930-31 and during 1932-33 and 1933-34 co-operated with the State Department in completing the investigation to date.(3)

1. INVESTIGATIONS DURING 1930-31.

During the 1930-31 season, buds were obtained from two Granny Smith trees growing at the State Experimental Orchard, Blackwood. Both trees were planted in 1910 and at that time consisted of Northern Spy root stocks worked over to Shockley. In the case of one (Tree E.5.5), however, a short intermediate stem of Rome Beauty was grown between the Spy root stock and the Shockley. Both of the mature trees of Shockley were grafted over in 1926 by inserting Granny Smith scions into the main limbs a short distance from the trunk. The heads of the trees during the 1930-31 season, therefore, represented five years' growth of Granny Smith. The trees were both well grown, their trunk circumference at 9in. above soil level measuring 21⅝in. (Tree E.5.5) and 24¼in. (Tree E.3.12) respectively. Up to the time of regrafting to Granny Smith the

(1) Numbers 1-4 of this series appeared in the *Journal of the Department of Agriculture of Victoria*, Vols. XXX., parts 7 and 9 (1932), and Vol. XXXI., part 1 (1933). Article No. 1 of the series dealt with a year's observations of Victorian apples.

(2) *Journal of Agriculture of South Australia*, p. 526, Dec. 1930.

(3) This work has been carried out by the Council for Scientific and Industrial Research and the Department of Agriculture, South Australia, in co-operation. The selection of varieties, the sampling of material, as well as the observations and measurements of tree growth, have been made by the South Australian Department, whilst the C.S.I.R. has carried out the examinations in connection with bud differentiation and development.

trees had borne good average crops biennially of Shockley apples. Since being changed to the Granny Smith variety they have cropped as follows:—

	Tree E.5.5. Lbs.	Tree E.3.12. Lbs.
1928-29	½	7
1929-30	48	159
1930-31	5½	97

No particular manurial treatment has been given to these trees, and during the last three seasons a green manure crop was sown with superphosphate at the rate of 2cwts. per acre. For the first two seasons the very strong growths from the regrafted trees were pruned fairly hard, but subsequently a system of light thinning out of laterals and topping of the leaders was followed.

Collections of buds were made at intervals of one week from the beginning of December, 1930, until the end of February, 1931, and consisted of terminal buds on new spurs produced on two year old wood. The dissection method ([4]) was used in the examination of the buds.

Differentiation of the fruit buds occurred during different periods in the two trees, though insufficient material had been collected to warrant a critical comparison. The buds of Tree E.5.5 commenced to differentiate about the 2nd of January, whilst those of Tree E.3.12 did not commence until the middle of January. It is possible that the difference in the vigour of the two trees (c.f. trunk circumferences and yields) was responsible for the difference in the time at which the fruit buds were differentiated. On the other hand, the difference may be attributed to the difference in the constitution of the two trees. The complexity of the Tree E.3.12 in that it consisted of Granny Smith on Shockley on Rome Beauty on Spy stock rendered it unsuitable for preliminary work.

2. INVESTIGATIONS DURING SEASONS 1932-33 AND 1933-34.

(a) The Trees.

Five trees of each of four varieties, viz., Dunns, Jonathan, Cleopatra, and Granny Smith, were selected at the Blackwood Orchard as fair average representatives of each variety.

The varieties—Dunn's Seedling, Jonathan, and Cleopatra—were planted in 1908 in the barrier rows associated with the Manure Plots. These trees are worked directly on to Northern Spy stocks and are fairly well grown types for the varieties, and have produced good average crops since 1918. They have received regular and moderate pruning and have maintained a fair average annual growth, the mean trunk circumference at 9in. above soil level being respectively 19.3in., 17.3 in., and 17.9in.

No particular manurial treatment has been given to these trees, though, as previously stated, they occupy positions as buffer rows between manured rows of trees, but as the planting is on the septuple system, they do not appear to have derived any benefit from the manures applied to adjacent trees.

The selected Granny Smith trees were planted in 1910, and their constitution is somewhat involved. In each instance the root stock is Northern Spy, but one tree has short intermediate pieces of both Shockley and Paradise, and two others a short intermediate piece of Rome Beauty between the Spy root stock and the Granny Smith. One tree (E.5.5) was used in the 1930-31 season, and the general remarks made on page 1129 in reference to the two Granny Smith apply equally to all. Tree E.2.19 was used for shoot and spur growth measurements, and the constitution of this tree is Granny Smith on Shockley on Paradise on Spy. The average trunk circumference at 9in. above soil level of the five Granny Smith trees is 23.3in.([5])

([4]) Vide *Journal of Agriculture*, Department of Victoria, Vol. XXX., part 7, p. 353 (1932).

([5]) Portion of tree where circumference measurements were made would be Shockley wood.

All the trees are grown under non-irrigated conditions, with an average rainfall of approximately 31in., though the rainfall for the seasons 1932-33 and 1933-34 has been much below the average, with low summer rainfall.

Normal development has not been retarded in any way through serious injury by either insect or fungal pests.

(b) Growth Measurements.

One tree of each variety was selected for detailed observation of growth, and the following records were made each week on each tree:—

(1) The length to the nearest millimetre of each of 10 selected and labelled shoots growing from the terminal bud of pruned leaders.

(2) The number of leaves and the greatest length and width of all leaves (omitting petiole) on each shoot.

(3) The diameter of each of the current season's selected shoots at a point 1in. from the base, and the diameter of the two year old wood at the base of the current season's shoots.

(4) The number and size (length and width) of the leaves on each of 10 selected and labelled spurs of two years or more of age.

In addition the time of blooming, defoliation, and of harvest, as well as relevant climatological data, were recorded.

(c) The Collection of Buds.

The fruit buds have been classified into three types on the basis of their position on the trees, viz., 1, terminal buds of laterals; 2, terminal buds of young spurs on two year old wood; 3, terminal buds on spurs two years of age or older. Only types 2 and 3 were used for the purpose of this investigation.

During 1932-33, samples of 60 buds were collected at weekly intervals from the end of November until the 1st of February, then at intervals of 14 days until the end of March, and thereafter at approximately three weekly intervals until the beginning of September, 1933. Each sample consisted of 30 type 2 and 30 type 3 buds, which were collected and examined separately. In making each collection, three buds of both type 2 and 3 were collected from each of the five trees used in the investigation.

During 1933-34, type 2 buds only were taken from Jonathan and only type 3 were collected from Dunns, Cleopatra, and Granny Smith. Weekly collections in this season were continued until collections ceased on the 26th April. In other respects the procedure was similar to that followed in 1932-33.

(d) The Structure of the Buds.(6)

The early development of the fruit bud is illustrated in the photographs of dissections of buds reproduced in Plate 1.

During late autumn and winter the flower or fruit buds of the apple may be distinguished macroscopically from the leaf buds by reason of the fact that the former are larger and plumper than the latter. The leaf bud consists of a short axis upon which a number of leaf formations are inserted in a close spiral sequence. The outer eight or nine formations are known as bud scales; the outermost being hard and dark brown in colour, whilst the inner ones are lighter in colour and very hairy. The scales serve to protect the rudimentary foliage leaves and growing point of the axis from frost, drying, and injury generally. The innermost bud scales are followed by several "transition" leaves which are also densely hairy. They differ from the true scales in the fact that when the bud opens they develop small green laminae and form true leaves in that the stipules are very large and the laminae comparatively small. Further,

(6) A more detailed account of the structure and development of the apple bud is recorded in the first article of this series, vide *Journal of Agriculture of Victoria*, Vol. XXX., part 7 (1932).

the transition leaves are often shed very early in the season. Inside the covering of scales and transition leaves a number of rudimentary foliage leaves are found. By early November a number of foliage leaf rudiments have been formed, and during the growing season the growth of the leaf bud consists of a slight elongation of the axis concurrent with the splitting off of further leaf rudiments from the growing point.

The fruit bud is known as a "mixed" bud, since it produces not only an inflorescence of flowers, but a cluster of leaves as well. During late autumn dissection of the mixed bud reveals its organisation. Approximately 21 leaf formations are inserted upon the axis which terminates in a flower primordium (young flower bud). These leaf formations are in the form of scales, transition leaves, and true foliage leaves as in the leaf bud, but above the youngest foliage leaf four bracts are produced upon the axis. A flower primordium is developed in the axils of three bracts and in the axils of the two uppermost (youngest) foliage leaves, so that each bud contains a cluster or infloresence of five or six flower buds. A small vegetative bud is produced in the axils of the second and third foliage leaves After flowering, these buds develop and result in the dichotomous branching of the spur. Usually nothing is produced in the axil of the lowest or first foliage leaf.

Early in the season and until differentiation occurs, the growth of the mixed bud consists of the splitting off of leaf formations from the growing point and no difference can be seen between the potential leaf bud and the potential fruit bud (Stage 1, Plate 2). The growing point is small and inconspicuous. The first indication that a bud is to become a fruit bud is revealed in an enlargement of the growing point and crown of the axis. From the enlarged apex the bracts are split off as shown in Figs. 1 and 2, Plate 1, and Stage 2, Plate 2. In Plate 1 the illustrations are photographs of dissections of buds looking down upon the growing points, whilst in Plate 2 sections through the centre of the buds are represented. The outer scales have been removed from the buds shown in Plate 1 and four of the foliage leaves broken off at the base. The youngest foliage leaf (L5) and two bracts (b_1 b) are seen beside the growing point (VP).

The growing point continues to enlarge whilst two further bracts are formed and the primordia of the axillary flowers appear in the axils of the upper foliage leaves (L4 and L5). The apex of the growing point then flattens preparatory to the formation of the terminal flower. In Fig. 3, Plate 1, a dissection of a fruit bud at this stage is depicted. The sepals of the terminal flower are forming at K; the axillary flower primordia (p) can be distinguished in the axils of three bracts (b_1, b_2, b_3) and also at FP in the axils of the two youngest foliage leaves L4 and L5. As each flower primordium enlarges it splits off two bractlets which can be seen at "S" in the case of the two large flower primordia (FP). The formation of the sepals of the terminal flower then takes place (K in Fig. 4, Plate 1, and Stage 4, Plate 2). Subsequent development consists of the growth of the flower primordia, and the parts of the flower arise in the order, petals, stamens, and carpels (pistils). In Plate 2 a series of photographs shows the development of the terminal flower of the cluster, and a date for each stage represented is given. As the same stage of development is reached at different times by different varieties, as well as by the one variety in different seasons, the dates shown on the plate only apply to the variety and season represented.

Some time before growth ceases in autumn all the parts of the flower have been formed, and as the buds enter the winter resting period they have reached the condition shown in Stage 8. The stamens are differentiated into anther and filament, though there is no indication of pollen or ovule formation until growth recommences in the following spring.

(e) Time of Differentiation.

The first morphological indication of the differentiation of the fruit bud is observed in the elevation and broadening of the crown of the bud axis as

described above. This does not occur in all buds simultaneously, but takes place during a certain period which varies somewhat in length. In Table I. the period during which buds were differentiating is shown in column 4, whilst in column 5 the time at which the majority of buds were differentiating is indicated. The date given under this heading has been determined with as much accuracy as possible and provides a trustworthy means for comparing the time of differentiation in different seasons and in different varieties.

TABLE 1.—*Time of Differentiation.*

Variety.	Season.	Bud Type.	Period of Differentiation.	Majority of Buds Differentiating.
Dunns	1932-33	2	14/12/32-28/12/32	21/12/32
		3	21/12/32-28/12/32	24/12/32
	1933-34	—	No Fruit Buds.	—
Jonathan	1932-33	2	14/12/32-11/1/33	21/12/32
		3	21/12/32-28/12/32	24/12/32
	1933-34	2	13/12/33-27/12/33	20/12/33
Cleopatra	1932-33	2	21/12/32-11/1/33	24/12/32
		3	21/12/32-11/1/33	24/12/32
	1933-34	3	6/12/33-20/12/33	13/12/33
Granny Smith	1932-33	2	28/12/32-11/1/33	4/1/33
		3	28/12/32-11/1/33	4/1/33
	1933-34	3	27/12/33-4/1/34	31/12/33 to 1/1/34 approx.

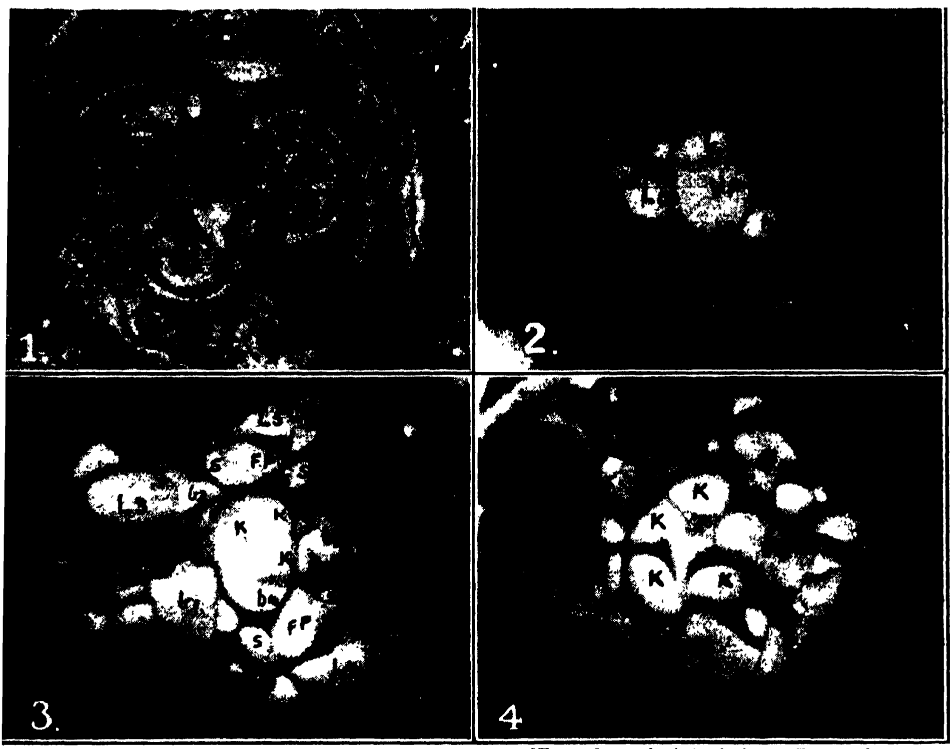
During 1932-33 the buds of Dunns, Jonathan, and Cleopatra differentiated at the same time, *i.e.*, during the third week in December, whilst those of Granny Smith were about 11 days later. Both types of buds were examined in each variety in 1933-34, and it is to be noted that buds from spurs on two year old wood differentiated several days earlier than those of older spurs in Jonathan and Dunns, whilst no difference is apparent in the case of Cleopatra and Granny Smith.

During 1933-34 insufficient fruit buds were formed in Dunns to permit of the determination of the time of differentiation. In Jonathan differentiation occurred during practically the same period as in the previous season. In Granny Smith the majority of buds differentiated four to five days earlier in 1933-34, whilst in Cleopatra the fruit buds formed about 11 days earlier in 1933-34 than in the previous season. In the following section a description of the vegetative growth of the trees during the two seasons is given. This will enable us to compare these factors with the variations noted above in the time of fruit bud formation.

(f) Growth.

A comparison of the vegetative growth in each variety during the two seasons is made in Table 2, in which the main growth characteristics for each season are summarised. In all varieties a very light "off" year crop was borne in 1932-33, whilst a heavy "on" crop was matured in 1933-34. The growth of the

leading shoots ceased earlier in 1933-34 and less elongation growth was made. The internodes of the leading shoots were also shorter in 1933-34 and less leaves were produced per shoot than in the previous season. Cessation of leaf growth in the spurs possibly occurred about the same time in both seasons. Unfortunately measurements were not commenced sufficiently early during the first season to permit a more critical comparison. In both seasons elongation growth ceased first in Dunns and Jonathan, followed by Cleopatra, whilst the shoots of Granny Smith continued growth latest in the season. The cessation of growth in spur leaves also occurred slightly earlier in Dunns and Jonathan than in Cleopatra and Granny Smith. In both seasons defoliation occurred in the sequence, Dunns, Jonathan, Cleopatra, and Granny Smith, and was earlier in 1932-33 than in 1933-34 by about a month in Dunns, three weeks in Jonathan, and a fortnight in Cleopatra, whilst in Granny Smith defoliation occurred during the same period in both seasons. It would appear, therefore, that in the "on" season less vegetative



[From *Journal of Agriculture, Victoria.*]

Key:—FP, Flower primordia; S, Bractlets; Cr, Crown; VP, Growing point; b, Bracts; Tr. L, Transition leaves; L, Leaves; K, Sepals (calyx); C, Petals (corolla); A, Stamens (androecium), and G, Carpel (gynaecium).

growth is made than in the "off" season, and this is possibly due to the fact that growth ceases earlier during the season in which the tree is carrying a heavy crop. In this connection it is of interest to compare the different amounts of growth made in the two seasons of each variety (Table 3). It will be seen that the difference in the amount of growth produced in two seasons is greater in those varieties which continue growth late in the season, though the difference in the time of defoliation is least. The ratios of the average length of internode in 1933-34 to the average length in 1932-33 were 1.52 in Granny Smith, 1.24 in Cleopatra, 1.05 in Jonathan, and 1.05 in Dunns. If the internodes had elongated to the same extent in 1933-34 as in 1932-33, the average

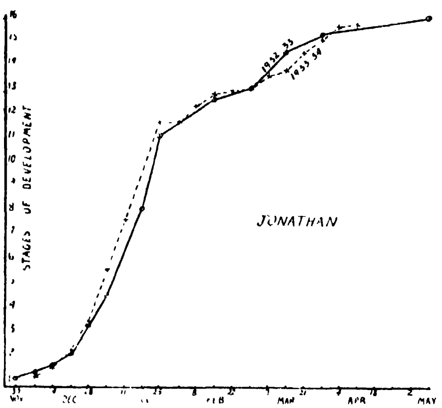
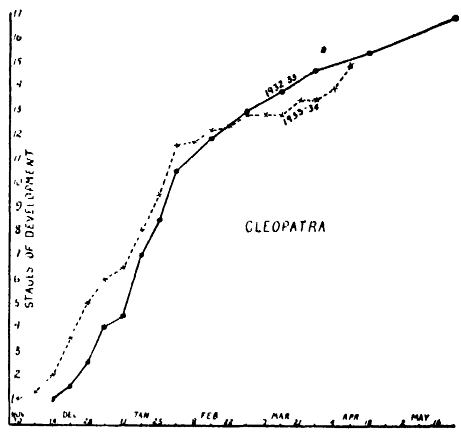
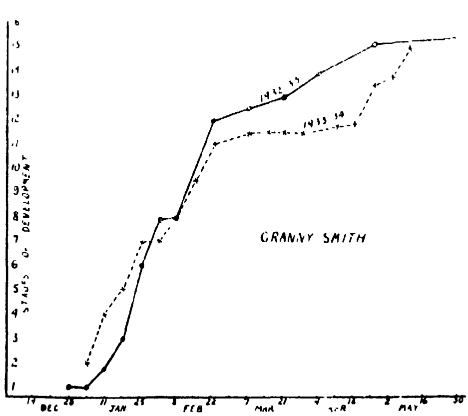
TABLE 3.

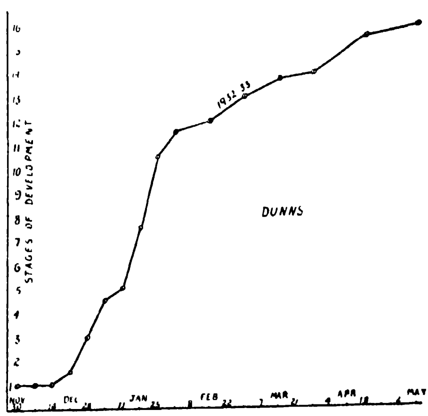
Variety.	Average Length of Shoot, 1932-33.	Average Length of Shoot, 1933-34.	Diff.	Diff. as Per Cent. of Length in 1933-34.
	cms.	cms.	cms.	%
Granny Smith	57·8	35·2	22·6	39
Cleopatra	56·1	45·8	10·3	18·3
Jonathan	51·6	42·5	9·1	17·6
Dunns	42·0	34·8	7·2	17·1

shoot length would have been increased by 2.07 cms. in Dunns, 4.30 cms. in Jonathan, 10.7 cms. in Cleopatra, and 16.32 cms. in Granny Smith. In other words, the difference in the length of shoot produced in the two seasons (1932-33 and 1933-34) was due entirely to a difference in the length of internodes in Cleopatra; 72 per cent. of the difference was due to this factor in Jonathan, 47 per cent. in Granny Smith, and 29 per cent. in Dunns.









A comparison of the climatological conditions during the two seasons fails to account for the differences which have been observed in the growth behaviour of the trees. It appears extremely probable that they are most closely related to the differences in amount of crops produced during the two seasons. In the "on" year elongation growth of shoots ceases earlier, the differentiation of the

buds occurs earlier, the internodes of the shoots are shorter and less leaves are produced per shoot, and defoliation occurs later than in the "off" season. The difference in the amount of growth produced and length of growing period is most marked in those varieties (Jonathan and Dunns) which have a short growing period.

(g) Development of the Buds Subseqent to Differentiation.

The development of the buds of the four varieties during the two seasons is graphically represented in the charts (Fig. 1). The developing buds have been divided into a number of stages (1-18), based upon the growth of the parts of the embryo flowers, and the stage reached by the majority of buds in each variety has been plotted at intervals of one week to a fortnight throughout the season. It may be observed that the buds of Jonathan developed at very much the same rate in each season. During 1933-34 development was slightly in advance of that of 1932-33 until about the third week in January; subsequently development was parallel in both seasons. In Cleopatra the fruit buds were more advanced in 1933-34 during the early stages of growth; about the end of January, however, the rate of development slackened, and during the period February and March was not so rapid as in the previous season. In Granny Smith development again was at first most advanced in 1933-34. From the end of January until the beginning of March the growth of the embryo flowers was considerably behind that of the previous season. Rapid development occurred again, however, during April, with the result that by the middle of May the fruit buds were just as far advanced in this season as in 1932-33. It seems very probable that these differences in the rate of development of the fruit buds are to be attributed to the differences in the time of maturation of the crops of the three varieties. In Jonathan the early maturation of the crops resulted in parallel development from the end of January during both seasons. The latter maturation of the heavy crops in the case of Granny Smith meant that the development of the fruit buds was retarded during the period of maturation and did not pick up until competition from this source ceased in early April. The effect of the developing crops on the growth of the fruit buds in Cleopatra might be expected to be less pronounced than in the case of Granny Smith. In addition to the time of maturation it is to be noted (Table 1) that crops produced during 1933-34 were heaviest in Granny Smith and lightest in Jonathan.

3. CONCLUSIONS.

Vegetative growth is less vigorous during the "on" season than during the "off" season. The carrying of heavy crops, irrespective of seasonal conditions, tends to cause the earlier cessation of shoot growth, the production of shorter shoots with shorter internodes, and less leaves and later defoliation. This less vigorous shoot growth is accompanied by a slightly earlier differentiation of the fruit buds. Studies elsewhere (*i.e.*, Abbott in Tung Oil Tree, *U.S.D.A. Jour. Agr.*, Res. 31, 1925, pp. 679-694) show that differentiation occurs later in the season in trees of the one variety which are most vigorous and vegetative. In these studies it was noted also that the more vigorous of the two Granny Smith trees examined in 1930-31 differentiated its buds later than the other slightly less vigorous trees. Irrigation (Wiggans, *U.S.D.A. Journ. Agr. Res.* 31, 1925, pp. 865-882) has also been reported as delaying the period of differentiation in the apricot and pear in California. This effect is associated no doubt with a prolongation of the growing period.

When differentiation has occurred, however, it would appear that conditions which favour vegetative or shoot growth also accelerate the development of the fruit buds. In the same way seasonal conditions, drought, &c., which retard shoot growth, have a similar effect upon the growth of the fruit buds. Studies in other localities show this point very clearly. In the present experiment the retarding influence of a heavy crop upon the development of the fruit buds is illustrated in a comparison of the three varieties—Jonathan, Cleopatra, and Granny Smith.

EXPLANATION OF TEXT, FIG. 1.

The developing buds have been divided into a number of arbitrary stages, and the stage reached by the majority of the buds in each collection is plotted against the date of collection. Stage 7 corresponds to the origin of the sepals and Stages 11, 12-13, and 14 to the origin of the petals, stamens, and pistils respectively.

SAND COLIC IN HORSES.

Mr. R. H. F. Macindoe, B.V.Sc., M.R.C.V.S. (Deputy Chief Inspector of Stock), in the course of a reply to the Secretary of the Bugle Branch of the Agricultural Bureau as to the treatment of sand colic in horses, says there are many ways in which the horses can be prevented from these dangers, *e.g.*, always feeding from nosebags, or if using feed mangers or boxes, either carefully sweeping up any spilt feed or making the floors of stable of stable of some hard material. Hay could be fed from nets or hayracks.

In the case of grazing on growing grass or cultivated crops, no horses should be turned into it until the grass is at least 6in. high or the crown of such plants as dandelions is well developed and well above the surface level of the soil.

It would probably pay better to roll the stubble, gather and stack it, and feed it to the horses rather than allow them to graze on it as they go for the "flag" at the bottom of the straw and in so doing gather a lot of sand.

If, however, some of these recommendations cannot be put into practice some good would be gained by periodically giving the animals a purgative dose of raw linseed oil (1 to 2 pints per horse).

Curative Treatment.—Affected animals as soon as noticed to be showing colicky pains should be given the following drench:—Raw linseed oil, 1½-2 pints; oil of turpentine, 4 tablespoonsful. Then give enemas of soapy water every three hours. Twice a day place on the tongue 1 teaspoonful of powdered nux vomica mixed with a little honey, treacle, or jam, and do so for at least 10 days. If the horse is still colicky 24 hours later, or lying about and not eating, repeat the oil drench and enemas of soapy water. Pollard gruels should be given as a drench two or three times a day, giving 2 pints at a time.

In obstinate cases it may be necessary to throw the horses, place them on their backs in a trench, and massage and knead the abdomen with the object of dislodging the sand from its lodgment in the bowels.

Feeding Molasses with Cocky Chaff and a Little Bran.—This is a very poor ration, but if given, molasses should be used at the rate of 2·4 pints per day mixed with water and mixed with the cocky chaff and bran. If horses are exposed to the danger of taking sand in with their feed, and no steps are taken to prevent them doing so, their owners will always have cases occurring, and unless these cases are seen to early and treatment is given before the sand has had time to accumulate, many horses will be lost. Horses become sanded if (*a*) allowed to graze on paddocks where grass is just coming through the ground or feeding on stubble grown on sandy soil; (*b*) hay is thrown down on the ground; (*c*) chaff is spilt out of mangers on to the ground and horses later attempt to pick it up.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

CONFERENCE OF MID-NORTH BRANCHES.

Branches of the Agricultural Bureau in the Middle North districts of the State, met in Conference at Red Hill on March 14th when there was an excellent attendance of delegates from Snowtown, Beetaloo Valley, Jamestown, Koolunga, Blyth, Gulnare, Narridy and Riverton.

Mr. H. J. Crouch (President of the local Branch) occupied the Chair.

The Hon. A. P. Blesing, M.L.C. (Minister of Agriculture), Hon. A. L. McEwin, M.L.C. (Member Advisory Board of Agriculture), Professor A. J. Perkins (Director of Agriculture, Messrs. H. B. Barlow, H.D.D. (Chief Dairy Instructor), R. C. Scott, R.D.A. (Supervisor Experimental Work), E. L. Orchard, R.D.A., W. C. Johnston, R.D.A., J. O. Hatter, H.D.D. (District Instructors), H. C. Pritchard (General Secretary), and F. C. Richards (Assistant Secretary, Agricultural Bureau) attended on behalf of the Department of Agriculture.

The Minister delivered the opening address, and the following papers were read and aroused instructive discussions:—"How to Make Sheep Farming Profitable," J. H. Crouch (Red Hill); "Mixed Farming," P. Curtin (Beetaloo Valley); "Veterinary Lodges," R. J. Rose (Laura); "Pigs on a Mid-North Farm," T. Welbourn (Narridy); and "Wheat Varieties for the Koolunga District," S. J. Pedler (Koolunga). Conference carried the following resolutions:—"That the 1936 Conference be held at Beetaloo Valley." "That in the opinion of this Conference it is desirable that action be taken to secure, by means of the formation of a Veterinary Lodge, or other means, the services of a veterinary surgeon for the district included in the Mid-Northern Agricultural Bureau Conference Area."

Officers of the Department replied to numerous questions and the evening session was occupied by an illustrated address, "Fat Lambs and Sheep," by Mr. R. C. Scott.

LOWER NORTH BUREAU CONFERENCE.

Delegates from Saddleworth, Riverton, Roseworthy, Farrell's Flat, Balaklava, Watervale, Penwortham, Alma, Owen, Wasleys, and Blyth Branches of the Agricultural Bureau met in Conference at Blyth on March 28th. Hon. A. L. McEwin, M.L.C. (Member of the Advisory Board of Agriculture) presided, the Department of Agriculture being represented by Mr. F. Coleman (Member Advisory Board), Professor A. J. Perkins (Director of Agriculture), Messrs. H. B. Barlow, H.D.D. (Chief Dairy Instructor), R. C. Scott, R.D.A. (Supervisor Experimental Work), W. C. Johnston, R.D.A., J. O. Hatter, H.D.D., J. B. Harris (District Instructors), H. C. Pritchard (General Secretary), and F. C. Richards (Assistant Secretary). The following papers were read and discussed:—"Management of the Farm Team," Mr. R. H. Eime (Blyth); "Mixed Farming," Mr. H. Bradley (Owen); "Marketing Farm Products," Mr. E. H. Lanyon (Blyth); "The State's Problem of Low Quality Wheats," Mr. W. J. Marshman (Owen); and "The Fall in Wheat," Mr. R. Robins (Saddleworth). The Agenda contained a wide range of Agricultural questions, which were replied to by Departmental officers, and the following resolution was carried:—"That the 1936 Conference be held at Owen." Professor Perkins presented the trophies to the successful competitors in the Midlands District Crop Competition.

The evening session took the form of a social, when the visitors were entertained by members of the Blyth Branch. Mr. R. H. Eime capably carried out the secretarial duties of the Conference.

SOUTH-EASTERN (UPPER) CONFERENCE.

South-Eastern Branches of the Agricultural Bureau held their Annual Conference at Mundalla on March 20th. This was the first occasion the Mundalla Branch undertook the responsibility of a Conference, and those who attended it were highly pleased with the arrangements, which were controlled by the Secretary (Mr. A. Ross). There was a display of produce of the district, including grain, fruit, vegetables, grasses, and other fodders, and Mr. Ross exhibited a special display of veterinary instruments, medicines, and specimens illustrating various ailments common to farm stock. Some time back the Mundalla Branch established a veterinary chest containing medicines and instruments, which are in demand by owners of stock. Mr. Ross personally superintends the use of the chest, and the advice and assistance he gives to his fellow-members are greatly appreciated throughout the district.

Mr. J. T. Ryan presided at the morning session, and besides members of neighbouring Branches there were present Messrs. S. Shepherd (Advisory Board of Agriculture), Professor Perkins (Director of Agriculture), Professor Prescott (Waite Agricultural Research Institute), H. B. Barlow (Chief Dairy Instructor), R. C. Scott (Supervisor of Experimental Work), L. J. Cook (Manager Kybybolite Experimental Farm), E. S. Alcock, W. H. Downes, and A. L. Warren (District Instructors), C. A. Goddard (Assistant Wool Instructor, School of Mines), and H. C. Pritchard (General Secretary).

In his opening address Mr. Shepherd made a short reference to his visit abroad. He was informed in England that there would always be a demand for Australian wheat on account of its colour and quality. It was necessary, therefore, that all concerned should do something towards improving the existing baking quality of our wheats. The production of wool was small in Germany, but that country was making such strides in the manufacture of artificial wool that she was endeavouring to become self-supporting in this respect. Woolgrowers were paid 30 per cent. above world market rates, and it was a condition of clothing contracts that clothing must contain 70 per cent. of wool grown in Germany. Australia was shipping inferior quality butter which was being blended with the product of foreign countries. A valuable lesson could be learnt from Denmark, which follows up her sales in order to see that their customers actually receive the product of that country. If the exports from Australia were more rigidly controlled in regard to quality we would have a better name on the English market than we had to-day. In connection with experimental work, he considered that the system adopted at the Kybybolite Experimental Farm was the most practical he had seen. The plots were a reasonable size (from 3 to 5 acres), and gave a fair indication of what could be produced in the district. A striking feature of stock management in England was the system of confining districts to certain breeds. Thus in one district Guernsey cattle would be found on all farms and no other breeds were kept. The same principle applied to sheep, and he thought that such a system could be adopted in South Australia with advantage to the State. He kept Jersey cattle on his farm at Kybybolite, but he would be willing to change to some other herd provided that it was suitable to the district and that all other farmers did the same.

The following papers were read and discussed:—"Side Lights and Side Issues of Pig Farming," by Mr. J. T. Ryan (Mundalla); "Some Digestive Diseases of Farm Animals," by Mr. A. Ross (Mundalla); "Seeding," by Mr. G. D. Butler (Wolseley); and "Topdressing of Pasture Lands," by Mr. R. A. Dinning (Mundalla). Numerous questions were answered by Departmental Officers and members of Branches.

Resolutions were carried as follows:—"That a veterinary surgeon be attached to the staff of the Department of Agriculture to lecture to Branches and attend Conferences, &c."; "That the next Conference be held at Bordertown."

Members of the Mundalla Women's Branch held a special meeting during the afternoon, when Mrs. W. Golding presided, and 17 ladies were present.

Mrs. W. Jones read a paper on "Breadmaking." Mr. Pritchard spoke on the various means to secure the best results from meetings, and Mr. A. L. Warren (District Horticultural Instructor) gave an address on "Fruit Preserving and Drying."

IMPORTANT WEEDS OF SOUTH AUSTRALIA.

[By G. H. CLARKE, B.Sc., Botanist at the Roseworthy Agricultural College.]

No. 12.—THE MILK, OR VARIEGATED THISTLE.

Silybum Marianum, Gaertn.

The Variegated Thistle is a native of Southern Europe and the Mediterranean region, and is of common occurrence as a weed throughout the settled parts of the State. It has proved troublesome in parts of the South-East and has been proclaimed noxious for the district of Mount Gambier. A conspicuous feature of this thistle is the curiously mottled or variegated appearance of the leaves, due to the presence of an irregular network of whitish veins on the upper surface, an appearance such as might be caused if milk were to be poured on normally green leaves. In mediaeval times this was accounted for as being of miraculous origin, the legendary explanation being that the Virgin Mary poured drops of milk on the foliage, and that the milky appearance became, henceforth, a permanent feature of this plant, which came to be known by the names "Milk Thistle," "Holy Thistle," and, sometimes, "Lady's Thistle." This legend may, perhaps, explain the miraculous powers attributed to thistles during the middle ages. In many parts of Europe thistles were used by peasants to combat the machinations of witches. The true thistles are spiny plants; but, as was explained when describing the Star Thistle (this *Journal,* February, 1934), the name "thistle" is also applied to a few non-spinous plants closely related to the true thistles, notably to the "Sow Thistle" (*Sonchus oleraceus,* L.). Unfortunately the "Sow Thistle" has a copious milky sap, on which account it is sometimes called "Milk Thistle," and so confused with *Silybum Marianum.* Owing to this confusion the name "Variegated Thistle," which is also in common use, is to be preferred to "Milk Thistle" for the plant under discussion.

Silybum Marianum is one of the largest of the true thistles, the individual specimens varying from less than 2ft. to more than 8ft. in height. Of those naturalised in this country it is exceeded only by the Wild Artichoke (*Cynara Cardunculus,* L.) in size of the leaves and massiveness of the flower-heads. The plants are sometimes annual, but more usually biennial, and they show a preference for moist situations. The stem is at first short and bears a number of broad-lanceolate crowded leaves which may be a foot or more in length and are more or less deeply cut in an irregularly pinnatifid manner. The margins of the leaf-lobes are furnished with rigid spines, so that it is difficult to handle the leaves without injury. The colour of the leaves varies, according to their age and thickness, from pale-green to a dark, almost bottle-green, against which the white network of veins stands out in bold relief. The plants at this stage have a curious "sprawling" habit. Later the stem begins to grow, forming, perhaps, one or two branches, and, towards the time of flowering, it shoots upwards rapidly, the stem-leaves becoming progressively shorter and separated by long internodes. The stem is terminated by a large pink or purplish flower-head, the massive appearance of which is greatly enhanced by the very numerous and large reflexed bracts of the surrounding involucre, as well as by contrast with the relatively slender terminal part of the stem.. The uppermost stem-leaves are very small and appressed, and clasp the stem by rounded prickly auricles.

Botanical Name and Classification.—The name *Silybum* is from the Greek *sillubos,* meaning "a thistle-like plant." *Marianum* means "pertaining to the Virgin Mary," and is on account of the supposed miraculous origin of the white

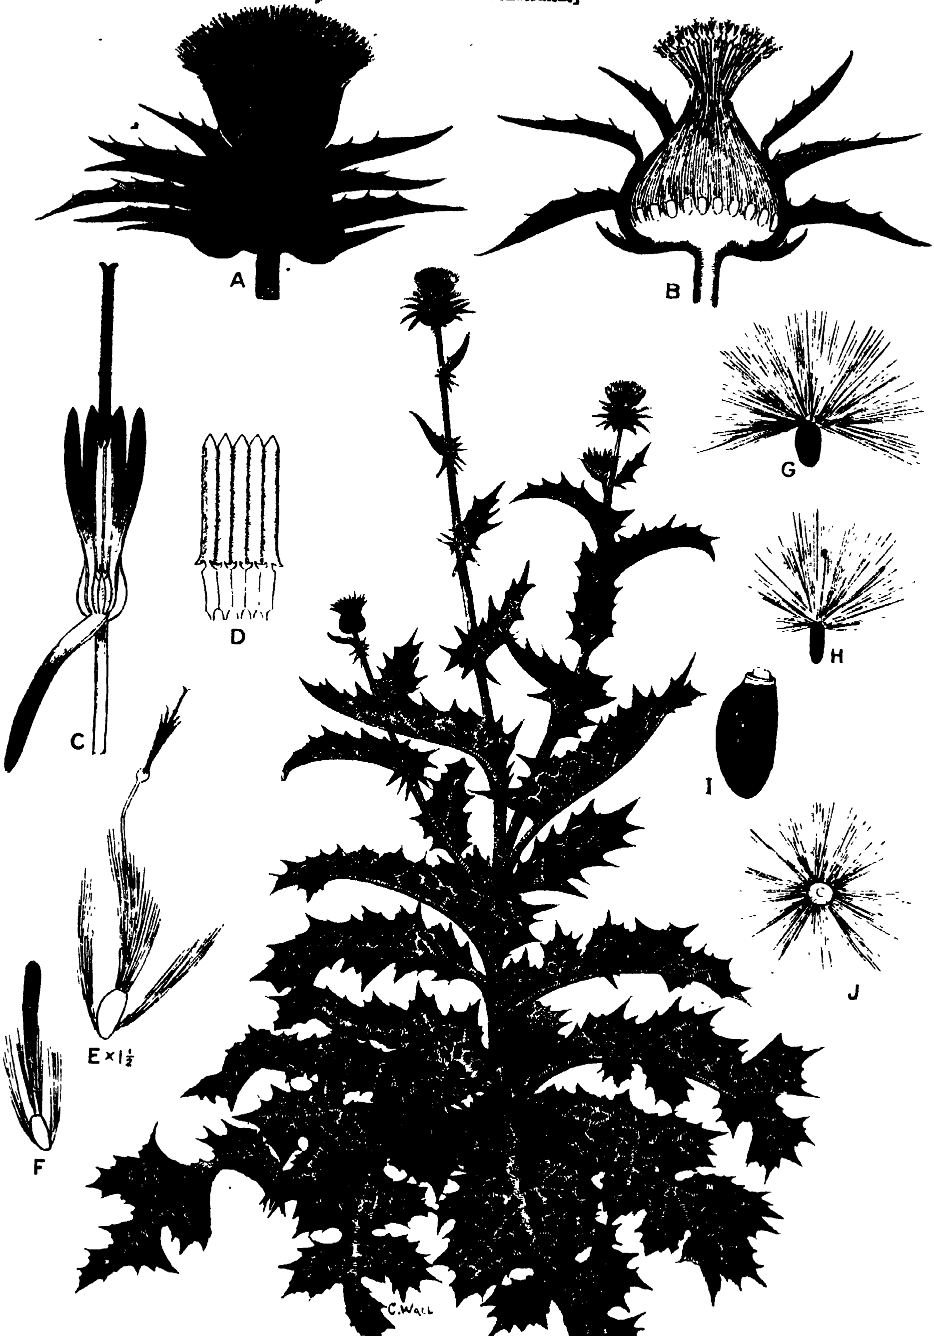
mottling of the leaves. In common with other true thistles this plant belong to the tribe *Cynareae* of the large family *Compositae*. The botanical characters of both the tribe and the family have already been dealt with in these articles (see this *Journal*, Vol. XXXVII., No. 7, p. 856, February, 1934). The genus *Silybum* is included by some authors within the larger genus *Carduus*, from which, however, it differs in having the filaments of the stamens united into a tube instead of their being free. Otherwise the two genera are the same and are distinguished from other members of the tribe by the mode of attachment of the fruitlets (achenes) to the receptacle or swollen axis of the flower-head, by the presence of hairs between the florets and borne by the receptacle, and by the pappus of simple bristles united by their bases into a ring which fits into the tip of the achene and falls away entire at maturity. There are two species of *Silybum*, namely, *S. Marianum*, and *S. eburneum*, Coss. et Dur. Both have purple flowers, but the latter differs from the former species in having the lower leaves with rough instead of smooth surfaces, stronger spines, and with a narrow terminal lobe much longer than the others; also, the intermediate bracts, only, of the involucre are prolonged into spines.

Botanical Description.—An erect glabrous herb, biennial or sometimes annual; stem not much branched, from 18in. to more than 8ft. tall; leaves smooth and shining above and variegated by white veins, the lower ones deeply and irregularly pinnatifid with broad very prickly lobes, the upper ones clasping the stem by rounded prickly auricles. Flower-heads large, solitary at the ends of the branches, with purple florets; outer involucral bracts broad rigid with a rounded spinulose-ciliate appendage ending in a long spine; receptacle hairy; florets all tubular, purple; achenes black, glabrous, shining; pappus of numerous simple bristles united to form a ring at the base. Period of flowering—June-February.

Properties.—The Variegated Thistle is objectionable chiefly on account of its prickly nature. It seeds rather freely, and the seeds germinate very readily after rain to produce large numbers of seedling plants. The first two leaves produced (cotyledons) are entire and ovate-oblong in shape, and they do not show the variegation characteristic of the subsequently formed leaves. Such seedlings spring up in large numbers on and around the sites previously occupied by older plants, and, as they enlarge, become crowded together to form dense clumps and patches which greatly impede the progress of animals, including man. When the plants are full grown, such areas are almost impenetrable, or at least it is practically impossible to pass through them without injury to skin or clothing. The plants prefer moist situations and, despite their spiny character, contain a high percentage of water and are of soft, herbaceous consistency. For this reason the thistles are easy to cut down with a scythe. These thistles are good ensilage plants, and, when wilted, are said to be of moderate value as fodder. The use of the fresh plant, however, as stock feed is attended with a certain amount of risk, as the plants are known to be poisonous at certain times, due to the development of cyanogenetic glucosides, comparable with those sometimes responsible for poisoning by Sorghum and Sudan Grass. On this account it is not advisable to feed the freshly cut plant to stock. But when fully wilted, or as ensilage, it should be safe enough. The seed is said to be good feed for poultry.

Control.—Seed formation should be prevented whenever possible, and, to this end, single plants should be hoed out before the flower-heads develop. Large clumps should be cut down with the scythe, followed by the hoe as soon as the cut parts are wilted sufficiently to allow of access to all parts of the clump. Where a large patch is in full flower the plants should be cut down and allowed to dry *in situ*, the whole patch being fired as soon as the plants are sufficiently dry. The dried flower-heads should be disturbed as little as possible, otherwise the seed will be scattered far and wide. By burning off, a good deal of the seed will be destroyed, but much will remain, and the hoe will require to be used persistently on plants that subsequently appear.

Photograph of a clump of Variegated Thistles. See coloured plate opposite.



VARIEGATED OR MILK THISTLE (*Silybum Marianum, Gaertn.*)

A.—Flower head showing bracts of involucre and florets. B.—The same in section.

POTATO COMPETITION—MOUNT COMPASS SCHOOL BOYS.

[H. H. Orchard, R.D.A., Horticultural Instructor.]

Four years ago the Mount Compass Branch of the Agricultural Bureau initiated a Potato Competition for school boys attending the local school. Under the rules of this Competition each boy is given 1lb. of selected Carmen seed potatoes, and in the presence of stewards appointed by the Branch from amongst members, must cut and plant his pound of seed. The digging of the crop and weighing of the tubers are also done under supervision, so that the two operations of planting and digging are strictly controlled. No restrictions are placed on the number of sets, planting distances, fertilizers, or treatment of the land before and after planting. The prize goes to the boy who obtains the highest yield. Mr. J. Johnson, of Adelaide, has kindly presented the seed each year.

The progress made is well illustrated by the highest yield obtained each year since the Competition started:—

Highest Yield from 1lb. of Seed Potatoes, Mount Compass.

Year.	Winner.	Highest Yield.	Second Highest Yield.
1932	Kelvin Peters	108lbs.	—
1933	Linton Jacobs	217lbs.	—
1934	Don McKinley	278lbs.	268lbs.
1935	Don McKinley	270lbs.	261½lbs.

At the request of the Branch, the writer was present at the digging this year, and in association with the local stewards supervised the work and weighed the potatoes. The digging was done in most instances by the competitor's father or older brother,

while the actual competitor, with commendable keenness, was close handy—sometimes dangerously so—to see that no tubers were left in the ground. The whole-hearted manner in which the adults entered into proceedings was a feature, and the boys with this practical support can be expected to remain enthusiastic. Certainly there was no lack of enthusiasm on this occasion.

Cutting and planting was done on October 27th, 1934, and the number of sets obtained by the lads from 1lb. of seed was remarkable, ranging from 83 down to 40. It would appear, however, from the general appearance of the plots that a very high number is not desirable, as growth was not uniform throughout the largest plots. Five of the lads certainly dug their complement of sets, but the yields were not evenly distributed, many dwarfed plants giving negligible returns. Presumably some sets lacked the necessary vitality to carry them successfully through the season. Most of the potatoes were grown in swamp land with soil of a black peaty nature, and the dry season experienced did not affect them; in fact, two lads had their yields reduced by 15lbs. and 11lbs. because of the effects of moisture on the tubers. From the results obtained up to date the maximum number of sets appears to be about 50.

Fertilisers and the quantities used covered a wide range. Both cow and fowl manures were extensively used in addition to artificial fertilisers. Unfortunately no definite records of weight were kept, but heavy dressings were the rule. From the commercial point of view, where clean skinned potatoes are required, some of the dressings of farmyard manure were not in the best interests of the crop. Probably an alteration in the time of application would make an appreciable difference.

Digging was done on March 6th and 7th, 1935, and the following table gives the results:—

Yields of Potato Competition, 1935, *Mount Compass School Boys.*

Competitor.	Sets planted.	Sets shot.	Sets dug.	Yield. lbs.
Don McKinley	70	70	70	270
Brian Simons	80	78	65	261½
Linton Jacobs	59	59	59	223½
Alex Anderson	63	60	54	218½
Ross Williamson	58	58	58	209
Ray Chigwidden	63	63	63	182½
Kelvin Peters	40	28	22	174
Douglas Chigwidden	54	54	54	167½
Ben Peters	40	31	22	164½
Sam Miller	53	37	37	146½
Ralph Coles	47	46	46	109½
Noel Jacobs	83	83	50	107

The winner, Don McKinley, is to be congratulated on his success in the Competition. Twelve months ago he also won with the record figure, or only 8lbs. more than this year. This lad has now left school and is no longer eligible to compete. Brian Simons, who is only eight years old, put up a splendid performance, and as he will be a competitor for some years to come he has opportunities of breaking the present record. Kelvin Peters obtained the heaviest yield from one set, viz., 26lbs., and Sam Miller the heaviest potato, 4½lbs.

Probably the most interesting feature of the Competition is the planting distance as a guide to the average acreage yield. The general average this year was about 3ft. both in and between the rows, and whilst yields obtained from 1lb. of seed were high, this wide planting affected the average acreage yield rather surprisingly. What is remarkable, however, is the small amount of seed that would be required per acre to give these results, based on the figures obtained this year. To illustrate this point the prizewinners' plots are summarised below:—

Competitor.	Area occupied by sets. Sq. yards.	Yield from 1lb. of seed. lbs.	Yield per acre. t.	c.	Quantity of seed required per acre. lbs.
Don McKinley	60	270	9	14½	81
Brian Simons	48	261½	11	15	101

DAIRY AND FARM PRODUCE MARKETS.

MESSRS. A. W. SANDFORD & CO. LIMITED reported on April 1st, 1935:—

BUTTER.—Since our last report the London butter market has shown some improvement after a sagging in prices, and at date of report sales of Australian choicest were being made at 74s. per cwt., but, under the Equalization Plan, the rates in the local market have continued steady. Production has declined to minimum, and the general rains received in March have resulted in the grass having made a start in most districts. If following rains are received this month the outlook should be promising. Present rates are:—Choicest creamery fresh butter in bulk, 1s. 4½d. per lb.; prints and delivery extra. (This price is for local sale only, and, under the quota system, the equalised price manufacturers will receive will be 1s. per lb., on which basis payments to cream suppliers will be calculated.) Separator lines from 9d. to 1s. 1d. per lb. for choicest; stores, 6d. to 8d. per lb. (these prices are subject to Equalization Levies).

CHEESE.—As with other dairy products this commodity is shortening in supply, although, with the development which has taken place in the South-East, there are still more than sufficient quantities being manufactured than for the corresponding period last year, and one or two more shipments will go forward to Britain before the close of the season. Meanwhile, there are ample quantities for local and interstate trade and values have continued steady at: Large and medium, from 8½d. per lb.; loaf, from 9d. per lb. at store door, delivery extra; semi-matured and matured, 10d. to 10½d. per lb.

EGGS.—As is usual at this time of the year, supplies are cutting off, and, under this influence and the improved rates ruling in the Eastern States, values firmed, and at date rule as follows:—Ordinary country eggs, fair average quality, 9d. per dozen net; long distance rail or shipping eggs lower. Selected new laid clean eggs, 1⅞ozs. and over, 11d. to 11½d. per dozen net.

BACON.—With the setting in of cooler weather the consumption of bacon increased, but this was only to be expected, and extra supplies were received from the factories from week to week. The quantities of live hogs offering in the various markets were well maintained, so that stocks of bacon in process of curing are ample for all forward requirements. The sale of hams is now shortening, which is usual when the winter season approaches. Rates are:—Best quality sides, 9½d. to 9¾d. per lb.; middles, 10½d to 11d.; heavy middles, 9d. to 9½d.; rolls, 8½d. to 9d.; hams, 1s. 1d. to 1s. 2d.; cooked hams, 1s. 3d. to 1s. 4d. per lb.

ALMONDS.—Much heavier quantities were marketed last month, but good interstate and local trade cleared parcels and rates improved. Also, there was a very ready demand experienced for kernels, and all lots were cleared satisfactorily. Quotations are:—Softshells and Brandis, 8½d. to 9½d. per lb.; hardshells, 5½d. per lb.; kernels, 1s. 10d. to 1s. 11d. per lb.

HONEY.—Although there was a slightly improved sale for honey, the turnover was disappointing in view of the heavy stocks held by distributing merchants, and market continues somewhat depressed. Quotations were without change, being:—Prime quality clear extracted, 2½d. to 3d. per lb.; lower grades, 1d. to 2d. per lb.

BEESWAX was in better supply throughout the month, and all good quality lots sold readily at 1s. 4d. to 1s. 4½d. per lb. according to quality. Discoloured lines lower.

LIVE POULTRY.—Sales are held every Tuesday, Thursday, and Friday, and our sale rooms are the best equipped in South Australia. Clearing sales arranged in any part of the State. With the approach of Easter the demand for poultry has increased and there were heavier supplies offering at each market. The demand was more particularly for prime quality heavy weight table birds, although the smaller sorts, such as Leghorns, were cleared from sale to sale at prices commensurate with the size and quality. We advise consigning Crates loaned free on application. The following are prices realised:—Prime roosters, 3s. 9d. to 4s. 6d.; nice conditioned cockerels, 3s. to 3s. 8d.; fair conditioned cockerels, 1s. 9d. to 2s. 9d.; chickens lower. Heavyweight hens, 1s. 11d. to 2s. 7d.; medium hens, 1s. 6d. to 1s. 10d.; light hens, 11d. to 1s. 3d.; couple of pens of weedy sorts lower Prime young Muscovy drakes, 3s. to 4s.; young Muscovy ducks, 1s. 9d. to 2s. 3d.; ordinary ducks, 1s. to 1s. 9d.; ducklings lower. Geese, 3s. to 4s.; goslings lower. Turkeys, good to prime condition, 8d. to 10d. per lb. live weight; do., fair condition, 6d. to 7½d. per lb. live weight; do., poor and crooked breasted lower. Pigeons, 3½d. to 4d. each.

POTATOES.—New season's, 9s. per cwt.

ONIONS.—Brown Spanish, 9s. per cwt.

AGRICULTURAL BUREAU REPORTS.

INDEX TO CURRENT ISSUE AND DATES OF MEETINGS.

INDEX TO BUREAU REPORTS—*continued.*

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying.	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator *v.* Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

SOUTH-EASTERN DISTRICT.

Other Reports Received.

Allandale East .	21/3/35	9	Annual Meeting	R. Laslett

UPPER NORTH DISTRICT.

(PETERBOROUGH AND NORTHWARD.)

WILMINGTON (Average annual rainfall, 17.32in.).

February 12th.—Attendance: 15.

HARVEST REPORTS.—Most crops were badly affected by grasshoppers and to a less extent from hail. Late sown varieties gave the best returns. Lodging was not responsible for any appreciable loss, Nabawa being the only variety to suffer in this respect. During the latter part of harvest, heavy wind was experienced and this had a depressing effect on yields. The grain was somewhat bleached with a corresponding drop in the bushel weight. Ranee was reported as having yielded the best crop: 9 bags to the acre. Reporting on the different varieties, Mr. E. L. Orchard (District Agricultural Instructor) said Sword was badly knocked about and in some crops traces of bunt were detected. Ranee, with its short growth, yielded as well as any variety through the north. Nabawa was badly injured by heavy winds. Ghurka, only recently introduced to the district, will most likely replace Nabawa. Quality: a variety for which the millers were offering a premium, but was very subject to shaking and inclined to lodge. Dundee is a high quality milling wheat for which higher prices than f.a.q. would be paid by the mills. A decided falling off was noted in the sowing of Ford. (Secretary: C. Cole.)

MIDDLE NORTH DISTRICT.

(PETERBOROUGH TO FARRELL'S FLAT.)

BLYTH (Average annual rainfall, 16.80in.).
March 1st.—Attendance: 8.

HARVEST REPORTS.—Mr. W. Eime reported favourable crops notwithstanding the lean rainfall. Sword 18bush., and Bencubbin 32bush. Mr. H. E. Zweck, fair crops of Ranee and Bencubbin, the latter variety being very tough to reap after rain. Mr. R. Eime—favourable crops of Ranee and Sword; a farm average of 18bush. over 605 acres.

WIRRABARA (Average annual rainfall, 19.29in.).
February 19th.—Attendance 12.

Mr. E. L. Orchard presented Life Membership Certificates of the Agricultural Bureau to Messrs. W. H. Jettner, B. Joppich, W. Stephens and C. H. Curnow.

HARVEST REPORTS.—Mr. W. H. Stevens reported: O.B. 27bush., Sword, which shook badly, 15bush., Canberra 24bush., Ranee 19bush., Ranee 4II, 27bush., Nabawa 27bush; farm average, 24bush. Mr. B. C. Joppich—Gallipoli 27bush., Ranee 4II, 21bush; farm averge 21bush. Mr. W. H. Stephens—Ranee 4II, 18bush., Early African and Merriden, 15bush., Nabawa 17bush., Waratah 14bush. Mr. F. Borgas—Federation, 17bush., Sword 18bush., Nabawa 21bush.; farm average, 18bush. (Secretary: F. Borgas.)

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

SADDLEWORTH (Average annual rainfall, 19.60in.).
February 22nd.

DAIRYING: THE MAIN SIDELINE ON THE FARM.—Mr. A. Marrett read the following paper:—"The first essentials for success in dairying are that the farmer be in sympathy with his work and have a natural liking for the handling of dairy cows. South Australia cannot be regarded as an ideal State for dairying; nevetheless, much depends on this industry from a farmer's point of view. It should be the aim of those who take up this sideline to obtain a good class of cow and head the herd with a bull of proved parents. If this is done there will be more interest taken in the cows and they will receive more attention. This will result in better feeding. There no is need to go to extremes and stuff the cows. Perhaps the best guide is 2½lbs. of bran and oats to every gallon of milk produced. The cows will appreciate a change of pasture and respond by maintaining their milk yield. Pigs go hand in hand with cows. During the past 2 years there has been more money in pigs than in dairying. The farmer who keeps cows and has surplus milk should either breed pigs or purchase animals for fattening. The former is the more profitable method, but with the latter less labour is required. I carried out tests with the following types of pigs:—Large White, Large White x Berkshire, Large White x Tamworth and pure Berkshire. All were bought as suckers and each given as much milk and dry crushed barley as they could consume for 1 month. The pigs were kept in a pen supplied with plenty of water and a self feeder. The Large White pure-bred weighed 65lbs. at 57 days, Large White x Berkshire at 57 days weighed 65lbs., and realised 1s. less. The Pure Berkshire at 75 days weighed 65lbs. and was sold for 2s. less. The Large White x Tamworth tipped the scale at 80lbs. when 97 days old and was sold for 4s. less. I buy about 20 pigs each month and because there are not enough animals of the right type that come into the market I have to obtain them on farms." Many farmers, he thought, could with advantage use better cows, and too often the boar that was used was of a poor type. (Secretary: F. W. Coleman.)

SUTHERLANDS (Average annual rainfall, 10.84in.).

March 7th.—Attendance: 11.

A REVIEW OF THE PAST SEASON.—Mr. W. Doecke read a paper on this subject. He first reviewed the climatic conditions that prevailed during the year, the rainfall totalling 10.78in. Over the district he estimated the hay yield to be in the vicinity of 15cwts. to the acre and wheat 5bush. Because of the late spring rains and the second growth that came up in the late sown crops, reaping could not be started until the middle of September. Wheat harvested prior to New Year's Day was very plump, but the rain that fell following 1st January caused a good deal of pinched grain. Grasshoppers did some damage towards the end of the year. On the whole the season had been a trying one and had again proved the necessity for the light working of the land and doing all cultural operation at correct times. (Secretary: C. R. Schiller.)

WASLEYS.

February 14th.—Attendance: 14.

HARVEST REPORTS.—Reports were given by Messrs. L. Mackereth and R. Sires: Barley, all the grain was of No. 1 sample, the best returns being from fallow land, 13 bags to the acre. Light grey land cultivated in March, 7 to 8 bags. Barley on wheat stubble, 4 to 6 bags. Oats on fallow yielded 10 bags to the acre and cut 1½ tons for hay. Oats on stubble, 7 to 8 bags per acre. The following returns were obtained from wheat:—Nabawa 27bush., Sword 24, Ranee 21. All crops were exceptionally clean. Malting Barley—All plots seeded at the rate of 65lbs. of seed per acre: 90lbs. super, 25bush. 18lbs.; 80lbs. super and ammonia: 27bush. 16lbs. Average, 26bush. 34lbs. Oats and wheat mixed—Nabawa wheat and Cape oats, 2 tons per acre. Ford and Nawab wheat cut for hay, 1¾ tons per acre. Grain yields, 12½bush. (Secretary: C. Currie.)

YORKE PENINSULA DISTRICT.

BOOR'S PLAINS (Average annual rainfall, 15.64in.).
February 7th.—Attendance: 19.

HARVEST REPORTS.—Mr. M. Wright, in his report, said crops were very free from disease, but the heavy winds in November were responsible for the shaking of the early varieties. The sample in most cases was very good. Sword and Waratah on fallow, 18bush.; Ranee, 24bush.; Free Gallipoli, 21. Wheat on grassland, 12bush. Hay cuts were in most cases ilght, and yielded ¾ ton to the acre. Barely was of a good sample, the yield being about 15bush. (Secretary: S. Chynoweth.)

Other Reports Received.

WESTERN DISTRICT.

ROBERTS AND VERRAN.
February 13th.

HARVEST REPORTS.—Mr. S. Barber—Average yield, 3bush., due to the ravages of grasshoppers. Mr. K. Masters—9bush. farm average; 250 tons of hay and 40 tons of ensilage were conserved. Early Burt oats on fallow cut 1 ton of hay to the acre. Ranee on grassland, 13bush., Gluyas on fallow 9bush., and Sword 7bush. Mr. A. Ramsey —Wheat on fallow 9bush. Mr. H. Smith reported very extensive damage from hoppers, prior to their attacks he estimated crops at 15bush. Dry weather and severe damage by hoppers were the reasons for the low yields on Mr. C. Masters' farm. (Secretary: C. Masters.)

YADNARIE (Average annual rainfall, 14.09in.).
February 12th.—Attendance: 30.

Mr. H. D. Adams (District Agricultural Instructor), on behalf of the Advisory Board of Agriculture, presented to Mr. J. Quick a certificate conferring on the recipient the honour of Life Membership of the Agricultural Bureau. Mr. Quick has been actively associated with the Bureau for 20 years, and during that time has occupied every office in connection with the Branch. Mr. Spriggs presented the trophies to the successful competitors in the Jervois Wheat Crop Competitions. (Secretary, E. A. Spriggs.)

WATER CONSERVATION ON THE FARM.

Paper read by Mr. C. Zippell (Hon. Secretary of the Wallalla Branch), at a meeting held on November 14th.

One of the many problems confronting the settler in the lighter rainfall districts is the insufficient supply of water, without which he is unable to develop his holding or carry the necessary stock to make farm sidelines a paying proposition. In districts where no underground supplies exist, preparations have to be made for surface catchment with underground tanks or dams for storage; whilst in districts where the soil is of a more sandy nature, artificial catchments have been made, such as laying out large quantities of galvanized iron or treating areas with asphalt. Both of these types of catchment assure water being added to the storage after every shower of rain.

It is usual in districts where the soil sets readily to rely on private or public roads and tracks for catchment purposes. Whatever method or catchment is used, it is always advisable to build sufficient tanks to hold at least 12 months' supply. This should avoid the possibility of water carting during summer. Providing there are suitable catchment areas, small tanks should be built on various parts of the farm, so that water can be readily available to each paddock. The addition of a small overhead tank, with windmill attachment, troughs, and ball-taps, on the main storage tanks, will ensure a plentiful supply of water to stock during the farmer's absence from home, should this be necessary for a few days.

The method of constructing underground tanks varies a good deal according to circumstances and districts. Certain types or soil make it difficult at times to decide the class of material which will give the best and most economical results in tank building. The following are some of the methods more generally known and used:—

Method No. I.—Squatter's tank.
Method No. II.—Stone mason work.
Method No. III.—Lime concrete.
Method No. IV.—Cement concrete.

The squatter's tanks are made of light steel plates of various sizes, bolted together in the position in which they are to remain. The cost of this type of tank is approximately £5 per 1,000 gallons, and is much too costly for the farmer. Therefore, no further mention of this type is necessary.

Stone mason work is perhaps the oldest method of tank-building and has given satisfactory results when care was taken to see that when building the walls the correct class of stone and mortar were used, that the correct ties were made—not only in the corners, but throughout the whole wall. The wall must also be properly backed up when building.

Lime concrete is also extensively used, good results being obtained when care is taken to leave the face of the wall rough, with plenty of stone showing. Too much mortar should not be left on the face of the wall, as the cement coating will not adhere to a lime surface, and will eventually leave the wall and crack.

With the two foregoing methods the only cash outlay to the farmer is the purchase of cement to complete the job.

Cement Concrete.—This method, although it must be considered the best, has not been generally used for tank building on the farm, chiefly on account of its costliness. It requires much more cement than the methods previously mentioned, yet, when time is taken into consideration, cement concrete may not prove so costly when compared with other methods. With both stone mason work and lime concrete a large quantity of stone is necessary. This entails a good deal of work by way of stone raising, carting, and lime burning.

A good material which can be thoroughly recommended for cement concrete work, and has proved its worth in the past for various building purposes, is beach shells. These when mixed with cement in proportion of 6 to 1 give good results in tank walls. A wall 6in. thick of this mixture would have sufficient strength for a farm tank of any size, and if reinforced with cyclone fence wire, will give a lifetime job for both under and over ground tanks. Whichever type of wall is built, only reliable material should be used and the walls of underground tanks built a foot above the ground level. Earth should also be placed that height around the tank to prevent the possibility of water getting behind the walls. Tank walls and floors should receive a priming coat of cement of a 4 to 1 mixture and a final coat of 2 to 1 mixture. In addition, a cement wash is also recommended to guard against any flaws caused by trowelling. As soon as the cement is firm enough, water should be placed in the tank to prevent the cement from drying out too quickly. A covering should also be placed over the tank to prevent damage from the sun. Farm tanks can and should be one of the most permanent improvements on the farm. A good tank, well built, is a credit to the builder, as well as an asset to the farm, and also another step towards assuring sufficient water for the farmer to carry the required stock.

SOUTH AND HILLS DISTRICT.

FRAYVILLE.

February 14th.—Attendance: 9.

HARVEST REPORTS.—The following reports were received:—Mr. W. Lindner—Ranee, 10bush.; Nabawa and Nawab, 12bush.; Sword—poor germination—12bush.; Ghurka, 15bush. Mr. H. A. Helbig—farm average 18bush., the best wheats being Ranee and Nabawa. Mr. L. Eichler—Ranee, 20bush.; Ford, 18bush.; Nabawa, 17bush.; Crossbred, 16bush. Mr. H. B. Scheer—Aussie and Nabawa on stubble, 10bush.; Sword, 15bush. Mr. G. Faehrmann—Ranee, 7bush.—due to frost—Nabawa, 15bush.; Ghurka, 18bush. Mr. H. Rosenzweig—Farm average of 15bush. Mr. H. Ramm—Nabawa and Ranee, 15bush. Mr. S. Bretag—Sword and Nabawa, 20bush.; Ranee, 19bush.; Ghurka, 17bush. The Chairman reported on the carbonate of lime experimental plots; the following being the results:—No manure, 13bush. 35lbs.; 1cwt. carbonate of lime, 13bush. 27lbs.; 1cwt. super, 20bush. 45lbs.; 1cwt. super and 1cwt. carbonate of lime, 20bush. 22lbs. (Secretary: H. Ramm.)

HARTLEY (Average annual rainfall, 15in. to 16in.).

January 16th.—Attendance: 8.

AILMENTS OF CATTLE.—Paper read by Mr. A. Brook:—"*Lumpy Jaw.*—This complaint is characterised by a hard, bony swelling, and usually occurs on the lower jaw; but it may affect the upper jaw below the eye, the glands of the throat, and udder, and the tongue. The swelling usually breaks with a number of small openings, which later join together and form a large one. Pus, tinged with blood and sometimes particles of bone, are discharged. To treat this trouble, clean out the cavity with a clean, blunt knife, removing fragments of diseased bone and tissue, and syringe twice daily with a 2 per cent. aqueous solution of iodine. Also give 2 dram doses of iodide of potassium in the feed twice a day for a fortnight; allow 1 week to elapse, then repeat. *Mammitis.*—This complaint is well-known to all dairymen, and takes the form of an inflammation of the udder, caused by knocks, cold, overstocking with milk, and by a contagious germ. The injured quarter becomes infected through the opening in the teat. Mammitis is characterised by a tense, painful swelling of one or more quarters of the udder; the milk is altered in colour and texture, and is clotted and watery, or pus-like. Treatment consists in stripping out as much milk as possible, and if a teat syphon is used, precautions must be taken to see that it has been carefully sterilised before inserting it into the teat. Make a mixture of ½gall. of warm water and ½ pint of strong vinegar; bathe the udder thoroughly, and subsequently dry it to guard against a chill. Next apply warm antiphlogistine packs to the affected part, which can be held in position by a strip of chaff bag tied over the back. *Bloat.*—This fairly common complaint usually follows feeding on a growing crop of lucerne or other gaseous fodder. The animal becomes blown up on the left side, is generally frightened to walk; the tongue protrudes from the mouth, breathing is difficult, and the animal groans. To afford relief, place a stick in the cow's mouth, and fasten with straps to keep in position. Then give a drench of 1lb. Epsom salts, 1oz. of ginger in 2 bottles of warm water." (Secretary, W. Brook.)

THE WHEAT INDUSTRY.—Mr. C. Brook in the course of a paper dealing with this subject said the quality of Australian wheat that was exported was so low that at present No. 1 Manitoba was bringing in 1s. per bushel more than Australian wheat. He contended that such would not be the case if only good quality wheat were grown and properly cleaned before it was exported. To encourage the growing of these wheats he suggested that the money at present allocated by the Government to encourage crop competitions

should be given to the farmer whose crop consisted of the highest percentage of strong or medium floured wheats. The R.A. & H. Society could also assist in this direction if the grain in the show for seed wheat entries was milled and one point awarded for every unit of gluten. Too many varieties were grown. A reference to the catalogues of the Show Societies would show the types of wheat exhibited; Adelaide, strong 9 varieties, medium 15, weak 46; Melbourne, strong 6, weak 25; Sydney, strong 5, medium 17, weak 48. Roseworthy College for some years passed has used King's White in the breeding plots. It was a weak floured variety and in the Southern districts a poor yielder. Although agricultural authorities stated that the high quality wheats were poor yielders he found that in practice, that was not so. He had had higher returns from the wheats of good gluten content than from Nabawa. Mr. Brook expressed the opinion that Ford was the best wheat that the College had produced. Sword had taken the places recently held by Federation and Gallipoli. He had grown it for 2 years and found that the sample was not so good as that from other wheats growing alongside of it. Further it was rather hard to thrash. His experience went to prove that by selecting the large heads with a good sample of grain from the plants with the greatest number of stools the yield per acre could be increased by 1 to 3 bushels. The recent World's Grain Exhibition held at Regina, gave an excellent indication of the varieties best suited to the English market by placing Comeback 10 times out of 28 sections. Ford made a name for itself by winning third prize. Present indications led one to believe that there would not be any very marked fluctuation in the price of wheat for the next 25 years. France was selling wheat in England for 18s. per quarter (480lbs.) and flour for less than 10s. per sack of 280lbs. as against the home price for flour with an exchange equivalent of 58s. to 68s. per sack of 280lbs. Italy was selling flour in England for 7s. 3d. for a sack of 280lbs. and the home consumption price in that country was 50s. per sack. If Australia could send full cargoes true to type of such wheats as Comeback, Quality, Florence, Ford and others, there would soon be a greater demand and better prices. Mr. Brook considered that bulk handling would not help in this direction, because good and bad wheats would be mixed in the silo and the whole wheat would have to be sold as a bulk sample. His experience of pooling was that he never received less than 2d. per bushel than those farmers whose wheat went into the pool, but one year 1s. 3d. more was received and during another season 1s. 5d. per bushel more. Mr. Brook referred to the effects of the tariff. In conclusion he said that land not suited for the growing of wheat could be utilised for the cultivation of other cereals, pastures, and root crops for live stock.

INMAN VALLEY (Average annual rainfall, 26 to 27in.).

February 21st.—Attendance: 16.

LESSONS FROM 1934.—Mr. C. Davenport read the following paper:—"The past year was an exceptionally good season. Paddocks which had been topdressed showed remarkable growth and only with heavy stocking was it possible to keep the feed from getting ahead of the sheep. If the latter happens, it is just as bad as to allow the paddock to be eaten right out. In the first place foot rot is almost certain to be experienced and the flock master is bound to have trouble with worms. Late autumn is the worst period for the latter pest and it has always been my practice to hand feed from this stage onwards. The treatment of all affected sheep is done in the branding race which is 3ft. wide by 30ft. long with a gate at each end. I have found the tetrachloride drench give the best results. One objection to the copper sulphate drench is the time that it takes to treat a number of sheep. It is best to give 2 doses at about weekly intervals, but to get best results drenching should be done each month. All healthy sheep should be drenched twice a year—during crutching and shearing. The best preventive measure against worms is burning the pastures and fencing off swampy areas. Coupled with these, rotational grazing should be adopted and salt licks provided. Pastures that have been stocked at all heavily should be treated with the pasture harrow. It will help to promote an even growth all over the paddock. Wet weather had precluded the best quality of meadow hay from being made. Cocking the hay with a rake and making a stack in the paddock saves a tremendous amount of time. The middle of August is the best time to shut up the hay paddocks. The cheapest method of killing bracken fern is with the aid of cattle. Get the clover into the land, use adequate dressings of super and the cattle will do the rest. Cutting by hand involves a good deal of labour, but if it has to be done the best time is late summer and early autumn. Kikuyu grass has proved invaluable for planting on the edges of washes and creeks. Yorkshire Fog is another grass which is worthy of more attention. It is the best grass to put down when seeding new land. It will stand up to heavy grazing and grow on very poor soil. The following hint may be useful in treating a sheep with a broken leg; it has proved most successful. Cut strips of brown paper 3in. to 4in. wide, dip the paper in water and roll it up in a similar manner to a linen bandage. Bind the broken leg by unwinding the bandage and tie tightly with string above and below the break. In a few days the paper will become quite stiff and the sheep will require no further attention.

Mr. C. A. Goddard, of the School of Mines, delivered and address, "Preparation of Wool for Market." (Secretary: A. M. Fuller.)

Mr. Norman Brookman, of the Meadows, invited the Mount Compass Branch to hold its Annual Field Day at "Burbrook" on December 6th. There was a large attendance of members and officers of the Department of Agriculture, and in the above photo Mr. Brookman is shown explaining the treatment of one of his pasture paddocks.

The process of baling grass hay was of special interest to visitors at "Burbrook."

LONGWOOD (Average annual rainfall, 37in. to 38in.).

January 19th.—Attendance: 12.

HOMESTEAD MEETING.—The monthly meeting was held at the residence of Mr. J. Roebuck, who has occupied his present holding for 47 years. The property is equipped with an electrically driven pump, which delivers 2,000galls. of water per hour. Eleven sprinklers water 9 acres of vegetables, which at the time of the inspection were very healthy; 160,000 onions from seed raised on the property had been planted out. The orchard contains 2,000 fruit trees, the greater number of them being apples. The latter were carrying a good crop, but quite a lot of the fruit had been hail-marked. An ingenious home-made power spray came in for very favourable comment, as did a red Jonathan that had been worked up by Mr. Roebuck. Other items inspected included the machinery, stock, grafting appliances, and codlin moth bandages. At the evening meeting Mr. H. H. Orchard (R.D.A.) spoke on the coming fruit export season. (Secretary: H. Haines.)

CONFERENCE OF MID-NORTH WOMEN'S BRANCHES.

Mrs. E. L. Orchard (Belalie) presided over an excellent attendance of delegates from Mid-North Branches at the Conference which was held at Red Hill on 14th March.

The Hon. H. G. Hawkins, M.L.C., and Mr. H. B. Barlow (Chief Dairy Instructor) explained the regulations of the Dairy Act. Conference discussed the activities of Women's Branches and the following resolution was carried:—"That this Conference desries a broadcast talk once a month on the activities of Women's Branches and on subjects of interest to the members in general. Mrs. H. J. Crouch acted as secretary.

The following papers were read and discussed:—

SUMMER DRINKS.

[Mrs. R. C. Hawke, Belalie.]

If the body is deprived of water, the tissues become dry and shrunken, the blood is thick and circulation sluggish. The body thus requires a certain amount of water to maintain health and life.

The natural drink is water, and its place can only be taken to a limited extent by other beverages. On an average about 3½ pints of water are necessary each day. A certain amount of this is taken in solid food, but the bulk of the day's supply should take the form of beverages.

During hot weather, one usually likes something cold to drink, although a cup of hot tea is always very popular, and beneficial too, if taken properly prepared and in moderate amounts.

To make a good cup of tea, allow 1 teaspoon to every pint of water, and 1 teaspoon over. Heat the teapot, then put in the tea and pour freshly boiled water over the leaves, allow to draw for 3 minutes in a warm place, then pour. If tea stands too long, the

tannin, which is harmful, is extracted from the leaves. Cold weak tea is an excellent thirst quencher. Iced tea is good too, it is made as ordinary tea, poured into cups with the addition of a slice of lemon, ½ cup of crushed ice, and sugar to taste; drink when chilled.

There are numbers of fruit essences sold these days, which besides being economical, are mostly delightful to drink; and if they are served icy, are tempting on a warm afternoon or evening. That something cold to drink can very well become almost a whole meal in itself is not so familiar an idea, yet it is a very practicable and delightful one.

Food beverages, as they may be called, are most appropriate for between meal luncheons, when appetites flag in the summer, and if they are served in interesting glasses, accompanied by a straw or two, they will almost invariably be hailed with delight, and partaken of with gusto. Prepare beforehand a jar of simple sugar syrup which sweetens the beverages much more satisfactorily than does sugar alone, and makes a much smoother, richer produce. 1½ cups of sugar to a quart of water, and boiled for 5 minutes is the recipe.

There are numbers of concentrated fruit extracts in rich flavourings which can be purchased at most grocery stores for a small amount, and these, with the addition of sugar and water, will make about 5 bottles of essence and are always popular, especially with children. A good tip, when oranges and lemons are cheap, is to procure a quantity and extract their pure juice and store it. To do this, a large squeezer is a time saver. The juice should be squeezed through a muslin bag in order not to include pips or pulp, then pour the juice into small bottles (½ pint ones are handy) which must be perfectly dry. Fill almost to the top with juice, but leave enough space for about 2 teaspoons of sweet oil, a little more or less according to the size of the bottles. After putting in the oil, cork the bottles securely, and keep in a cool place. When the juice is required for use, fasten a small piece of cotton wool on to a skewer and dip in, until the oil is absorbed. The juice should be used within two or three days after opening the bottle.

Milk drinks are many and delicious, milk shakes being the simplest form of this group, are easily varied and always nourishing and refreshing. When making cold drinks of any type, a shaker will be found a most convenient utensil, but a quart, or a ½ gallon fruit jar, fitted with a reliable rubber ring and a lid is a good substitute.

Pink milk shake is always a favourite with children. Make it by shaking together ½ cup of crushed ice, 6 tablespoons of strawberry or raspberry essence and 1½ cups of milk. When frothy and light, pour into small glasses and top with a teaspoonful of whipped cream, flavoured with the essence.

Orange Sullabus is an unusual milk drink, and as it is so nutritious and refreshing, it should be better known. Pour ½ cup of orange juice into the shaker, add ½ cup of beverage syrup (that is the sugar and water) and 1 cup of crushed ice, shake until well mixed, then add 2 cups of milk and continue shaking for a minute or two. Fold in ½ cup whipped cream, shake again, then serve frothy and chilly in colourful glasses.

Recipes for a Party Punch Bowl.

Fruit Cup.—A delicious drink at an evening entertainment and looks nicest served in a large punch bowl with slices of fruit and lumps of ice floating on the top. Allow 2 lemons and 4 oranges to each quart of liquid, and add any other fruit juices. One may have the addition of passion fruit juice, and also crushed pineapple gives a nice flavour. Sweeten with sugar dissolved in a little warm water. The fruit juice can be prepared beforehand and left standing in the bowl. Just before it is to be used, fill up with dry ginger ale, lemonade or soda water, and if one wants to make it specially good, add a bottle of cider.

Claret Cup.—Make a syrup of 1½lbs. sugar and 1½ pints water, thinly peeled rind of 4 oranges, and ½ nutmeg, 4 slices of cucumber, strain and allow to cool, add 1 gallon of water, 3 bottles of claret, 1 glass of brandy and orange juice. Just before using, add 4 bottles of ginger ale. This is enough for 60 glasses.

GRAPE-MENT ADE.—Cook together to a thin syrup 1 cup sugar, 2 cups water, add 3 drops of essence of peppermint, cool, and mix with 1 cup of lime or lemon juice, and a quart of grape juice, and serve garnished with thin slices of lemon. To make the grape juice, pick grapes from stems and to every 8lbs. of grapes add 1 pint of water and ¼ cup of sugar, boil for 8 minutes, then strain into sterilized warm bottles and cork tightly.

ICED COFFEE.—A welcome change from fruit drinks, and is stimulating. The coffee essence is simply made by putting 3 tablespoons of coffee (ground) into a saucepan with a cup of water and a pinch of salt. Simmer slowly for 2 minutes, remove from fire and allow to stand for 5 minutes. Strain carefully into another saucepan, add 1 cup of sugar and stir until dissolved, bring to boil and boil for 5 minutes without stirring. Cool, then pour into a jar and keep in a cool place until wanted. Put 4 cups of milk and 2 tablespoons of essence into a large jug and stir well, then chill thoroughly and pour into glasses. A teaspoon of whipped cream on top adds to the appearance and flavour. This recipe is enough for 6 glasses.

GINGER BEER.—Always a favourite. Take 4 cups of sugar, 4 gallons water (cold) 2 teaspoons cream of tartar, 4 teaspoons ground ginger, 3 tablespoons yeast. Mix all well together and bottle.

CIDER.—Makes a wholesome drink—appears to benefit some people who suffer from rheumatism. Here is a recipe for cider cup. 2 bottles of cider, 1 bottle of soda water, peel of a lemon, a few drops of orange bitters. Mix all ingredients together and serve very cold with a little lump of ice in each glass.

An immoderate use of acid liquids, that is, lime juice, lemonade, &c., in hot weather is a bountiful source of dyspepsia. Fruit salts, if taken first thing in the morning, are excellent for one's health during hot weather. This recipe is a good one:—2 ozs. cream of tartar, 2ozs. tartaric acid, 2ozs. bicarb. of soda, 6ozs. castor sugar, foz. Epsom Salts. Rub all through a sieve and mix thoroughly. Bottle and keep in a dry place. Use 1 or 2 teaspoons in a glass of water.

THE USE OF LEMONS.

[MISS L. DESILVER, Nelshaby.]

No garden is complete without a lemon tree, as lemons can be used in a number of ways every day in the home. Lemon trees are very hardy and grow in almost any soil, and with reasonable care, will bear most of the year. They are surface feeders so always use a fork when digging round a tree in order not to disturb the roots. A tree that does not bear should be cinctured. The fruit should always be cut, never pulled, as the stem holds the gas in the fruit. Sulphate of ammonia is a good tonic for a tree, also plenty of rotted stable manure, the more fertilizer used the more water is needed.

I have better results in keeping lemons by using vaseline and storing in a cool place. When a small quantity of juice is needed, puncture with a prong and squeeze out the juice. By placing lemons in a hot oven for a minute or so more juice is procured. Peelings and pips of oranges and lemons contain tonic properties, soak either in cold water overnight, and drink the water before breakfast. Lemons sliced and put in the bath make it very refreshing. Slices of lemon in the copper whiten the clothes. Lemon and salt remove stains from the hands; glycerine and lemon is a good skin whitener. Use lemon in the water when rinsing the hair, also use the juice in cakes, biscuits, &c., instead of essence.

RECIPES.

LEMON JELLY.—First day, cut lemons in slices and to each pound of fruit add a quart of water; leave for 24 hours. Second day, boil 20 minutes and stand 24 hours as before. Third day, boil pulp, strain, and to every cup of syrup, add a cup of sugar, boil until a spoonful placed on a saucer will jell, generally about 30 minutes.

LEMON PEEL.—Soak peel in a brine that will float an egg, next day, boil in clear water until it can be pierced with a straw. Make a syrup of 2 cups sugar, 1 cup water—boil peel in syrup until transparent. For show purposes add 2 more cups of sugar to remaining syrup, dissolve and pour over peel.

LEMON SAUCE.—Half a pint of water, 1 or 2 lemons, according to taste, 1 teaspoon cornflour, dessert spoon butter. Heat water with thinly pared lemon rind, sugar, and butter. Boil 10 minutes, blend cornflour with a litle water, add to other ingredients and boil 5 minutes. Remove peel, add lemon juice and more sugar if desired.

Sugar and water syrup is more economical for lemon squash. Lemon juice is an improvement to milkless tea. Lemon juice bottled, with a film of olive oil added will last for months. Use lemon juice in place of vinegar for beetroot, lettuce salads, &c.

HONEY AND ITS USES.

[MRS. A. SANDERCOCK, Belalie.]

Before sugar came into universal use, honey was commonly used for sweetening purposes. A tablet of sunbaked clay, has been found containing the epitaph of a Babylonian ruler, paying tribute to honey. The Hebrews traded extensively in it, and the Bible contains numerous references to it.

Honey is a substance derived from flowers, but modified and changed by the honey bee. It is a mistake to suppose that bees get ready made honey from the flowers. No flowers contain honey as we know it: honey is specially made by the honey bee from materials derived from flowers. The sugary material produced by flowers is not honey and does not exist to the bee. It is made by the flower for its own purposes; but it serves the flower indirectly, because the visit of the bee is of value in helping to fertilize it. The bee stores honey in a hive with moveable combs which the apiarist now provides. When it has ripened, the bees cover the cells with a cap of wax, which is removed with a hot knife; the honey is then thrown from the cells by being whirled rapidly. Hence the term "extracted" honey.

The finest of this kind is bright and clear, of a light amber colour, as well as delicate in flavour and aroma. Yet other colours also occur, being due to the food of the bees. Moreover, honey may occur in a semi-fluid, in addition to a solid form. The colouring, however, does not affect its eating qualities, while the most popular honey in England—heather honey—is very dark and gelatinous. It commands the highest price. Lucerne-fed honey is almost white, in fact, practically colourless and the flavour is delicious.

Apiaristic honey consists chiefly of levulose and dextrose, the former being the fluid, and the latter the sugary portion. It is this latter that is so largely called upon in the composition of diets. Yet, honey alone requires very little work from the digestive system, being immediately ready to be absorbed into the blood, carrying the necessary vitamins and mineral salts to give energy and health to the human system. The only inorganic element required by the human body not available in honey is silicon, which is supplied by glacial stalks like celery, asparagus and silver beet.

Candied honey is the result of cold weather causing it to set in one large block. It may be liquefied by placing in warm water, care being taken not to over heat, which

often spoils the flavour. Candied honey can be used as a filling for sandwiches, a delicacy much appreciated by school children.

Honey may be used to sweeten porridge; it makes excellent eating with bread, and children like it so, followed by a cup of milk. Delectable biscuits can be made from it according to the following recipe:—

HONEY OAT COOKIES.—4ozs. rolled oats, 6ozs. flour, ½ teaspoon carbonate of soda, ¼ teaspoon ground cinnamon, ground cloves, grated nutmeg and salt, 4ozs. raisins, 1 teacup honey, 3ozs. butter (melted) and 1 egg. Sift the flour with the salt, soda and spices. Add rolled oats and raisins, then honey and melted butter. Mix well so that the last two ingredients may be well worked in. Add the egg well beaten, and stir for 5 minutes. Drop small portions on cold oven slides and bake for 15 minutes. These cookies improve with keeping.

Leading physicians reccommend honey as a pure food, although it is incomplete, inasmuch as it does not contain silicon, an element necessary to build flesh. Dr. Philpots recently advised its use for the prevention of dental decay, in that it contains natural calcium, with which to repair the teeth. Yet it is this that refined sugar takes from the teeth. It is of particular benefit for nervous exhaustion, heart weakness, digestive disorder and general lack of tone. Honey may be used as a demulcent and laxative, but large doses induce flatulence and gripe. Doctors allow diabetic patients to eat honey, whereas they cannot take sugar. Sufferers from gout, dyspepsia or rheumatism also find honey to be the safest kind of sweetening for their food.

Drugs are sometimes administered with it, while it aids gargling, and may be applied to ulcers. Affections of the throat are relieved by its soothing properties, and mixed with lemon juice it forms a cure for coughs. A recipe for this preparation is as follows.—Pour the juice of a lemon over 2 teaspoons of honey and mix well. One teaspoon of brandy in addition is useful as a corrective, and assists in cutting the phlegm.

Even the toilet may benefit from honey. A soap most soothing for tender skins may be made thus:—2lbs. common white or yellow soap cut into thin shavings with enough water in the pan to keep it from burning. When melted add ¼lb. honey and stir until it boils. Add a few drops of perfume and pour into a deep dish to cool.

Mention of honey recalls the fact that many may learn economy from the beehive, and be stimulated to industry by the bee's galvanized energy, rendered necessary by its brief life.

MINOR AILMENTS.

[SISTER HARSLETT, Gladstone.]

Burns and Scalds.—To burns and scalds apply oil of any kind. The best to use is carron oil (so called because first used at the Carron Works). It is one half lime water and one half linseed oil. Picric acid is very good to relieve pain; when the skin is unbroken moisten it and apply cooking soda (carbonate soda). If severely burnt, the patient should be disturbed as little as possible. He is suffering from shock and the pain of having the wounds dressed may so increase the shock as to cause his death. Burns are sterile wounds and can safely wait for 24 hours. If a child's clothes catch on fire, avoid draughts. Do not let the child run outside, but roll him up tightly in a blanket, or a woollen tablecloth. Always send for a doctor, or immediately send him to hospital, for the shock may be very serious. To prevent burns and scalds where fires are open, and there are children, fire guards should be used. Boiling water, &c., must be kept well out of reach of the children.

Strains and Sprains.—For strains and sprains apply either hot foments or cold compresses, and keep the part elevated and at rest.

Bruises.—Bathe alternately with hot and cold water, and then apply hot foments.

Cuts and Wounds.—To stop bleeding from a cut or wound, hold the part *up*, not down, and wrap firmly in a clean dry rag, or bandage. If a wound is not clean, wash it in clean hot boiled water, encourage bleeding, then make it as dry as possible with clean cotton wool, paint with methylated spirits, and tincture of iodine, and bind firmly

with a clean rag. Bad cuts that gape open can be held together by placing across the wound thin strips of adhesive plaster, or strapping. This can be bought in small reels and is very handy to have in the home. Should the wound become septic, a doctor should be consulted. If the accident has occurred in the vicinity of animal manure, or garden soil, a doctor should be consulted for fear of acquiring tetanus.

Fainting.—When a person loses consciousness or faints, place him so that his head is on the level of or lower than his body. Loosen all clothing and sponge the face and hands with very cold water. Turn the head to one side so that the tongue does not fall back and block the throat. If he does not soon recover consciousness, send for a doctor.

Sunstroke.—When a person has been overcome with the heat of the sun's rays, place him on his back in the shade, loosen all clothes, wring cloths out of very cold water and place them on the head. As soon as possible get him to bed, and sponge him all over with very cold water. Send for the doctor and *do not* give brandy.

Nose Bleeding.—When a child's nose bleeds, apply ice or cold water compresses to the back of his neck, raise his head, and keep him very quiet. Gently plug the bleeding nostril. If severe or frequent, take him to a doctor to find out the cause of the nose bleeding.

Apparently Drowned.—When a person is apparently drowned, send for a doctor. Loosen his clothes and clear the mouth of foreign matter. Turn the patient over on his stomach, and press regularly up and down on his back over his lower ribs 15 times a minute for 5 minutes. Then turn the patient on to his back; see that the tongue is not blocking the throat, and perform artificial respiration by raising the arms above the head, then bringing them down with the elbows flexed and pressing on to the chest. Do this 15 times a minute, until he revives, or the doctors pronounces it useless. Afterwards the patient should be removed to bed, and warmth applied by blankets and hot water bags, and body being rubbed with methylated spirits, towards the heart, and then also rubbed with hot dry towels. When consciousness returns, stimulating drinks can be given, such as coffee, brandy, &c.

Poisoning.—In all cases of poisoning send for a doctor. Make the patient vomit by giving a drink consisting of mustard (1 dessertspoon), or salt (1 tablespoon) in a tumbler of water. If an acid or alkali has burnt the throat give oil or raw white of egg, and milk. If phosphorus (as in matches) has been taken, do not give oil, after the emitic give water with Condy's crystals dissolved in it, and then a dose of Epsom salts. If an overdose of opium has been taken, give strong coffee and keep the patient awake. In a case of coal-gas poisoning, get the patient out in the open air, and perform artificial respiration. In a case of carbolic acid, or lysol, give a large dose of Epsom salts, or carbonate soda, followed by brandy or whisky. Put the patient to bed, apply warmth, and demulcent drinks.

Snake Bite.—When a person is snake bitten, send for a doctor, tie a ligature round the limb, between the bite and the heart. Scarify the wound, and rub in Condy's crystals.

Bites of Insects.—To bites of insects apply damp cooking soda or a squeeze of the blue bag, peroxide of hydrogen, Friar's balsam or rub an onion on the spot.

Covered with Ants.—Sometimes a child will play on an anthill, and get covered with ants. Plunge the child into a tub of water, and so drown the ants.

Fish Hook in Finger.—When a fish hook is caught caught in a finger, push the point of the hook on and out. Do not try to withdraw it, or the barbed point will tear out the flesh. When pushed through, cut off the barbed point with wire cutters, and then withdraw the hook, a crochet hook can be treated the same.

Knee Jammed between Palings.—It often happens, when a child climbs on to a chair and leans over the back of it, that his knee becomes caught between the wooden uprights. Get a piece of wood broader than the space between the uprights, put it on the slant in between them, and wedge it so tightly that they separate. This will release the knee.

Foot Jammed.—When a foot is jammed, remove the shoe or boot by unlacing if possible. It may be necessary to cut the shoe. Try to wedge the space wider for the foot to be released.

Pediculosis.—This denotes lice in the hair or on the body. The best preparation is a 5 per cent. solution of heliotropin in vaseline. It has a pleasant odour, resembling vanilla.

Ringworm of the Scalp.—Consult a doctor when possible. If unobtainable, cut all remaining and broken hair as close to the surface of the skin as possible, then clean the area well with ethereal soap. Wait until it is quite dry and then paint with tincture of iodine.

Warts.—Warts can be removed by frequent applications of acetic acid, or dilute nitric acid. Care must be taken not to let the acid touch the surrounding skin.

Sore Eyes.—Never meddle with the eyes. If there is anything wrong, consult a doctor at once. For a squint or any other indication of defective vision, go to a good oculist and have the eyes thoroughly examined.

Common Cold.—For a common cold give an aperient and put the child to bed. If everybody with a cold went to bed, there would be a great reduction in the number who catch cold. Not only does the person thus isolate himself from others, instead of being for weeks a carrier of germs, but also he recovers far more quickly. There would also be far fewer cases of pneumonia. Children are very liable to broncho-pneumonia and this is always very serious. Broncho-pneumonia often follows a cold and infectious diseases such as measles, mumps, and whooping cough. Colds are infectious diseases, most dangerous to babies, who should be carefully protected from infection from relatives, friends, visitors, overcrowded rooms, pictures, &c.

Sore Throat.—Nurse the child with a sore throat in bed. A simple remedy is a mixture consisting of equal parts of honey and vinegar. Always ask a doctor to examine it thoroughly. There is always the possibility of diphtheria and early treatment is most necessary for this disease.

Croup.—Laryngitis or larygeal spasm causes the child to breathe with difficulty, making a peculiar noise in doing so. Apply hot flannels to the throat. If not soon relieved, send for the doctor, for it may be due to diphtheria of the larynx, which needs urgent treatment.

Scabby Sores.—Scabby sores are very prevalent among school children. Each sore begins as an inflamed blister, containing yellow fluid, which later becomes dry, forming a crust. All crusts or scabs must be removed, and the sore kept clean. The scabs can be removed by applying a little boiled starch or starch poultice, which is made as follows:—Take 4 tablespoons of starch and 1 teaspoon of boracic acid powder, and sufficient cold water to melt the starch. Pour on ½ pint of boiling water, stirring all the time until starch is dissolved. Leave until cool, then apply to scabs. When the scabs are removed an ointment consisting of equal parts of white precipitate, and zinc oxide ointments may be applied. These sores are very contagious. They must always be kept covered, and if on the face and hands the child should not be allowed to attend school.

LOWER NORTH, BLYTH, 28th MARCH, 1935.

Mrs. Dux of the Clare Branch presided over the special session for women which was held at the Blyth Conference. Delegates were present from Sheoak Log, Clare, Auburn, Saddleworth and Wasleys. It was decided to ask that the Department of Agriculture should institute wireless lectures on items of special interest to women. Miss Campbell, of the Education Department, addressed members on the uses of pectin. The following papers were read:—

POULTRY FARMING.

[Mrs. V. A. Bowden, Sheoak Log.]

The culture of the domestic fowl has always had a great fascination for mankind. Years ago poultry keepers were more concerned about the beauty of their birds than egg production, but of recent years the latter has become a valuable industry in a number of countries, and has made rapid progress in every direction.

The first thing is to examine one's own qualifications, and consider if you are the right kind of person to adapt yourself to this kind of work. It is very important that you be fond of fowls, willing to work long hours and it cannot be too strongly emphasized to beginners to "hasten slowly." Start in a small way and increase your flock as experience is gained, as in other things you learn by your mistakes.

Choose the breed on which you intend to concentrate. For egg production alone, the White Leghorn is very popular. For egg and table purposes, the Black Orpington is suitable. For table purposes alone the Light Sussex is one of the best. Two other foremost breeds are the Black Minorca and the Rhode Island Red.

There are several recognised ways of making a start; purchasing breeding eggs, day-old chicks, pullets or breeding hens, but it is essential to success that the very best be purchased from reliable breeders. It is far better to pay a good price at the outset, than to find later that the birds are worthless.

Years ago poultry was kept in a very haphazard way, with all ages, breeds and sexes running together, but research work has proved that fowls should be properly housed, bred and fed for results. Houses should face north or east, and in this country preferably be made of iron. Every fowl should have 4 square feet of floor, and the shed should be high enough for the attendant to walk under at the back, and slope upwards towards the front, the roof extending out about 2 feet is high enough. Some sheds are built with dropping boards, and scratching litter all over the floor, but they do not allow air to circulate freely and are condemned by some on that account. Other sheds have perches at the back, and the rest of the shed partitioned off for the litter. It is also important to have suitable drinking vessels, and an adequate number of nests, which should contain shell grit. If possible build on sandy soil.

Hatching.

Hatch at the right period of the year, for heavy breeds July, August and early September; for light breeds, August, September and early October are the recognised months. Some poultry farmers rear in early autumn and others are very much against it. As a rule, autumn hatched chickens do not grow so big as the spring ones, and if one rears in the two seasons, it is impossible to spell the chick rearing sheds and runs.

The old practice of hatching with hens, is strongly condemned by all successful poultrymen. The incubator is less work and more profitable in every way. Incubators are extremely simple to operate, there being two main types, the hot air and the hot water. No hard and fast rule can be set, as the makes vary a little in operation. Before placing in the eggs see that the machine is properly regulated to obtain an even heat of 103° for about 24 hours with the thermometer on a level with the eggs. When the eggs are put in the temperature will drop considerably, but will rise again to 103° if correctly regulated. This heat should be maintained until towards the end of the period, when a shade hotter often gives better results. Some use water in the trays only the last week, others believe in it right through the hatch, and oft-times use sponges and damp the floor, &c., as well, to obtain more moisture.

The eggs should be kept turned at least twice a day until the 19th day, when the door is kept closed until the 22nd day, then all the chicks should be fit to be removed to the brooder. On the 17th day it is the usual custom to scrub the water trays and fill with clean water. The thermometer should be hung in line with the eggs. The room in which the incubator is installed should be well ventilated but free from draughs. It is also very necessary to use judgment when selecting eggs for incubation, and it is absolutely essential that all eggs be over 2ozs. in weight, and fresh. Whilst keeping for incubation, they should be turned every day and kept covered to save evaporation. Never incubate eggs that are opaque, have large pores or bands or any that have blood spots, &c. It is very wise to candle them first.

CARE OF CHICKS.

On taking chicks from the incubator the brooder should be ready to receive them. It is a bad practice to put the chickens with broody hens, which is a common habit on a number of wheat farms. There are various makes of brooders, and anyone only wishing to rear a few chicks can do so by use of flannel boxes. Some poultry farmers advocate the colony system, with a brooder house of two or three rooms, each containing a suitable brooder. At first it is necessary to supply artificial warmth by means of a heat brooder, then later by flannel brooders. The time in each generally depends on weather conditions and the time of the year. On leaving the brooder house, they are transferred to colony houses, usually with free range, or grass runs.

Do not feed the chickens for the first 24 hours, give only clean water and fine sand, then a majority of poultry farmers use No.1 chick grain. About the fourth day, give the chicks greens, lettuce or silver beet for preference. Some give chicks dry mash, and others wet mash, but they must be provided with the proper nutriments to build the bone structure. Grains and mashes are not sufficient, it is very important that they have milk in some form with plenty of greens. Bonemeal and charcoal are beneficial. Most people on wheat farms have plenty of separated milk, and this cannot be utilised in a better manner than to feed it to your chickens.

The following is the Parafield mash formula for chicks:—

	Chicks to 3 weeks.	3 to 6 weeks.	6 to 12 weeks.
Bran	3 parts	2 parts	1 part
Pollard	1 part	1 part	1 part
Buttermilk powder	5 per cent.	5 per cent.	5 per cent.
Bone meal	5 per cent.	5 per cent.	
Charcoal	5 per cent.		

Greenfeed, shell grit, charcoal and Epsom salts from 12 weeks onwards. Besides the mash the chickens require various cracked grains.

It is only within the last few years that the question of growing rations has received serious attention, but it is a mistake to force chicks, therefore it is not advisable to feed high protein rations, because instead of adult fowls of good size, they will grow into stunted culls. It is also necessary that chickens have plenty of sunlight, failing this, it is then advisable to feed Cod Liver Oil, the amount varies, but about 2 per cent. is the general rule.

CHICK DISEASES.

The dreaded diseases with young chicks are White Diarrhoea and Coccidiosis. The symptoms of White Diarrhoea are chalky pasted deposits below the vent and later severe diarrhoea, generally weak looking condition and drooping wings. The germs of this disease may be transmitted from parent to offspring through the egg. To prevent this trouble, feed plenty of milk, preferably sour.

In Coccidiosis the chicks feathers become ruffled, and they stand around with drooping wings, the droppings are of brick red or salmon colour, liver congested. If some of the chickens are opened, it will be observed that the blind pouches are filled with blood or cheesy matter. It is a common belief that minute parasites burrow into the intestinal walls and cause haemorrhages; this trouble generally occurs when the chicks are about a month old. Strict cleanliness is a prime factor in abating the disease, and again sour milk is looked upon as a corrective. Other troubles to be guarded against are Rickets or Leg Weakness. Mineral Deficiency, and Cannibalism.

Young roosters should be separated as early as possible and when the pullets are nearing production—about 5 months—this varies according to breed and time of hatching—the heavy breeds take longer to mature than the light ones—they should be put into the laying sheds. Strict culling is now essential, and success in this industry lies here, as it is very important to be able to pick the layers and market the culls.

Feeding.

A number of poultry farmers prefer to continue feeding the growing mash a while longer, gradually working in the laying one, as care must be exercised to prevent the pullets from going into a false moult. There are quite a number of formulas for laying hens, but all are divided into two sections, dry mash feeding and the other wet With dry feeding there is an undoubted saving of time, this being fed in large hoppers, often holding several days' supply of food the birds having free access to it all the day or any portion of the day that is thought necessary. In wet mash feeding, it is claimed that the birds lay considerably better and that returns in consequence are higher. As an offset against this, however, the fact has to be borne in mind that fewer hens can be attended than the case where dry mash is employed.

The following is the Parafield Laying Mash:—Bran 1 part, pollard 2 parts, and 10 per cent. of either butter milk powder or meat meal, but not both. Greenfeed is fed at the rate of 40 to 62 per cent. according to season. Shell grit and charcoal are always available in the hoppers, and Epsom salts, 1oz. to 20 birds once a week. In mixing wet mash it should be of a crumbly nature, care should be taken not to mix it too wet, as this causes diarrhoea. The usual practice is to scald the meat meal with sufficient liquid and add to the bran, then add 40 per cent. of chaffed greenfeed, and dry off with the pollard. Some poultrymen believe in using about 1 per cent. of common salt; special care must be exercised in order that it is free from lumps, or the birds are apt to get salt poisoning. Sulphur is often added to the mash at the rate of ¼lb. to 100 birds fed once a week.

The mash is the recognised morning food, and wheat in the evening, 2ozs. per bird is the required quantity. Some believe in feeding a portion of this amount at noon, together with chaffed greenfeed. It is very essential that the same system must always be employed, together with regular hours of feeding. Barley and silver beet are excellent winter greens, and undoubtedly lucerne stands on its own for the summer months. Should any hens become broody during the year or ill, ring their legs in order to exclude them from the breeding pens. In this way broodiness can be eliminated entirely from the flock, and to breed from a hen that has been ill (however good a layer) is courting disaster.

Picking the Layers.

To be successful one must have the ability to pick the layers; seek the alert, active kind, and one that is a good worker, who scatters the litter vigorously. The eyes are very important, they must be bold, bright and good sight in both; the comb should be medium in size and of fine texture, wattles and ear lobes thin and smooth. The head should be long and fenimine, with an inclination to be lean and narrow and neck fairly long. The back of the hen should be long, with broad shoulders, and a good oil valve. The pelvic bones to be fine, short and not too far apart, the breast bone thin and straight, and the skin of fine texture, with the feathers lying flat on the bird; this is known as "tightness of feather." The legs fairly long, wide apart and covered with tight fitting scales, feet with toes well spread, long and thin with curved short nails.

It is very vital in these days of low prices, to breed birds of productive qualities and in order to ascertain this, it is necessary to single test or trap nest, and the pullets treated in this way should lay at least 220 eggs in a year. These birds are then mated with a rooster, whose pedigree is already known. A great deal of importance is now attached to the ancestry of the male, as it has been shown that a hen transmits her laying qualities to her sons, who in their turn pass the same capabilities to their daughters. While high scores are essential, the general health and stamina must not be lost. Like produces like, therefore, never breed from any who are physically unfit, undersized, or any noticeable defect or broodiness.

The cockerels thus reared are mated when a year old to the hens (after being strictly culled) that have been in the laying sheds for the past year. Two years is the recognised period to keep hens for profit, occasionally those of extra good performance are kept a third year for breeding purposes.

Some believe in giving their breeding fowls free range, as they consider the chicks are stronger and eggs more fertile. The number of cockerels required varies according to breed and condition, heavy breeds requiring more than light ones. Others have small breeding pens with about 7 or 8 hens to 1 cockerel in light breeds and 5 or 6 in heavy ones. Less roosters are required when hens are on free range.

In these days of over production, we are compelled to look further than Australia for a market for surplus eggs, and all countries have eyes on Britain in this respect. For our own benefit as well as the State in general, we should only market the very best article, care in breeding to obtain only eggs of 2ozs. and over, small eggs are a menace to the industry. Eggs should be gathered 3 times daily, and kept in as cool a place as possible, marketed twice weekly during summer and once a week in winter. All eggs should be spotlessly clean, and only breeding eggs to be kept fertile, because the keeping qualities of the fertile egg are poor, and it soon deteriorates, and even when new laid is occasionally unfit for human consumption. The difference between the price of the export standard and the pulping class is so great, that it more than warrants the extra care in producing the right article.

DISEASES AND PARASITES.

It is also necessary to have a knowledge of the disease and pests one has to contend with; in the case of disease the axe is usually the best way out of the trouble.

Roup is undoubtedly one of the most common of fowl diseases. The beginning of this complaint is a cold with some fever, thin and watery discharge makes its appearance from the nasal openings, which in a few days becomes thickened, obstructing the breathing. Inflamation sets in, extending to the eyes. The eyelids swell and close, and may become stuck together; bathe with bluestone or blue bag. In severe cases the birds are a picture of dejection, practically all the head terribly swollen, the eyes contain a cheese-like matter. Some birds die within a week, others may have a chronic form and live for months; the axe is indispensable for birds in this state. However, in the early symptoms of this disease a cure may be effected; some prefer blue stone, 3ozs. to 2 gallons of water, dose, 1 cup to 1 gallon. Some recommend red oxide; dose, 1 teaspoon, permanganate of potash, oil, kerosene, eucalyptus and quite a number of chemicals are often advised. There are a number of forms of this disease. Diphtheritic Roup, Canker, Catarrh, &c.

Chicken Pox is also another fairly common complaint, the symptoms are sores over the comb and wattles, or black patches; bathe in iodine. This is really a blood complaint, and Epsom salts and sulphur are well known blood purifiers, some authorities say mosquitoes are the cause of this trouble.

Egg bound: Castor Oil should be administered at once, should this prove ineffective, steam vent over boiling water to which a few drops of Tincture of Iodine is added. If by any chance the egg should become broken in the oviduct, special care must be exercised to remove all the shell, or otherwise the pieces may cause considerable damage.

Ptomaine Poisoning is also met with when proper feeding is not adhered to. It is usually caused by eating soiled or decayed foods, unburied animals or dead fowls left lying about. The sudden appearance of several birds with paralysis of the neck, head hanging limp is a sure sign. This condition is so rapidly fatal that little can be done for the affected birds, 2 teaspoons Castor Oil or 1 of Epsom salts may be administered.

Diarrhoea is also fairly common, though not contagious. It has a serious effect on the laying flock; withhold feed for 24 hours, then dissolve 1lb. Epsom salts in water and add to the mash for 100 birds is recommended.

Protrusion is another common trouble, generally caused through an over fat condition of the hen. Death is quite often caused by other hens picking the affected one. If noticed in time and isolated, it quite often recovers, but generally has a white discharge from then onwards.

There are quite a number of other diseases found at times, but cleanliness is a wonderful preventive; all sick fowls should be isolated as soon as noticed; if they do not respond to treatment, kill or burn or bury deep. Always clean up sheds and yards and thoroughly disinfect after any outbreak.

The poultry farmer has also to contend with a number of parasites, tick being perhaps the most undesirable. These pests hide in crevices and cracks of the perches and houses during the day and visit the birds at night. They are found from the small 6-legged larva up to the adult tick with 8 legs, oval in shape with no eyes. Ticks are very tenacious of life, and have been known to live for years without being on any birds. These creatures are responsible for the disease known as "Tick Fever." Burn everything possible that is infested, a blow lamp helps considerably in abating these parasites. Waste crank case oil to paint all perches and woodwork, &c., is very beneficial, as keeping the tick in check is the only alternative.

Worms are another source of annoyance; the three main types are Round Worms, Tape Worms and Cecal Worms. The adult Round Worm is round in shape as the name implies, yellowish-white in colour, about 1 to 3 inches long. Tape Worms are flat, ribbon-like and segmented, they attach themselves to the intestines by means of little hooks on their heads. Cecal Worms are round and small—¼ to ½ inch long and are to be found in the blind pouches of the fowl. For single treatment Nema Worm Capsules are very effective; for flock treatment some recommend turpentine, others various worm remedies on the market.

The Red Mite is another blood sucker, its only food being the blood of the birds. They are not very hard to kill, but are hard to find; spray with kerosene emulsion.

The Scaly Leg Mite is only 1/100th of an inch long, and lives under the scales of the legs and feet. Sulphur and fat, or kerosene and fat should be applied and if repeated in a week, should effect a gradual cure.

Unlike Red Mite or Tick, Lice live permanently on their hosts. Occasionally they may be seen on the roosts, &c., but die in a few days for want of warmth and nourishment, if they do not return to the fowl. All fowls should be supplied with a dust bath; individual fowls can be dusted with insect powder. In the case of head lice, rub the affected birds with Castor oil or vaseline.

There are numerous other trials the poultryman has to contend with and with the low price of eggs, it will be realised that to be successful, one must be alive to every phase of the industry, careful in every detail, and adopt as many labour-saving devices as possible.

HOUSEHOLD HINTS.

[MRS. MCKENDRICK, Clare.]

The following hint will save many tedious minutes in apple paring:—When preparing apples for cooking instead of cutting the peel with a knife, pour boiling water over the apples and stand for a few minutes. The peel will then come away as thin as paper. To crack hard-shelled nuts, put them in a dish and place in a hot oven for 5 minutes. In this way the moisture is extracted from the shells, making them brittle and very easy to crack. A quick and agreeable way to clean sponges is to squeeze them in water to which has been added the juice of a lemon. A pinch of salt added to mustard will keep it fresh for several days. Mixing it with milk instead of water is a very great improvement. To remove grass stains from tennis flannels, &c., which should be done before the flannels are washed, apply a solution of equal parts of glycerine and yolk of egg. Allow to remain on the stain for 1 hour then wash in the usual way. To give glassware or crystal a brilliant polish, add a little ammonia to the water in which it is washed.

Coffee stains can be removed by soaking in glycerine. Allow to soak for several hours, then wash in lukewarm water. A small piece of butter added to the water in which vegetables are to be cooked will prevent them from boiling over. To restore discoloured

brown shoes, paint with iodine, let them dry overnight, and then polish in the usual way. Scorch marks on white silk may be removed by covering them with a little peroxide of hydrogen, then pressing with a warm iron. When sewing on hooks and eyes or press fasteners, sew on the hooks or press parts first, then rub them with soft chalk and press this to the side to which the eyes are to be sewn. The mark left will be a sure guide Fly smears on windows should be rubbed over with a little washing blue.

To remove grease stains from wicker furniture rub with a cloth dipped in methylated spirits. Flower vases that are discoloured at the bottom can be made clean and sparkling by placing a mixture of vinegar and salt in them for a time. Thin slices of cork glued firmly to the edges of chairs will prevent many scratches on the floor, and save unnecessary noise. When using fresh cream as a filling for sponges, dissolve a teaspoon of gelatine in a little warm water, beat it in with the cream and allow to set for 1 hour.

Soap rubbed along the edges of an obstinate drawer will make it run smoothly. To refresh navy-blue material, use equal parts of methylated spirits and ammonia. The mixture should be rubbed in with a piece of material of the same colour. Ink stains can be removed from linen if they are dipped in pure melted tallow, then washed in the ordinary way. The ink washes out with the tallow. Bottom crusts of fruit pies will not become sodden with juice if after lining the dish with pastry, it is brushed over with beaten white of egg. Darn stockings on the cross, instead of up and down, and the darn will wear much longer. Try a new flavour in cakes by blending lemon and almond essences. A very nice flavour is made of equal parts of vanilla and lemon essences. If it is necessary to use a sewing machine needle which has become blunt, place a sheet of medium grade sandpaper, rough side uppermost under the guide, and run the needle through it once or twice. This sharpens the needle considerably. Old gramophone needles are useful for keeping the back of pictures in place. To prevent sausages bursting, roll in flour before frying. Lamp wicks soaked in vinegar a short time before being used for the first time will give a much better light. To invisibly mend torn cotton window blinds, take a piece of the same material, dip it in hot starch, then place over the tear and press with a hot iron.

To prevent any sauces, milk, &c., from boiling over, lightly smear round the inside of the saucepan with butter. If a little vinegar is added to the final rinsing water when washing any silk articles, it will help to make them last much longer. The vinegar removes every trace of soap, which is apt to make silk rot. Instead of washing a nutmeg grater after using it, put it in a cool oven for a while, then brush lightly. This is a good hint to remember after grating lemons and oranges. Needles will not rust if they are put in a piece of chamois leather, instead of flannel. If the blades of the mincer have become blunt, sharpen them in the following easy manner:—Place several small pieces of bathbrick inside and turn the handle a few times. This will re-sharpen the knives and the bathbrick dust can easily be washed away with hot water. New calico or lace curtains should be soaked in warm water to which 2 handsful of salt have been added. To lift clothes from the copper make a few cuts with a saw around the end of the copper-stick; this will make the stick grip the clothes betted. Tomato juice removes fresh ink stains from carpets like magic. As soon as the ink is spilt cut a ripe tomato in half, rub the stain thoroughly, then wash over with a clean cloth, wrung out of warm water; repeat the process for an old stain until ink is removed. A quick way to preserve new-laid eggs is to rub them over lightly with good butter, store in usual way. Eggs preserved in this way are good for 12 months. Eggs beat up very quickly if a drop of cold water is added to them before you start beating.

It is possible to remove iodine stains from any washable fabric by soaking them in a solution of ammonia and water. Wash finally in warm soapy wter. For a successful baked custard, warm milk before adding the eggs and butter. A length of flexible rubber hose-piping makes an excellent carpet-beater, which is much better than the cane type as it does not damage the carpet. When storing dry materials, such as coffee, tea,

rice, &c., in glass jars, paste the name labels on the inside of the jars. They will not become soiled. When replacing elastic or ribbon in clothes, do not pull out the old elastic before inserting the new. Instead sew the new elastic to one end of the old, then draw out the latter by its other end, and so pull the new piece into place. If the edges of a carpet are beginning to wear, get some wool the same colour as some part of the carpet and buttonhole stitch the worn edges. A teaspoon of glycerine added to 1lb. of flour in bread and cake making, is a great improvement. Not only will the dough be better, but the bread or cake will keep fresh much longer. To keep cheese from going mouldy, rub the cut part with butter, then wrap in white paper.

Stockings that are marked with grease should be soaked in olive oil overnight, and washed the next morning in the usual way. A cork that is stuck in a bottle of polish can be easily removed if it is moistened with a few drops of oil. Glycerine will remove tea-

stains from fine tea-cloths. A quick way to remove bloodstains from articles which cannot be boiled is to make a paste of mustard and spread over the stains; then wash in warm soapy water. If a little butter is added to blanc mange, it will have a richer flavour, and an attractive gloss, when turned out. It is a good plan to wrap a piece of wool round the neck of bottles containing iodine, oil, or any similar liquid. It catches the drops and prevents stained tables and clothes. Always add a few grains of rice when making a baked custard, and it will not go watery. Next time cutting sandwiches, do not throw away the crusts. Sprinkle a little salt over them and toast in a quick oven. They are delicious served with soup.

THE FLOWER GARDEN.

[Miss V. E. Currie, Wasleys.]

In a flower garden one can spend spare time to advantage, and in course of time will bring much pleasure, and a return of flowers which will repay for work done. Practically every home can have a garden where a supply of water is available, and with very little expense the most humble home may be beautified by a garden, however small it may be.

The Lay Out.

First draw a plan of the garden that will make an appropriate setting to the front of the home, taking into consideration the amount of time at your disposal for the working of it, &c., and arrange the size of flower beds accordingly. Lawns may take up quite a large area, and will also add to the appearance. The Mail lawn needs much more attention than the Buffalo grass, though when kept well trimmed makes a very fine one, and one that is green all the year. A palm can be planted in the centre, if so desired, and for this purpose I suggest *Chamaeropes humilis*. It is of dwarf habit, not growing more than 5ft. to 6ft. in height, is of a bushy nature, and ideal for the small garden. Not only lay out the garden for small flower beds and lawns, but leave a space on one side for the planting of a few shrubs, and along with these can be planted a mixture of perennials as well as annuals. Border each bed with jarrah edging 1in. thick by 4ins. deep. Around the lawn it is advisable to have it 6ins. deep. With shallow edging the grass is likely to go under it and come up either in the flower beds or the paths.

Choose a suitable hedge for the front; it will not only enhance the appearance, but shelter the growing plants from all weather. Coprosma makes an excellent hedge for a small garden; it has bright green shining foliage, is almost dust proof, and always looks clean and bright. This hedge is very healthy, rarely dies out, and requires very little water. Plants should be staked, and allowed to grow at the top until they reach the desired height, but should be constantly clipped at the sides. The clipping assists them in making upward growth.

A few roses must be included. Plant one in the centre of each of the small beds intended for the annuals. June and July are generally the best months for planting roses; they are then at their most dormant stage, but planting can be carried on until the end of August. They thrive best in open spaces where they receive plenty of sunshine. Plants grown in shady and sheltered positions are liable to mildew and black spot. Pruning should be completed during July; if pruned too early the new growth will start and is likely to be damaged by frosts. April and May are the best months for planting shrubs, before the cold weather sets in.

Flowering Shrubs.

These are some of the most satisfactory plants grown in a garden. They give a dignity to it, and once established are very little trouble, and do not require much water. Many of them produce very beautiful flowers, and, if a careful selection is made, can be had in flower all the year round. The deciduous varieties are the most beautiful. One is the *Weigela rosea*; it is one of the most beautiful of the spring flowering shrubs, covering its branches with clusters of pale pink tubular-shaped flowers. It should be

planted in a well-sheltered position on the plains. Another is the Guelder Rose or Snow Ball Bush. This is a very handsome shrub worthy of a place in any garden, although seldom seen. When in flower the bush is covered with great balls of snow-white blooms, and makes a fine sight. All shrubs should be pruned immediately after flowering; one cannot go wrong if this practice is followed with all varieties. Most shrubs can be pruned to regulate the growth to a certain extent.

The Blue Iris Stylosa has become one of the most popular winter flowers, flowering as it does when other flowers are scarce. During April and May the long leaves should be cut back to within a couple of inches above the crown, and then given a dressing of lime to kill the slugs and snails, which are very fond of the flowers. Follow this by a watering, and this treatment will result in a wealth of bloom that make a pretty garden show. If wanted for decorating purposes, pick the blooms in the pencil stage and they will last much longer.

In April prepare beds for spring flowering annuals, and clear away summer growths. The beds should then be limed and roughly dug and sprinkled liberally with lime again. They should be left for a fortnight to be sweetened by the sun and air. This exposure of the soil in a roughly broken-up condition is most important, and without it one cannot expect good results. The use of lime can be overdone unless it be accompanied by liberal manuring. For average conditions, lime every other year. After a fortnight has elapsed water well and dig several times until the soil is broken to a nice even tilth. Then give a liberal dressing of stable manure, fork in lightly, rake evenly, and remove all lumps. The beds are then ready for the planting of young seedlings, which have been previously raised in pans or boxes.

More satisfaction is obtained in raising your own plants than buying them from the nursery. It is advantageous to be able to transplant them quickly from the seed-boxes to where they are to be grown, especially during summer, when great precaution needs to be taken only to transplant when a cool change springs up or even a dull day. After planting, water well, not overhead with a hose, but fill a bucket with water and with a dipper or watering-can pour gently around each plant. During the growing period keep the soil well cultivated. Keeping the surface loosened will encourage rapid growth. As the plants come into bloom, give them a little weak liquid manure once a week. Neutral Sulphate of Ammonia makes an excellent stimulant for this purpose, using a level teaspoon to 1gall. of water. Do not exceed this strength, and do not use it more frequently than once a week. The flowers will be much larger and of a brighter, richer colour than if it were not used. Make sure the ground is moist before applying liquid manure of any kind.

Where patches of clover exist in lawns, rub Sulphate of Ammonia well into them. It must be used in a dry state and allowed to remain dry for a few hours. It will cause the clover to turn black, and although the grass will have a scorched appearance, it will come through again without any difficulty. The clover will not reappear.

In a small garden it is easier to plant and to plan out the garden if the plants are massed. In doing this the effect will be far better than any mixed lot of flowers. Plant the mixed varieties in the border with a few shrubs. It is not suggested that in all cases only one variety should be grown in a bed, for some of the best results are secured when good contrasts of colour are effected. For example, I have planted beds of Rosy Morn Petunias edged with Blue Ageratum. These make a most brilliant show that lasted for months. I also have planted beds of Iceland Poppies and Papilio Blue Violas, and there are many other varieties that could be planted likewise.

Ranunculi and Anemones should not be overlooked, for these make a good show when planted in masses, especially Anemones, for their brilliant colouring places them in the front rank of bulbous and tuberous plants for massing, and one may obtain dozens of flowers from a single plant.

Raising Seedlings.

This is the cheapest way when a large number are wanted, and I have had good results by sowing the seed in January or February; then the plants will make a good deal of growth during the warm months of autumn and bloom early in spring. *Primula*

Malacoides is another favourite spring flower, and is very easily grown. Princess Mary was classed the best a few years ago, but now Giant Rose has proved itself to be the best variety of Malacoides yet grown.

At the end of September or beginning of October it is time to sow seed for the raising of summer annuals. Generally speaking, summer annuals are very much easier to raise from seed than many spring flowering varieties. The weather is mild and warm and seeds germinate well and quickly. Sow in shallow pans and cover seed with a light sandy loam with a little manure sprinkled on top. This will help to keep the surface from drying too quickly. The best method for watering is to place the pans of seed in a larger one, containing 3ins. to 4ins. of water, and allow them to stand until the dampness comes to the surface. There is no fear of washing fine seed, such as Petunias, etc., away. The earth will hold the moisture longer, and results will amply repay for the trouble.

During summer, hot and squally weather can be expected, so that one must consider those plants best adapted to such conditions and choose accordingly. Keep to heat-resisting plants such as Petunia, Phlox, Ageratum, Zinnia, &c. Get summer seedlings planted during the first or second week in December if possible. After planting, water well, and cover surface with a thick mulch of either stable manure or straw. It will then be only necessary to water once a week, and plants will stand up to the hottest days under such conditions. There are so many beautiful summer annuals to choose from that it should not be difficult to make the garden gay during that period. Zinnia Linaris is ideal for growing as a border to a mixed flower bed, and looks well in masses. It is a dwarf grower, having small narrow leaves. The plants cover themselves with tiny single deep orange flowers similar to small French Marigolds. The plants flower for months, and one never notices the withered blooms. *Amaranthus tricolour* grown in a mixed border makes a gorgeous show with its striking foliage in green, yellow, and crimson shades. The Miniature Sunflower is another favourite for the border, and will provide a wealth of blooms for cutting as well as a fine garden show. Zinnias are hardy, and make a brilliant show. The giant strain is particularly fine, having very large flowers. When about 6ins. high nip out the centre of plants to encourage them to branch out. This also applies to Phlox and Petunias. These should be grown in masses to get best effects. Asters are a much admired annual for their richness of colouring, beauty of form, and profusion of bloom. The Giant Crego is the finest type to be had, and looks best when grown in mixed colours. They do best in rich, deep light soil, and are much benefited by mulching with manure.

One of the prettiest ornamental grasses is the *Tricholona rosea,* that covers itself with fluffy copper-pink seedheads. It is excellent for mixing with floral decorations. November is the month for sowing the seed.

HOME DRESSMAKING.

[Mrs. M. Perry, Wasleys.]

The advantages of being your own dressmaker are that you can choose the material and just the way you want to have it made, whereas, if you buy a frock you more often than not have to take what fits you, regardless of colour and style, or otherwise you have to make it fit you after you have bought it.

The first and most important part in home dressmaking is to choose styles that will suit the figure and one that will be becoming in the material.

Very tall people should never wear stripes, they are inclined to make you look taller and if choosing a floral material for a stout figure choose a small design on a background, they are inclined to make the figure appear slimmer. Always pick a style suitable for the material you intend having. For instance, a sports style made up in an expensive material looks out of place anywhere. When choosing material for a new frock think what colour handbag and shoes you have so you will have something to tone in with them, it is too severe a contrast to have accessories not toning with the frock.

If a subscriber to any of the journals, you would very seldom have to buy a pattern, for with every journal there are free patterns given and they are always in very pleasing styles. These patterns are given in 36 inch bust measurement which is too big for most women, but are quite easily broken down to fit a small person.

When cutting out a frock from a pattern, always place it against the figure first, because even if you have obtained a pattern just the size—as they are obtainable from 32 to 40 inch bust measurement—it may not be long enough in the waist or some other detail may be wrong. The sleeves for instance, if too long or not long enough should be shortened or lengthened above or below the elbow whichever may be necessary, this keeps the elbow in place. To lengthen or shorten a skirt it should always be done below the hips.

After cutting out the frock, pin the pattern to fit it, if tacked, it may have to be done several times before getting it right. It is always wise to tack before machining as some materials will stretch. Neatness is one of the main things in dressmaking, if everything is finished off neatly, mainly the trimming, the frock will not look home made.

The best way to do kilting is to tack the little pleats first, then press over a damp cloth with a very hot iron. Frills look best cut on the bias and look very nice with edges hemstitched. I make the frills the length I require and half again; at that fullness they fall very nicely. Ruching looks best box-pleated, although it can be gathered. Soft thin material can be stitched without difficulty on the machine if a strip of paper is put underneath it to keep it firm.

THE ART OF ENTERTAINING.

[Miss J. Siebert, Wasleys.]

The first thing to consider is the type of folk to be invited. If old folk as well as young are asked, you must supply some form of amusement for them, therefore, have a couple of packs of playing cards on hand. Also see that you have enough games, musical items, and competitions arranged to keep the guests entertained. Choose an M.C. who is of a very lively nature. It is his duty to take over the responsibilities of the programme which must be prepared neatly beforehand.

If an evening party, see that the flowers are in harmony with any other form of decorations. The decorative scheme always shows up to advantage under artificial light, and is nearly always first commented on. An afternoon party calls for deeper shaded flowers than does an evening; choose flowers that do not wilt.

● FULL MOON.

Make the guests acquainted, and as each guest enters give him or her a tiny slip of paper on which the words cork, knife, fork, bottle, &c., are written. The person with cork will try and find the one holding bottle, and knife will seek fork and so on. After the partners are all found put on a game in which partners share. If competitions are started, have enough papers and pencils to go round.

Now comes the question of dress. If the party be a home one, do not choose evening dress; a light summery voile, chiffon or georgette with short sleeves looks nicest.

If there are toasts to be honoured, have a variety of drinks. A very popular fruit cocktail is made from shreds of grapefruit, juice from the fruit, and lemon juice and sugar, mixed well and iced.

Then there is the question of cigarettes. If your party consists of men as well as ladies, supply mild as well as medium "smokes." Place ashtrays in convenient places. It is the hostess's duty to light a cigarette first to signify that smoking is allowed. if she does not care to smoke herself she can extinguish her cigarette.

The most important part of all is supper. Be it set, buffet, or hand around, supper very often ends in disaster. Many a good frock is ruined by spilt tea or coffee. Be careful not to overcrowd the table with food and in the case of set, also do not overcrowd the table with guests. Have it set with space between each dish and place the cakes, &c., on stands, which look more effective and do not take up so much space. Have flowers in tall vases, or if preferred, crystal or glass bowls. Do not choose gaudy or strong-smelling blooms, but long-stemmed pastel-shaded ones, which must be arranged with a fair amount of green. Iceland Poppies are very effective, but if chosen for the table, do not forget to put a small piece of charcoal in the bottom of the vases in which they are placed. This seems to deaden the strong smell from them.

To give a festive appearance to the supper, do not forget sweets and nuts placed in dishes along the table. Devilled almonds, too, are very popular. For a party on a larger scale, trifles, jellies and salads are great favourites.

Fruit cake, biscuits and savouries too are essential. Savouries which are especially popular at bridge and cocktail parties are very nice and quite easy to make, and many folk prefer them to sweets. Cocktail Rolls are nice and dainty. They are tiny sausage rolls, seasoned with chopped parsley and other herbs, through which a tooth pick is stabbed.

Sandwiches, too, play an important part on the supper table. These must be very daintily cut and garnished with shreds of lettuce or sprigs of parsley. In addition to the usual ham and beef fillings it is wise to vary the sandwiches. There are many delicious fillings; a very popular one is minced sultanas, currants and nuts, moistened with a little milk. This is especially nice on brown bread. Another dainty summertime filling is tomato seasoned with grated cheese, salt, and a pinch of cayenne pepper. Many folks like to know the filling of the sandwiches, and the wise hostess will make little white paper flags, neatly print the name of the sandwiches on it, fix to a toothpick and stand up on the tray of sandwiches.

Recipes.

Four-in-One Biscuits.—Ingredients, ½ cup butter, 1½ cup sugar, 1 egg, 2 cups flour, ½ teaspoon salt, 2 teaspoons baking powder, ½ cup milk, almonds 1oz., chocolate, chopped nuts, cocoanut. *Method.*—Cream butter and sugar, then beat the egg in well. Add the sifted flour, baking powder and salt alternately with the milk, making a stiff dough. Have it of a consistency that it will not spread when placed in the oven. Divide mixture in 4 parts. Flavour first part with vanilla, put on baking sheet in little balls and put a blanched almond on top of each. The cooking will flatten them. Cook in a quick oven for 10 minutes, or until nicely brown. Remove from sheet as soon as they are cooked. Now take the second lot, melt the chocolate, add to the dough, spread out to about ½ inch in thickness in a square baking tin, and sprinkle top with finely-chopped nuts. Cook as for almond biscuits and cut into strips when taken out of oven. To the third section of dough, add 2 tablespoons of cocoanut, and put in square tin.

Sprinkle top with coarse cocoanut, and cook till brown. Cut into fingers when taken from oven. To the last quarter add a teaspoon of ground ginger and place in square tin. Sprinkle top with sugar and cook as above. When baked, cut into squares in tin and ice with pink water icing.

Sponge Fillings.—A mock cream made with butter, icing sugar and boiling water flavoured with mashed bananas or passion fruit is always delicious as well as popular.

Pineapple Filling.—Grate 1 cup of raw pineapple and cook in a saucepan with 1 cup of water until tender, add ½ cup sugar, and 1 teaspoon of butter and simmer for 2 minutes, then add 1 beaten egg yolk, and 1 dessertspoon of cornflour, moistened with the juice of ½ a lemon or orange. Passion fruit pulp can also be used. Cook another 2 minutes and remove from fire. Add 1 stiffly beaten egg white. When cool spread between sandwich.

Lemon Filling.—Take ¼lb. of butter, 2 small eggs, the juice of a lemon, the rind of ½ lemon, 1 oz. of butter. Put all ingredients into a saucepan and stew gently until it becomes the consistency of honey. Take off fire and allow to cool before putting in the sponge.

Banana and Jam Filling.—Mash 3 bananas with a silver fork, add 3 tablespoons of raspberry or any other kind of jam; if desired add 2 dessertspoons of fresh cream.

SAVOURY RECIPES.

Chicken and Ham Puffs.—When making these, make a double quantity, and when cold fill half with cream and the other half with this filling: Take 4 tablespoons cold minced chicken, 2 tablespoons minced ham, 1oz. butter, ¾ cup milk, I heaped dessertspoon of flour, 1 tablespoon cream, salt and pepper to taste. Melt the butter, remove from fire, add flour, blend well, using a wooden spoon, add milk by degrees, stirring well; return to fire and stir till it thickens, cook 3 minutes. Allow to cool. Stir in cream and chicken, ham, and seasoning.

Cheese Gondolas.—Bake some short pastry in boat-shaped patties. When baked, fill with this mixture: Whip some cream, flavoured with grated cheese, salt, and cayenne pepper. Sprinkle tops with grated cheese and a sprig of parsley.

Wrapped Olives.—Remove the stone from the olive by cutting spirally. Fill the cavities with a little minced ham, roll each olive in a small rasher of bacon and place in a hot oven until bacon is cooked. Serve olives with a toothpick stuck through them.

Savoury Prunes.—Soak prunes overnight, and in the morning drain and stew gently till tender. When cool split and remove the stones. Place a blanched almond in each, also a little salt, cayenne pepper, and grated cheese to flavour. Wrap each prune in thin bacon rashers, skewer them, and bake between two enamel plates in a hot oven until bacon is cooked. When ready, stick a toothpick through each and serve.

Fillings in Cream Puff Savouries.—Whipped cream seasoned with grated cheese, salt, and pepper is delicious. Brush the top of each puff with melted butter and sprinkle with grated cheese.

Minced tongue, chicken, or ham bound together with whipped cream and chutney is a delicious filling. Mashed salmon mixed with a good butter and breadcrumb sauce is another.

THE BENEFITS AND INFLUENCE OF SPORT TO THE YOUNGER GENERATION.

[Miss J. LINES, Wasleys.]

Sport is the best and most pleasant form of recreation young or old can indulge in. It is often the foundation of a young life, for through the medium of sport one becomes ambitious, alert, accurate, learns to be fair, to give and take in all things, and gener ally proves more efficient to gain success in life. Sport also keeps one young and active when advanced in years. People, although middle-aged or over, still enjoy two or three strenuous sets of tennis on an afternoon and declare that they could go on playing for years to come yet.

Some people say that sport preserves the figure; I do not think there is much hope for the tennis courts to aid slimming. One thing it does show is that the bigger girl still has the better chance in sport, and also that for small people it does help to develop the muscles and body.

Sport, while proving itself beneficial in several cases to young people, can also get such a grip on a person so that one becomes too keen, and then everything else is forgotten, and sport becomes their only ambition. There is probably more sport played at the present time than ever before, unemployment, of course, being the cause of a lot of it. It is going to be very hard on young people, especially when the time comes for them to give most of it up and return to work again after years of unemployment.

The real benefits and enjoyments of sport often result in giving most pleasure in the latter part of one's life, because when people get up in years and have any amount of spare time, what more enjoyment can they find in life than having a few hours' pleasant recreation at their favourite sport.

THE HOME LIBRARY.

[Miss JEAN DAY, Wasleys.]

The first books to be thought of for a home library are books of reference, a dictionary, encyclopaedia, and a map or good atlas. One would be very surprised to find how often people misspell, and almost everyone needs to look up a word in the dictionary now and then. Very often when a person is conversing with another he will hear some unusual word and not know the correct meaning of it. Consequently the dictionary is used and most likely that person will afterwards find himself using the word also.

The map or atlas is a book which is almost in constant use in most homes. Even the children will follow the flight of an aviator or the route of a ship, or maybe, in response to a parent's request, will find the place of the latest volcanic or political upheaval.

An encyclopaedia in the home is of great benefit to young and old. Think of the satisfaction of being able to find an answer to most of the questions that crop up, such as "Where does this or that come from?" "From which country and which part?" "Where is a certain city or river," "When and where did some great man live and why was he famous?" If there is a student in the home an encyclopaedia is indispensable.

If a member of the house has some special hobby you may be sure to find several books in their library concerning it, such as a bird book or a gardening book. Some may like to refer to a book of etiquette at times, and being able to do so may prevent embarrassment in unfamiliar situations, and it is reassuring to know how to begin and end some special letter. A medical book should find a place on the shelves; not to rely on it as a substitute for a doctor when he is necessary, but often his services may not be required and the medical book is sufficient. People who care for animals should always have the best veterinary guides, especially where advice cannot be easily obtained. The rest of the books may be novels and boys' and girls' books.

People say that girls should not be rushed into womanhood by reading trashy sentimental novels, but should read books like "Lorna Doone," "Little Women and Good Wives," or some of Ethel Turner's or Vazey's books. It is a particularly good sign in a girl when she enjoys a boy's book, and here in passing let us note how the average boy despises girls' books, and if he does read one it is usually accompanied by contemptuous snorts and sarcastic remarks.

For the boy who is growing up there is wealth indeed! "Robinson Crusoe," written 200 years ago, still interests the boys. Dickens' books and Sir Walter Scott's are typical boys' books also.

For boys and girls in their first stage of High School, Cassell's "Book of Knowledge" is recommended. A home cannot supply all the necessary books for reading, therefore a circulating library is always welcomed. The home library is not complete without some of Shakespeare's plays, and people will find they can read these many times without finding them boring.

All worth-while books broaden our minds, and help us to think for ourselves, and we find that our minds are not cold storage plants for the thoughts of others, but a powerhouse for our own.

SPONGE CAKES.

[Mrs. C. GORDON, Clare.]

Hints.—When making a sponge use eggs a few days old. Always beat eggs a few minutes before adding sugar; if eggs and sugar are put together before beating eggs the sponge when cooked often shows yellow streaks or specks. Never beat after adding flour and rising. When the eggs and sugar are ready, gradually fold in the flour a little at a time. Always sift flour for lightness. No matter how well a sponge is made it is never very attractive without a nice filling. In making sponge sandwiches the best results are obtained by using fairly high tins in baking; it gives the mixture enough room to rise. The oven will be the right heat if scones are baked properly first. It seems a good test; if they come out all right then it is ready by the addition of a very small supply of wood to bake the sponges. Line the bottom of the tins with greased paper and grease the sides with butter, preferably unsalted. When making butter keep a very small portion on one side before it is salted for greasing tins for cooking. It is not so liable to burn.

Plain flour and carbonate of soda and cream of tartar are always more successful than self-raising flour, except for sponge roll and sponge lilies. I have had great success with the self-raising flour for both of them, and have used pickled eggs as successfully as fresh, so long as the yolk is not broken when they are cracked. Do not beat any cake for 20 minutes, such as 10 minutes for eggs and 10 minutes later on. It would be a waste of time; they are eaten quicker than that. If a warm basin is used—just rinsed well with boiling water—the eggs and sugar mix very much more quickly and thoroughly, which is a most important item.

Prize Sponge.—Four eggs, 1 tablespoon cold water, 1 cup sugar (not heaped), beat well, add ¾ cup flour (good measure), 1 teaspoon cream tartar, ½ teaspoon carbonate soda, 1 heaped tablespoon cornflour.

Mock Cream Filling.—One cup milk; when boiling thicken with 1 tablespoon cornflour; set aside to cool. In a basin beat well 2 tablespoons icing sugar, 1 tablespoon of butter, then add gradually the thickened milk and essence.

Coffee Sandwich.—Three eggs, 1 cup self-raising flour, 1 cup sugar, 1 tablespoon butter melted in 4 tablespoons boiling water. Beat eggs and sugar well, then mix flour, lastly add butter melted in boiling water, stir, but do not beat. Bake in sandwich tins in moderate oven.

Filling.—One tablespoon strong coffee, as much icing sugar as it will take up 1 teaspoon butter; beat together and put between cakes.

Sponge Roll.—Six eggs, 1½ cups sugar, 1½ tablespoons water, beat well; add 1½ cups flour (level), 1½ tablespoons cornflour, 1½ teaspoons cream tartar, ½ teaspoon carbonate soda; bake 10-15 minutes. Turn out on warm damp cloth, roll up for a few seconds, then unroll and spread with jam or filling. A nice chocolate roll can be made by the previous recipe by taking out 1 tablespoon flour and replacing with cocoa and filling, being icing sugar mixed to a smooth cream with melted butter and essence.

Cake Fillings.—Two tablespoons butter, 3 tablespoons sugar, 1 egg; beat all together; add juice and rind of lemon, boil till thickens.

Cream Substitutes.—Beat well together 2 tablespoons each butter and sugar; add 1 tablespoon each milk and hot water. Beat all together for 5 minutes, add essence.

Delicious Filling.—Grate 1 cup raw pineapple and cook it in a cup of water until tender; add ½ cup sugar and 1 teaspoon butter and simmer for 2 minutes, then add a well-beaten egg yolk and 1 dessertspoon of cornflour moistened with juice of half a lemon. Cook for 2 minutes, take off, and add 1 white of egg, well-beaten. Use when cold in place of jam.

Sponge Sandwich.—Three eggs, small cup sugar. 1 cup flour, 2 teaspoons cream of tartar, 1 teaspoon carbonate of soda, 3 tablespoons warm milk beat eggs to a froth, add sugar, beat well, add flour with very little stirring. Put cream of tartar and soda in a basin, mix well, pour the warm milk over, and add to cake as quickly as possible and bake in moderate oven for 10 minutes.

Cinnamon Sponge.—¼lb. butter, ½lb. each sugar and flour, 3 eggs, 1 teaspoon soda, 2 teaspoons cream tartar, 1 tablespoon cinnamon, ½ cup milk. Cream butter and sugar, add eggs previously beaten; beat all together, sift cinnamon, cream of tartar, soda with the flour; add to the mixture; mix with the milk. Bake in sandwich tins in bottom of the oven ½ hour.

Butter Sponge.—Six ounces sugar, essence lemon, ½ pint milk, 3ozs. butter, 2 eggs, 1lb. flour, 1 teaspoon baking powder; cream butter and sugar lightly, add essence, beat in eggs singly, stir in milk, sift flour with baking powder and mix all thoroughly. Bake in moderate oven.

Three-Minute Sponge.—1 cup flour (level), pinch salt, 1 level cup sugar, 3 eggs, 2 tablespoons melted butter, 3 tablespoons milk, 2 teaspoons cream tartar, 1 teaspoon carb. soda. Put all ingredients in a basin in the order given, then beat vigorously for about 3 minutes. If it seems stiff, add 1 tablespoon cold water. Bake ½ hour in moderate oven.

Sponge Roll.—Two eggs, 2ozs. each sugar and S.R. Flour. Beat eggs and sugar to a froth. Sieve flour, add to the mixture very lightly. Spread the mixture in a flat tin and bake in a quick oven for 10 minutes. Turn out on damp cloth. Spread with warm jam. Fold twice.

Sponge.—Four eggs, pinch of salt, beat for 2 minutes. Add 1 cup of sugar, beat 10 minutes. Fold in 1 heaped cup of plain flour with 1 teaspoon cream tartar, ½ teaspoon carb. soda; lastly add 1 cup milk. Bake 25 minutes.

Sponge Lilies.—1 teacup sugar, 1 teacup S.R. flour, 3 eggs. Beat yolks of eggs until white and creamy, whip egg white to a stiff froth, then beat well with yolks and sugar. Sift flour and stir lightly into mixture. Drop dessertspoonful on a greased slide, allow

room to spread. Bake until a pale brown in a fairly hot oven. Do not allow them to become crisp or they will not roll. Remove the cakes quickly, one at a time, from the slide and while still hot twist into the shape of a lily. When cold, fill with sweetened whipped cream and put a small piece of jelly, preferably red, that has been made very stiffly, in the centre of the cream. When these are taken from the slide they cool very quickly, almost before you can roll them unless you have some one to help. By covering them with a slightly damp towel or cloth they keep soft until you can get them rolled.

TOMATO GROWING.

[MRS. GARRETT, Saddleworth.]

Seed should be sown in hot bed early in the season from April to June or in pots in a warm window facing the north. They should be started early and forced as rapidly as possible, whether by hot bed or open air culture. When about 2 inches high, they should be transplanted in single plants into warm, light, rich soil. It is a good plan to use a sprinkling of sulphate of ammonia in the ground for each plant. Water freely at the time of transplanting and shelter from the sun a few days or until well established. Also protect from frost in spring. A good plan is to cut old kerosene or petrol tins and cover at night. Train upon trelliswork or support by driving sticks into the ground and tying to them; they should also be pruned as they grow up on the trellis.

Of late years tomato production has become considerably reduced by "Spotted Wilt." The only cure known for this disease when noticed is to uproot the plants and burn them. One can usually tell when the plants become affected as the leaf becomes curly and the plants do not thrive. The fruit of a sick plant becomes striped and speckled; has no flavour, and consequently is unfit for use.

An early variety and good bearer is "Excelsior," the fruit being large and round, solid, and of good flavour. There are many other good varieties, which should be selected according to climatic conditions.

RECIPES.

Tomato Sauce.—12lbs. tomatoes, 1lb. each of apples, onions, and sugar, ¼lb. salt, 1oz. garlic and allspice, ¼oz. each of chillies, mace, and cloves, ½oz. curry powder, 1 quart of spiced vinegar. Wipe tomatoes, peel apples and onions, and cut garlic. Boil all together for 3 hours, then strain and bottle. If liked hot add teaspoon cayenne pepper.

BREAKFAST DISHES.

Tomato in Batter.—1 egg, ½ cup milk, flour, mix together, slice tomato and dip in batter and fry.

Onion and Tomato.—Slice and fry. Serve on toast.

Fry tomatoes in a little fat and their own gravy. Beat up one or two eggs, add pinch sugar and stir in. Serve on toast.

Tomato Relish.—6lbs. tomatoes peeled and sprinkled with salt overnight. Also 2 large onions cut and sprinkled with salt overnight. Strain off the water and add 1lb. white sugar, ½oz. cloves, 2ozs. bruised ginger in muslin bag, 1 teaspoon (level) cayenne pepper, 1½ bottles white vinegar. Boil all together 1 hour.

Tomato Sauce.—Take 12lbs. tomatoes, ¾lb. salt, ½oz. garlic, 1oz. bruised ginger, ½oz. cloves, ½oz. mace. Take the stalks from tomatoes, and put the whole into a copper or porcelain pan without covering. Beat the whole mass through a hair sieve if the seeds are objected to; if there be no objection to the seeds, beat through a colander. Pass the liquid through the sieve several times until the consistency of cream; then pour over the refuse 1½ pints of vinegar and beat the other liquid. Return the whole into preserving pan and add ½ teaspoon of cayenne. Stand over fire until it comes to the boil. Skim and let stand until cold, when it will be ready for bottling.

Tomato Relish.—6lbs. tomatoes (not too ripe), 3 or 4 large onions, 1lb. golden syrup, ½oz. whole cloves, 1 teaspoon whole white pepper, 1 bottle white vinegar, 2ozs. whole ginger (bruised). Cut tomatoes and onions into slices, place in a pan, and sprinkle freely with salt. Stand all night. Next morning drain off liquid and put ingredients in muslin bag before adding. Boil for 1½ hours.

Mock Raspberry Jam.—6lbs. tomatoes, 1 bottle essence raspberry, 6lbs. sugar. Remove any stems and peel tomatoes (by placing into hot water). Then slice and cover with sugar. Boil until some will jelly when put on a plate to cool (about 2 hours). Take off fire and add raspberry essence, and mix well. Bottle when cool.

Tomato Chutney.—4lbs. ripe tomatoes, 1lb. each apples, onions and sugar, 1 pint vinegar, 1oz. each salt, allspice, and pepper (whole). Boil ½ hour to 1 hour.

Tomato Sauce.—18lbs. tomatoes, 1½lbs. each apples and onions, 2ozs. garlic, ½lb. salt, 1 teaspoon each of mace, cloves, ginger, little cayenne pepper if liked, 1½lbs. sugar, 1lb. golden syrup, 3 pints vinegar. Cut up tomatoes and apples without peeling, put all other ingredients in stewpan and boil slowly about 4 hours. Then mash through colander. When cool stir well and bottle. If too thin boil a little more. If too thick, add a little vinegar.

Tomato Chutney.—12lbs. ripe tomatoes, 2lbs. sugar, ¼oz. cayenne pepper, 2 tablespoons salt, 2 pints vinegar, ½oz. cloves, 12 large apples, 2 large onions, 4ozs., garlic, ½lb. each currants and sultanas. Chop garlic, tie in bag with cloves and ginger; pour boiling water on the tomatoes and skin them. Peel and slice apples, chop rather finely. Boil all together for 3 hours or until thick.

TOMATOES AND THEIR USES.

[Mrs. J. W. Mullen, Wasleys.]

Tomatoes are used extensively in every home and can be used in numerous ways. For the hot days their use as a salad ingredient cannot be excelled. Mixed with lettuce, 2 or 3 tomatoes sliced and mixed with finely shredded lettuce make a very nice dish with mayonnaise salad dressing poured over it. Tomatoes are also nice if used as a garnish only for lettuce salads. Tomatoes are used extensively for sandwiches; many a child's and farm man's lunch is made appetising on a hot summer day by their addition. For a breakfast dish many an appetising meal can be made. Tomatoes are also used as a vegetable, also for soups, sauces, chutney, pickles, and jam.

Recipes.

Tomato, Cucumber, and Onion Salad.—Four large tomatoes, 1 medium size cucumber, 2 onions, 1 cup vinegar, 1 tablespoon sugar, ½ teaspoon salt and a little pepper.

Tomato Salad.—Peel and slice 12 medium-size tomatoes and pour over a dressing made with the following ingredients:—1 cup cream, 2 teaspoons Worcester sauce, 3 tablespoons vinegar, 2 tablespoons sugar, and little salt and pepper to taste.

Tomato Omelette.—To each egg used add the following:—1 tablespoon breadcrumbs, 1desertspoon milk, 1 tablespoon peeled and chopped tomato, pepper and salt to taste. Fry in hot fat.

Tomatoes on Toast.—Peel some tomatoes, put in saucepan or fryingpan with 2 thinly sliced onions, a piece of butter the size of a walnut, ½ teaspoon salt and little pepper. Stew in their own liquid until cooked, then add a pinch of carbonate soda and a teaspoon sugar. Thicken with a little cornflour and serve on hot buttered toast.

Fried Tomatoes.—Peel and cut in halves some tomatoes, sprinkle with salt and pepper, dip in egg and then in breadcrumbs. Fry in very hot fat.

Baked Tomatoes.—Peel and cut in halves some tomatoes and onions. Butter a piedish. Put a layer of tomatoes and then a thin layer of sliced onions. Last layer to be of tomatoes sprinkled with a little salt and pepper. Sprinkle breadcrumbs over top and put little bits of butter over it. Bake in oven ½ to ¾ of an hour.

Tomato and Meat Au Gratin.—Cut slices of cold cooked meat, place in a well-buttered piedish with a little minced parsley, onion, and breadcrumbs, pepper and salt. Put in a layer of tomatoes, then more seasoning, then meat. Cover with breadcrumbs and bits of butter and bake ¾ hour or longer.

Mutton and Tomato Pie.—1lb. loin chops, 4 tomatoes, 3 tablespoons breadcrumbs, 1oz. butter and a small slice of onion, pepper, and salt. Cut chops quite small and trim them. Butter a piedish and put in some crumbs, then slices of tomato, chops, and seasoning and another layer of tomato. Sprinkle breadcrumbs on top and bake from ½ to 1 hour.

Tomato Soup.—Take 12 tomatoes, 1 quart of milk, 2ozs. butter, a little carbonate soda, salt and pepper to taste. Cut up tomatoes, stew 20 minutes in their own liquid, throw in soda, and strain through a colander into milk and other ingredients which should have been boiled and thickened with cornflour. The soup must not boil after tomatoes are put in or it will curdle.

Ripe Tomato Chutney (1).—4lbs. ripe tomatoes, 1lb. each apples, onions, and sugar, 1 pint vinegar, 1oz. each salt, peppercorns, and allspice. Boil till thick enough.

Tomato Chutney (2).—4lbs. each tomatoes and apples, 2lbs onions, 2 teaspoons each whole spice, cloves, pepper and ground ginger, 2 tablespoons salt, 2 cups brown sugar, 3 pints vinegar; boil 3 hours.

Green Tomato Relish.—6lbs. green tomatoes, 2 large onions, 1 cup treacle, 2 bottles vinegar, ¼oz. cloves, 2ozs. whole ginger, 1 small teaspoon cayenne. Peel and slice tomatoes and onions and put them in an enamel dish, sprinkle with plenty of salt, and leave overnight. Pour off liquid. Place all ingredients in stewpan and boil one hour. Tie ginger and cloves in muslin bag.

Tomato Sauce.—25lbs. tomatoes, pulp by boiling rapidly until quite soft. No water should be added, but the tomatoes should be slightly crushed to commence the boiling. Pass the pulp through a sieve which will retain only the seeds and skins, then measure the strained pulp, and to each gallon of this allow 4ozs. salt, 1½lbs. sugar, 1½ozs. garlic, 1oz. each wholespice and cloves, 1 tablespoon mustard, ½ teaspoon cayenne, 1 quart vinegar. Boil sauce until of a right consistency. Acetic acid may be used instead of vinegar, but must be added after sauce has been removed from the fire. For this quantity of tomatoes use 5ozs. I have made this for a number of years with success.

Tomato and Raspberry Jam.—6lbs. each tomatoes and raspberries, 9lbs. sugar, juice of 2 lemons. Boil for 1 hour. This is a very good way in which to make raspberries, which are usually dear in price, go further.

THE USE OF LEMONS IN THE HOME.

[Mrs. W. MILLER, Clare.]

What drink is nicer in summer than a cold lemon squash and in winter a hot lemon drink? With two aspros added it is very good to break up a cold. The juice of 3 lemons, undiluted, and without sugar will generally stop vomiting.

Lemon juice in hot coffee will relieve a headache. Equal parts of lemon juice and glycerine are excellent if taken for an irritating cough. Before squeezing lemons place them in the oven for a few minutes, and you will get twice as much juice. When aluminium pans become black and dull, clean them with a soft cloth dipped in lemon juice, and rinse in warm water. To freshen stale vegetables soak them for one hour in cold water in which the juice of a lemon has been added. When cooking prunes add the juice and rind of half a lemon. To remove iron rust quickly and easily from any material, invert a medium-heated iron, place on it the stained fabric, and gradually squeeze the juice of the lemon on the stain. The mark will be carried away by the steam.

For removing verdigris from a copper, lemon juice is excellent. A few drops of lemon juice on the tooth brush will keep the teeth perfectly white. Slice 3 or 4 lemons and put in the bath water till the juice is extracted; they impart a delightful sense of freshness and cleanliness to the skin.

Lemon juice makes an excellent substitute for shoe polish. A few drops rubbed briskly on black or brown shoes imparts a brilliant sheen. Half a teaspoon of lemon juice added to the water when making puff pastry makes it light and fluffy. A little strained lemon juice added to the water when mixing icing will keep it soft for some time. The juice of a lemon added to the blue rinsing water when washing white silk will keep the silk pure white instead of turning yellow. A few drops of lemon juice added to the water used for rinsing the hair will make it both glossy and fluffy. Equal parts of lemon juice and milk mixed together make an excellent lotion which can be used to improve the colour of a dark-coloured neck. The same lotion can be used with pleasing results to remedy red hands.

Stains on the hands can be removed by rubbing with lemon juice. Lemon peel thoroughly dried and ground to coarse powder is very good for flavouring biscuits, small cakes and puddings. Lemons can be made into very nice marmalade, jelly and many different kinds of jam may be improved by adding lemons or juice of lemons. Lemons keep much better if put in a string bag and hung in a cool airy place or wrapped in tissue paper and kept in a crock of dry sand.

Candied Peel.—Save the skins of lemons. Soak in salted water for 3 or 4 days. Drain and boil in clean water until soft. Test with a skewer. Make a syrup by boiling 2 cups of sugar with 1 cup of water for 5 minutes. Put the peel in a basin, pour the syrup over it. Stand for 4 or 5 days; then strain off the syrup and boil it. Next, put the peel into the boiling syrup and boil until clear—about 15 or 20 minutes. Then spread the peel on a dish, put a little syrup in each. Sprinkle with sugar and dry in a cool oven or in the sunshine.

USES OF COLD MEATS.

[Mrs. J. C. Dux, Clare.]

When there is only a very small piece of meat of any kind, mince it and make a batter as for pancakes, put the mince in the batter, season to taste, drop spoonful of the mixture into a pan of hot dripping, fry a nice brown. This makes a good breakfast dish, especially with fried left-over vegetables.

With cold mutton make the following dish for dinner or tea:—Prepare vegetables, chiefly potatoes and onions, then carrots, turnips, parsnips and marrow. Use a casserole, or any deep dish with a lid or one piedish covered with another to keep in the steam. Lay sliced potatoes in the bottom of the dish, also on the sides, then a layer of sliced mutton or vegetables, repeat, until the dish is full, finishing with the sliced potatoes. Add tomato or parsley to make it tasty. This is an easy dish to prepare as it needs no watching. Use any gravy that is left, if not, use a little water, put it in the oven and bake from 1½ hours to 2 hours, according to size.

Dip slices of cold mutton, veal or any lean meat in a batter, as for fish and fry a nice brown. If a very small piece of cold meat, and it is desired to make it go a long way, mince it, add a chopped onion and seasoning to taste, make a scone mixture, roll out, cut into rounds, place a spoonful of meat in each round, roll in the shape of a dumpling and either bake, boil or fry it. Cold meats of any kind can be treated still in another way. Fry 2 or 3 onions a nice brown, take them and put aside. In the same dripping put what meat you have, cut into small dice or cubes, removing all fat and gristle, fry a nice brown, adding seasoning, then drain all dripping off, add browned onions, gravy, hot water and tomato sauce, simmer a few minutes and then thicken.

Corned lean meat can be made into a salad, cut into dice, add chopped onion, pepper, salt and vinegar to taste; just before serving add some cream. I often curry cold meat by simply adding curry to the flour when thickening an ordinary hash. Cold minced mutton mixed with tomato sauce makes nice sandwiches.

THE BENEFITS OF SOCIAL AFTERNOONS.

[Mrs. A. Page, Clare.]

One of the chief benefits derived from the meeting together of ladies in the afternoons is that it takes them away for a time, from their homes, and gives them an opportunity to meet together for social intercourse. Most women love their homes and take pleasure in home duties, but there is a time when one needs relaxation from the daily round, which, if it is not relieved, would be in danger of becoming dull and almost drudgery. Usually the most convenient time to meet is the afternoon, when domestic duties of the morning are over, and before the preparation of the evening meal. Some room should be selected for the meeting place, which is sufficiently large for the purpose, but not too roomy for the number of the company. Care should be taken to make the room comfortable, cosy in winter, and cool and airy in summer. Some care can reasonably be taken with the decorations so that a tasty and attractive appearance is given to the room which is to serve the purpose for the time being, at least, of a collective drawing-room.

The essence of these social afternoons is fellowship, for, unless every person in the room is made to feel "at home," the purpose of the gathering will not have been entirely met. Naturally the responsibility for this social atmosphere will rest upon the leader or the convenor of the meeting, or upon the persons who have been chosen to perform these special duties, but there is a part to be played by each lady, and everyone can contribute to the success or otherwise of these social afternoon gatherings. It is recognised that there are some people who have more social gifts, or are what is sometimes called, better "mixers" than others, and it is an opportunity for them to use their gifts to create a good social atmosphere and to make their more retiring neighbours feel perfectly at ease.

The aim should be to cause a pleasant impression to be formed by those who may attend the gathering for the first time, so that they wish to come again. While the primary object of the social afternoon should be fellowship, it should not be overlooked that it also affords an opportunity for instruction and the gaining of useful knowledge.

There are always some people who have specialized upon certain branches of knowledge. They should be encouraged to come forward and give their less informed sisters the benefit of their special knowledge. This may not be found easy, for there are many people who are efficient and capable of doing things, but cannot always put their knowledge into words, especially before a company of people. There are people whom we need who can talk in a most interesting and descriptive way about their travels, and yet if a suggestion is made to them to speak at "an afternoon" they immediately say, "No, I could not possibly speak in public."

Some people may think that they have no gifts as a public speaker, but they should be encouraged to make a beginning. In this manner a retiring lady may be brought out and thus bring pleasure and profit to others and indirectly to herself. There is also an opportunity given for a lady who has gifts as an entertainer. There are some who have the gift of music, and skilled performers. Possibly when they learned music they

had little idea of using their gifts in any place beyond the borders of their own home, but it should be remembered that the social afternoon room is for the time being a "collective home" and the pleasure that is given to the inmates of the home may well be given to the company assembled in the social room.

The essential purpose in these afternoon gatherings is to develop the art of profitable and entertaining conversation. Some may say that the power to converse is a gift, and cannot be cultivated, but experience has proved that this is not so. The more one practises the art of expressing thoughts and opinions and placing them into correct and suitable words, the more readily will the gift be exercised. There are those, however, who have not much brilliancy in expression and have no great command of words, but they are able to tell news in a kindly way. Everyone likes a person who tells something that he did not know, and is glad to know, and they are very welcome at a social gathering and can make a dull afternoon something very much more interesting.

It is a custom of modern times that a meeting—especially of ladies—should not close without afternoon tea. This may be regarded by some as an unnecessary feature of the afternoon and some may not care to indulge. Yet it appears essential that some form of hospitality should be offered and this appears to be the most fitting form for it to take. It creates an opportunity for more intimate conversation than can be indulged in during the meeting, and can be profitably used by the ladies as an opportunity of "getting to know one another." The serving of the tea itself is an art, and may well be regarded as an expression of true hospitality coupled with refinement. It would be wise if a reasonable amount of restraint is observed in the matter of provisions and anything like extravagance should be avoided. The key-note of hospitality should be tastefulness and daintiness and a perfect meeting can be brought to a fitting conclusion by a perfect tea.

These meetings should not be extended for an excessive length of time. Some ladies have more pressing duties than others, and it is not fitting that they should be compelled to hurry away before the meeting is concluded. At the same time, a warning note might be struck against that restlessness which is so characteristic of modern times. If a lady feels that she has not time to settle down to the afternoon meeting of the Bureau, she would be far wiser to send an apology. One should never crowd several engagements into an afternoon. This destroys pleasure, as well as being discourteous.

The ideal "afternoon" is one where the time flits by without being noticed, and where the impression left is so distinctly pleasing that there is a keen desire to come again.

MILLICENT (Average annual rainfall, 27.79in.).

February 15th.—Attendance: 9.

USEFUL HINTS.—Miss K. Hutchesson gave the following:—Sprinkle the top of the stove with salt before frying and grease will not mark the stove, nor will there be any smell of burning. Before cleaning the stove rub it over with turpentine. Mix blacklead with cold tea instead of water. If the stove has a dull appearance, clean with a good polish, then rub over with furniture polish. New tinware should be rubbed over with fresh lard and then thoroughly heated in the oven before using. Sprinkle a few tablespoons of salt over the fire after it is made up and it will keep going for hours without any further attention. To skin almonds, first soak them in hot water. Hard boiled eggs placed in cold water will shell easily. Tomatoes plunged into boiling water for a few minutes peel easily and without waste. Raisins will stone readily if warmed slightly, and candied peel should always be placed in the oven before being sliced. Grease the bottom of the saucepan before cooking and it will save much work when washing up. Add a little water to the saucepan and place it on the stove after the meat has been served; it will be almost clean when ready for washing. After cooking jam, soak the utensils in cold water; they will then need very little washing. If roasting poultry in a gas oven, put water into the meat tin at the bottom of the stove; this will obviate continual basting. Add a little soda to the water in which potatoes are soaked before cooking and the skins will be scraped off more easily. Flour the tins in which cakes and buns are to be cooked instead of using grease. The cakes will not stick if this is done. Window curtains can be taken from the line half dry and hung in position, then they will require no ironing and will fall smoothly into position. On a windy washing-day sheets and blankets wrap over the line. To stop this, place 3 or 4 spring pegs on the bottom of the clothes. Keep a magnet in the sewing basket to pick up any needles that drop on to the floor. Thread needles before cutting the thread from the reel; make the knot at the freshly cut end and there will be no trouble with knots.

MONARTO SOUTH (Average annual rainfall, 14 to 15in.).

February 16th.—Attendance: 10.

GERMAN COFFEE CAKE AND BERLIN PANCAKES.—Mrs. C. Altmann read the following paper:—Good ingredients, good yeast and a reliable oven are the first essentials in making these recipes. It is a mistake to be continually uncovering the dough. An old eiderdown or a large feather pillow is ideal for keeping the dough warm. If covered and kept in a warm place in the kitchen the dough will take about 3 hours to rise, providing that the sponge has been set for a few hours before. A good plan is to mix it the night before, then it can be made early next morning. Have all ingredients warm, also the flour, and mix the eggs with warm milk. *Recipe for Yeast*—½lb. potatoes, 1 pint water, ½ teaspoon salt, 1 tablespoon hops, 2 tablespoons sugar. Peel and cut up the potatoes and put into saucepan with salt and water. Boil until the potatoes are done. Put the hops in a basin and pour boiling water with the potatoes over the top. Cover with a plate and when cool put all through a sieve. Add the sugar and stir well. Put into a bottle and stand in a warm place. If there is a little yeast in the bottle to start it, it will be ready next morning. Another good hint is instead of throwing away the water in which the potatoes have been boiled for dinner, pour it over the hops and add some of the potatoes. *German Coffee Cake.*—4lbs. flour, 1lb. of butter or butter and lard mixed, 1lb. sugar, 1 quart sweet milk, 4 eggs, 1 teaspoon each mace and essence of lemon, 1 tablespoon salt and the bottle of yeast. If dripping is used, add the juice of ½ a lemon. *To set the Sponge.*—Beat the eggs and half the sugar. Add the yeast and enough flour to make a stiff batter, cover with a plate and put in a warm place for two or three hours to rise. Meanwhile put the rest of the flour into a large dish in which the dough is to be mixed. Make a well in the centre, add the sugar, salt and mace and the essence of lemon to the butter. When the sponge has risen, add to it the flour, also the warmed butter and milk. Mix all together with the hands and then beat for several minutes with the hands. Should the dough become cold, place it in the oven to rise again after covering it with a rug. When the dough again rises to the right size, it is ready to put into the tins, which should be well greased. Melt a little butter, and butter the hands, take out a portion of the dough and flatten it out on to the tins as evenly as possible. Place it in the oven for a few minutes to warm and cover again with rug. Then set it aside for about 1½ hours and while it is rising, prepare the top in the following manner:—2½ cups flour, 2 cups sugar, ½lb. butter and a little ground nutmeg or cinnamon. Rub the butter and sugar together, then add the flour and rub until crumbly. Another top is made by adding the yolks of 2 eggs and 6ozs. of butter. Fruit may also be used on top; plums or apricots cut in halves and pressed into the top of the cake top side up and then covered with sugar. Finally bake in a fairly hot oven for 15 to 20 minutes. *Berlin Pancakes.*—2lbs. flour, ¾lb. sugar, 6ozs. butter, 1 cup sweet milk, 3 eggs, ½ teaspoon ground mace, little essence of lemon, 1 dessertspoon salt and ¾ pint of yeast. Mix in the same way as the coffee cake. When it rises to its normal size, take small pieces of dough and form into small buns, put on to a baking sheet, then put away to rise for 1½ hours. These pancakes are cooked in hot fat. While they are rising, get the fat ready in a deep pan, lard is best but dripping will do. About 1½lbs. to 2 lbs. are needed. When the cakes have risen, put as many as the pan will hold into the hot fat and cook until a nice brown on both sides. Try with a skewer. Drain on brown paper and when cold roll in castor sugar. If it is desired to put jam in the cakes, flatten them when the buns are being formed, and place a teaspoon of jam between 2 cakes and pinch them together. (Secretary: Mrs. F. Liebelt.)

PENOLA (Average annual rainfall, 26.01in.).

February 6th.—Attendance: 56.

The February meeting took the form of a Dark Cake Competition, and the judge (Mrs. B. Black) made the following awards:—First prize, Miss R. Hill; second, Mrs. C. Neilson; third, Mrs. B. McDonald. Mrs. R. Rymill gave an interesting talk on the "Penola" and its equipment for the Antarctic Expedition. (Secretary, Mrs. Edith Kidman.)

WASLEYS.

March 7th.—Attendance: 30.

The following papers were read and discussed:—"The Benefits and Influence of Sport," Miss J. Lines; "Home Dressmaking," Miss M. Perry; "Literature in the Home," Miss J. Day; and "The Art of Entertaining," Miss J. Siebert. (*These papers will be published in the report of the Lower North Conference.*) (Secretary: Miss J. Braun.)

WILLIAMSTOWN (Average annual rainfall, 27.77in.).
February 6th.—Attendance: 8.

USEFUL HINTS.—Mrs. Johnston gave the following:—An eiderdown placed between two blankets instead of on top of the bed will give double warmth, and in the case of a restless sleeper is not so likely to slip off. A thin coat of varnish applied to straw matting will add greatly to its durability. Footmarks will not show on polished floors if the turpentine and beeswax are mixed with a small quantity of linseed oil. Keep a piece of strong brown paper folded about four times under the door mat. This will keep grit from working through and damaging the linoleum or flooring. When cleaning a grate, make a cloth and rub soot from the back of the grate or flues on all the greasy parts before black leading. This removes all grease and produces a brilliant polish. To remove paint stains from glass, rub the stains with a cloth wrung out in hot vinegar. Equal quantities of white pepper and powdered alum dusted on the bookshelf will keep silverfish, borers, and other pests away. Two or three slices of pineapple eaten first thing in the morning is a good aid to reducing weight. Raw meat sprinkled with sugar is a never-failing bait for a mousetrap. A good recipe for a whooping cough mixture:—Steep ½ cup of minced garlic in ½ cup of good rum and rub the soles of the feet, palms of the hands, armpits, chest, and back with the liquid night and morning. If the cough is troublesome and frequent, give 3 or 4 drops of the mixture on a teaspoon of sugar occasionally. (Secretary, Mrs. A. Cundy.)

WIRRABARA (Average annual rainfall, 19.29in.).
21st February.—Attendance: 31.

The monthly meeting was held at the residence of Mrs. A. Watt, who invited members to inspect articles of interest about her home. A large hessian tabelcover was shown, which Mrs. Watt had made from four sugar bags, joined together and cornered with pieces of cretonne. Another very attractive article was a deck chair cushion made from cretonne and filled with wood wool. Several hooked rugs were admired, and Mrs. Watt gave a demonstration of the stitches. The well equipped pantry with well stocked shelves of jams, pickles, preserves, &c., gave evidence of good home management. The shade house contained a fine collection of ferns and pot plants. The washhouse, with cement troughs, copper and troughs fitted with taps and drain pipes to carry away the water, showed thoughtfulness for the womenfolk of the household. (Secretary, Mrs. A. Curtis.)

GARDENING NOTES.

[Paper read by Mrs. H. Miles at the October meeting of the Kybybolite Women's Branch.]

September and early October are the busiest months of the year in the garden. In the vegetable garden as much ground as possible should be sown to ensure having summer and autumn supplies, and the chief varieties recommended for sowing and planting at this time are—beans, of which the last sowing of broad beans should be made early in the month, and then a little later on the first sowing of French and butter beans can be made in warm situations, and at the same time make a sowing of climbing varieties of beans. It is advisable to plant these alongside a fence. This will greatly assist the staking, and will also help to protect them from strong winds.

It is also a good time to sow broccoli and cabbage, the best varieties being Burpees, Succession, and Drumhead; and cauliflowers, Eclipse, Autumn Grant, Phenomenal are the best for summer planting.

For the best results with beet, grow Crimson Globe Egyptian rooted or Obelisk, and do not forget to sow a little silver beet for summer greens. For carrots, the Early Scarlet Shorthorn and Manchester Noble, Oxheart, and James Scarlet Intermediate are the best varieties, September is the best month to sow Parsnips, a much better germination can be expected of all varieties. Hollow Crown and Student are the best. Lettuce are essential for salads, &c. Iceberg, Neopolitan and Webbs Wonderful will give the quickest and best results. Small sowings of White Stone Turnips and Swedes are advisable, and, for those who are partial to radish, Long Red, White Icicle or Turnip Rooted are best. The best varieties of Peas for main crop sowing are Greenfeast, and for later, Yorkshire Hero. A small plot of Parsley is useful in the garden; Triple Curl Leaf is the best.

The seed for early potaties should be sown in October, for light soils, Red Skins varieties; the White Skinned varieties generally give best results.

Early sowings of Cucumbers, Melon, Pumpkins and Marrows, can also be made in October. In colder districts, a hot frame is necessary, but in the warmer parts, they may be planted in the open. With Cucumbers, there is the choice of a number of varieties, the foremost being Crystal Apple, Apple Shape, White Spine, Short Prickly and Marrow. The Bush varieties can be recommended. They yield almost as well per plant as the trailing varieties, and only need at the most a quarter of the space.

Jerusalem Artichokes are worth a space in any garden, to some it is necessary to acquire the taste for them, but they are an excellent standby for a variation in the vegetable menu. The home gardener must give consideration to what is best to grow when space is limited. Undoubtedly the great majority of amateur gardeners grow the vegetables they are most partial to, and where pounds, shillings, and pence do not enter into the matter, this is the correct policy to follow, but when the garden is small, it is surely more profitable to concentrate on those varieties from which the biggest returns may be had, and this will include all quick maturing crops, so that the ground may be cropped at least twice during the season; when one's area is not limited, and help can be had, there is no necessity to consider which crops to grow, and what to leave out. In considering the most profitable vegetables for the small garden, commence with root crops, which usually constitute the first sowings, Early Beets, Carrots and Parsnips must find a space. They are useful and need not necessarily occupy much room. French and Butter beans usually can be relied on to do well under average conditions, and are profitable crops for a small garden. Choose stringless varieties, and successive sowings should be the rule—sow a few rows at a time at intervals of 2 weeks, and thus have a regular supply during the entire season.

Tomatoes must be included in this list, even if only a dozen plants, this number will give sufficient fruit for a small family, budded and carefully tended, each plant may produce up to 10lbs. of good tomatoes during the season. Lettuce requires plenty of moisture to make good firm hearts, and if the seed is sown where it is to remain, and the young plants thinned out, they are not so liable to run to seed. Although it takes slightly more room than the ordinary vegetable, space should be kept for the Apple Shaped varieties of Cucumber. They are small and round with fine white flesh, and sweet flavour. They are very early and productive and more digestible than other varieties.

Peas if pulled at the right stage are not surpassed by any other vegetable. The Dwarf varieties should be grown. The yield and size of pod and pea, equal any of the tall varieties and they are heavy croppers. By growing Dwarf Peas, the labour of staking the rows is unnecessary, and they can be grown in rows with little more than 18 inches between the rows. For an effective show, plant against fences the Scarlet Runner and White Monarch Beans, which are unequalled, but early sowing is not advisable as the flowers fall off and very few beans set, It is better to delay sowings until the end of November for successful crops.

The growing of Tomatoes from seed requires a certain amount of detail. The Tomato plant should be stocky and sturdy when planted out. Perfect plants can be grown from seed in a few weeks. In a mild, hot bed, the seed germinates in a few days, When sowing seed, the compost should be a light, sandy texture and seed sown thinly, for if too crowded, they damp off. Water at this stage should be given sparingly, just sufficient to keep the soil damp, and always in the early part of the day. The seedlings should have richer soil than that provided in the seed bed, and plenty of air and sunshine and soil. Keep moist, not sodden. Asparagus beds require thin regular spring dressings. The best method is to use a fork. Be careful to loosen all the soil to a moderate depth, taking care not to go too deeply to injure the crowns of the plants. This very necessary work of forking and dressing the bed will be necessary every spring in order to improve and loosen the ground, and give full liberty for the buds to shoot up as well as free access of the sun, air, and rain. After the beds have been forked, they should be raked over smoothly and evenly with a rake. The work should be done early in September, as the buds will now be making a start, and will shortly appear above the ground.

The Flower Bed.

The cleaning of all flower beds should be proceeded with early in the month in preparation for sowing and planting for summer display. Any winter flowering plants that have finished flowering should be removed, and their places given to hardy annuals for late spring and summer flowering. September may be classed as the month for annuals and where provision was made during autumn, young plants of some of the varieties should be nearly ready to plant out. These, of course, will give a longer display of bloom. The sowing of half hardy varieties such as Asters, Balsams, Cosmos, Marigold, and Zinnias will be better deferred until beginning of October, as they require a fair amount of warmth to ensure germination, and even then when above ground, require protection from frosts. Make the first sowing of these sorts in boxes or a frame so they can be covered when frosts threaten. Suitable seed boxes for the purposes are about three inches deep and of a convenient size to handle. Put a thin layer of decayed manure in the bottom. This will act as a drainage and will supply the plants with nourishment later on. Fill boxes to within ½in. of the top with good sandy loam, and sow the seed thinly on this, just cover out of sight with fine soil and give a light watering to be followed by a sprinkling occasionally to ensure the soil being kept moist. From sowing of hardy annuals made now, strong plants should be

ready for planting out in a few weeks. As the greater the amount of growth made before the hot weather sets in the better the display will be, so it will be seen that every week gained in getting the young plants fit for planting out is of much consequence, therefore commence sowing as soon as the weather conditions permit. A selection from the following popular varieties can be made for sowing in October. Ageratum, the floss flower, used principally for summer bordering, Amaranthus, the equivalent to outdoor Coleus is very effective in a border. Sow late in the month. Antirrhinum, all varieties of Calliopsis, both the Drummondi and Bicolor, and the double varieities of the Bicolor are particularly effective for decorative work. Candytuft, variety, Celosia, and Cockcomb are both beautiful annuals, but should not be sown until the end of the month. Dianthus, double and single; Gallardia annual and perennial, Hollyhocks of which there are gorgeous colourings, Lupins, annual and perennial; Mimulus, Musk, and Nasturtium, Phlox Drummondi, Portulacca, this plant in a warm situation. Pentstemons—Stock 10 week and Beauty of Nice; Salpiglossis, Sunflowers, Scabious, Verbena, Wallflower and Zinnia, Dahlia flowered. The transplanting of hardy annuals and perennials from autumn sowing should be done as soon as the plants are ready. They will quickly fill any blank spaces in the garden and be in flower in a few weeks. Sorts that should be planted out are:—Calliopsis, Antirrhinum, Stocks, Phlox, Calendulas and Petunias. Be sure and plant Salpiglossis into the bed they are to grow, they will give excellent results from seeds sown into flowering quarters and stand up admirably to the heat; after the first flowering is finished cut the plants back and they will respond with new growth to continue flowering into autumn. A bed of Zinnia, the Dahlia flowered variety, with a border of Linaria, make a marvellous show. These plants require to be set about four inches apart, otherwise the planting will look somewhat thin, pinch them back in early stages and they will grow bushy, which is most desirable. Setting the seed of these plants where they are to grow is more satisfactory as they get a very hard set-back in transplanting.

At the November meeting Mr. McCarthy spoke on "The Work of the Education Department." (Secretary, Mrs. W. Keckwick).

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences—1935.

River Murray, at Moorook, Thursday, June 20th (S. Perkins, Secretary).

Upper North, at Booleroo Centre, Wednesday, July 17th (Wepowie Branch, E. C. Roocke, Secretary, Booleroo Centre).

Hills, at Lenswood, Thursday, August 22nd (B. F. Lawrance, Secretary).

Murray Lands (East), at Alawoona, Thursday, October 3rd (A. J. Pengilly, Secretary).

Fruit (Non-irrigated), at Lyndoch, Tuesday, November 5th (J. S. Hammat, Secretary, Williamstown).

Each Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda of the Conference in their respective districts.

Pruning Competitions.

McLaren Flat, June 22nd; Berri, June 25th; Barmera, June 26th; Moorook, June 27th; Cadell, July 2nd; Waikerie, July 3rd; Moorook (Championship), July 4th.

AGRICULTURAL INQUIRIES.

[Replies supplied by Mr. H. B. Barlow, H.D.D. (Chief Dairy Instructor).]

Effect of Ensilage on Quality of Milk.

South-East Conference, "What would be the effect on the quality of milk for cheese making purposes when cows are fed on ensilage which has a decidedly objectionable smell?"

Reply—If high smelling ensilage is fed to cows, either just before or during milking, it would be very liable to taint the milk. In addition, feeding ensilage in the bails would have a tendency to impregnate the atmosphere, especially in enclosed bails, with mould spores and certain types of organisms often associated with ensilage which is not perfectly cured. Normally, if well-cured, good ensilage is fed at least four hours before milking and preferably fed in the open, away from the bails, no trouble from tainted or contaminated milk is likely to occur. Although many cheesemakers appear to think that the feeding of ensilage is detrimental to the quality of the milk, it is interesting to note that the cows at the Hawkesbury College Dairy are always fed with ensilage whilst being milked, and the year before last the factory exported 100 per cent. choice cheese made from this milk. At Roseworthy College the cows are regularly fed with ensilage whilst being milked and no taint is noticeable in the milk. Ensilage with a very objectionable smell would indicate some fault in the curing, and in this case it should be fed outside and after milking.

Quality of Cream at Kalangadoo Factory.

South-East Conference, "Why are so many producers receiving 'second grade' for their cream from the Kalangadoo Factory?"

Reply—The reason that a greater amount of second grade cream is being noted from the Kalangadoo Factory of late is that the graders at the different factories are now compelled by law to grade the cream correctly and notify the suppliers if the cream is second grade. Previously the suppliers may not have been notified when their cream was second grade. The percentage of second grade cream received or reported at Kalangadoo is considerably less than the percentage noted at most other factories. Because of the favourable climatic conditions, if reasonable care is taken of cream on farms, the percentage of second grade should be comparatively low.

F.A.Q. WHEATS COMPARED.

The Director of Chemistry (Mr. W. T. Rowe) has reported to the Hon. Minister of Agriculture that the f.a.q. samples of South Australian wheats for the seasons 1933-34 and 1934-35 have been milled in his department, and the flours obtained from the wheats have been analysed with the following results:—

WHEATS.

	1933-34.	1934-35.
	Per cent.	Per cent.
Moisture	9.9	10.1
Impurities (screenings, &c.)	—	4.2
Protein (N x 5.7)	11.1	10.7
Bushel weight	60lbs	60½lbs.
Milling test—	Per cent.	Per cent.
Bran	19.2	19.5
Pollard	9.7	9.7
Flour	71.1	70.8

The protein of each sample was calculated on wheat containing 10 per cent. of moisture.

FLOUR.

The analyses were calculated to flour containing 13.5 per cent. of moisture.

	1933-34	1934-35
	Per cent.	Per cent.
Ash	0.44	0.44
Protein (N x 5.7)	9.2	8.3
Wet gluten	24.2	23.8
Dry gluten	8.6	8.1
Water absorption	56.0	56.0
Hydrated maltose	1.36	1.70
Colour	Excellent	Excellent
Standard loaf volume	437 ml.	425 ml
Standard loaf weight	133.4 grammes	131.4 grammes
	Per cent.	Per cent
Baking score	39	38

Mr Rowe points out that there is a considerable falling off in protein in this season's wheat

VETERINARY INQUIRIES.

[*Replies supplied by Veterinary Officers of the Stock and Brands Department.*]

Hon. Secretary, Blackheath Agricultural Bureau, asks (1) *Are sheep affected with "dry bible" in the same way as cattle?* (2) *If sheep are affected with "dry bible" what could be done to prevent it?* (3) *Is there any remedy when once a sheep is affected?*

Reply—The term "dry bible" is a misnomer as "the bible" (third compartment of the stomach) is always dry and hard, its function being to squeeze and pulverise the food eaten before going on to the fourth compartment (abomasum) where the main act of digestion takes place.

The term "dry bible" is often used by stockmen to cover any condition of constipation of the bowels or impaction of the paunch (rumen, the first compartment of the stomach), and in other cases affections in which there is a paralysis of certain groups of muscles, brought about by the eating of damaged fodder or chewing bones

infected with certain germs which secrete a poison. These paralysed conditions are known as "parabotulism" and the parts generally affected are the muscles governing swallowing or movement of the limbs and sometimes those of the stomach and bowels.

Sheep may become constipated or the paunch impacted with food, but it is uncommon when running free in the paddock, except in those cases where "fibre balls" form in the paunch, or in the fourth compartment of the stomach, as the result of swallowing wool or fibre from dry grass which is formed into various shaped hard masses by the movement of the stomach, and blocks the onward normal movement of food. In such cases the symptoms exhibited are very vague and the condition can only be determined after death by finding the balls.

In any case, there is little that can be done in the way of treatment, except to give a purgative such as Epsom salts (4ozs. to 8ozs. in water) or raw linseed oil, 4ozs., with the hope that the obstruction is not too great to pass on. Many sheep remain healthy until they die, depending upon the size which the balls attain.

While sheep are on dry feed a laxative may be supplied (with the object of preventing any risks of constipation) such as:—Common salt, 90lbs.; Epsom salts, 5lbs.; molasses, sufficient to make the lick palatable.

Hon. Secretary, Agricultural Bureau, Black Springs, asks (1) *Is it possible to make common salt into a solid to be used as a lick? and* (2) *Cure for greasy heels in horses.*

Replies.—(1) Commercially, blocks of salt can be purchased which apparently are turned out by machines under pressure and generally mixed with other ingredients such as sulphur, phosphates, and iodine. The crude form of common salt (sodium chloride) often occurs in the form of natural deposits which is sold as "rock salt." Equal parts of coarse common salt and superphosphate placed in a kerosene tin and slightly moistened will set as hard as a brick and is a good lick for cattle.

(2) There are two conditions which must not be confounded with one another, namely, grease and greasy heel. The term "grease" is applied to a chronic inflammation of the skin in the region of the fetlocks and pasterns, and which may even extend almost up to the knees and hocks. The skin secretes an excessive amount of moisture, is red and inflamed and thickened, and often there develops small wartlike growths. The discharge becomes thick and gummy and has a very offensive smell, which is a characteristic of the complaint. It usually affects horses with thick, coarse legs, kept in dark, damp stables or other unhygienic conditions. The cause has not been discovered.

The term "greasy heel" is applied to an inflammation of the back of the pastern which becomes inflamed and exudes a yellow coloured, clear discharge and generally accompanied by a fissuring of the skin. In this complaint there is not the same offensive odour and it is usually brought about through washing of the legs and exposure to the wind before they are thoroughly dry. Another cause is the accumulation of mud, sweat, and other debris.

Treatment—"Greasy heels."—Clip hair back close to the skin, then wash with warm water and soap. Dry and apply a dressing of zinc ointment, cover with a layer of cotton wool, and bandage. Remove in 24 hours and apply zinc oxide powder, 4 (four) parts, powdered starch 1 (one) part, cover with wool and rebandage. Continue this treatment on alternate days for 7 to 10 days. After the first washing do not wash again for a week. There are other dressings that can be used, such as white lotion (obtainable from the chemist). "Grease" is very difficult to treat successfully, but the following treatment may be tried:—Clip the affected leg or legs as high as the knee or hock, wash thoroughly with hot water and soap, and apply the following dressing daily—Formalin, 1 part; methylated spirits, 5 parts; glycerine, 10 parts.

INCREASING THE STOCK CARRYING CAPACITY OF MALLEE FARMS.

[By R. L. Griffiths, D.D.A., Agricultural Instructor.]

Future developments in the recently settled Mallee areas of South Australia present a problem which is exercising the minds of many people at the present time. Much of this country possesses a moderate to low rainfall, and soils of only medium average quality. This is certainly so in the Murray Mallee District, where the rainfall has a range from 17in. in the south to 9in. in some of the northern marginal land, and where the soil, though including some parts of high fertility, partly consists of more or less sandy areas, reasonably fertile when just cleared, but becoming impoverished very quickly by usual cultivation methods. There are also other districts in the State with soil and climatic conditions somewhat similar.

Initial Methods of Mallee Farmers.

It has been considered necessary, for economic clearing of the land, to grow cereal crops. The procedure adopted in most cases—that of growing several crops,

Farms may be ruined by sand drift unless farming methods are changed.

mostly wheat in succession—in order to obtain a burn of stubble material for assistance in destroying mallee shoots, has been effective so far as the land clearing is concerned, though probably less crops and more fallow would have been more effective, even in this respect.

The clearing method adopted has had a very bad effect on both farmer and land. It has tended to develop farmers who are entirely wheatgrowers, who are very loth to alter their methods after the farm is cleared, and who, in some cases, even continue the attempt to grow part of their wheat crops without previous fallowing.

The land has been depleted of humus content—which, because of low rainfall and scanty vegetation, is never very high in such lands. Small amounts of vegetable matter have decayed and been incorporated with the soil during the countless years that the land was growing scrub, but very few crops, grown for grain, and with all residues burnt, quickly reduce the amount. The effects of low humus

content soon appear. It seems certain that the bacterial content of the soil is largely controlled by the amount of humus, and that the amount of available fertility is largely governed by the bacterial content.

The actual effects of low humus content are three in number:—

(1) The available fertility and moisture-holding capacity are reduced, so that—even with adequate dressings of commercial fertilisers, it is difficult to sustain high yields from the crops grown.

(2) The mechanical condition of the soil alters, making more difficult the control of sandy areas, so that drifting sand becomes an increasing menace.

(3) Plant diseases increase in severity. Recent investigations by Samuel and Garrett at the Waite Agricultural Research Institute tend to show that crops grown on soils deficient in humus are most subject to severe attacks of fungus diseases, particularly of Takeall, and experience in the field confirms this finding.

Methods of Retaining Soil Fertility.

It is quite essential, then, if Mallee areas are to remain fertile and profitable, that some method shall be adopted which will increase, and not further deplete, the humus content of the soil. There are three methods generally adopted throughout the world for this purpose:—

(1) Topdressing the land with animal manure from compost heaps or pits where the material has been carefully stored.

This applies chiefly to countries with such low winter temperatures that livestock are stabled during the cold weather, and is not practicable throughout the areas under consideration, except to a very minor degree.

(2) The growing of crops, preferably leguminous, to be ploughed into the soil while still green.

This is possible, but, because the land must remain unprofitable while such a crop is grown, and because the actual growing of the crop entails considerable labour and expense, it is not likely to be an economic way of increasing the soil fertility. Incorporating grass and weed growth with the soil, in such a way that the growth is thoroughly covered by the plough when fallowing, is a modification of this practice, and is undoubtedly useful where insufficient livestock are kept to graze down the growth before fallowing.

(3) Changing the farm methods from cereal growing to the keeping of livestock, or a combination of the two, so that the land is not overcropped, but a large proportion of the vegetable matter and the actual plant foods are returned to the soil in the droppings from the livestock.

This is the only manner in which mallee farms may remain profitable, while the drain on humus and soil fertility is checked, and the farm commences to increase in productivity and actual value.

The older countries of the world teach a lesson which should be learnt here concerning soil fertility on farm lands. Areas have been farmed for hundreds of years and are more fertile to-day than formerly. A good farmer makes this his object. It can be calculated almost exactly, if necessary, and provision made always to replace depleted plant foods, and to restore damaged soil condition.

It is certain that many of the cereal-growing methods on Mallee farms in this State are such that in a short period of years the soil will be so depleted that it will be of no further use for agriculture, and of little value as pasture. Farmers should therefore change, as soon as possible, from present methods, and realise that soil and climatic conditions in most Mallee areas will not allow continued narrow cereal-growing rotations, but are suited only for cropping in conjunction with the keeping of livestock.

Livestock on Mallee Farms.

During the recent period of low prices for wheat many farmers have attempted to increase their income by the keeping of different classes of livestock, developing what are known as sidelines. The breeding and management of horses, dairy and beef cattle, pigs, and poultry may be very useful and profitable sidelines, and have proved so on many occasions.

A mistake is made when the keeping of sheep is classed as a sideline. It is not so, but should be one of the two main industries on Mallee farms—wheat and sheep. Probably in the better rainfall parts wheat growing will remain the more important industry of the two, with the sheep becoming increasingly important as the rainfall decreases, until, in some of the low rainfall areas now growing wheat, this will be almost abandoned, and the properties become chiefly pastoral. Considerable adjustment will be necessary, of course, in these low rainfall parts, and in many cases larger areas than those now held are essential.

The majority of Mallee farmers do keep some sheep. In many cases only sufficient are kept to assist in the clearing of fallows, and to serve as a ration flock. In other cases sheep are bought when there is a surplus of feed, and sold when the flush of feed is over. This is often not profitable, as the stock are bought on a rising market and sold on a falling one. Some farmers successfully deal in sheep, but such farmers are exceptional. It must be realised that on a farm a man has not the opportunity to keep in intimate touch with market conditions, and so the buying and selling of sheep flocks may be disastrous.

A much more profitable way is to keep a permanent flock, choosing the type most suited to conditions, and depending for profits on wool and lambs. This is done now by a percentage of the best farmers; the knowledge necessary for efficient management has been gained by them, and can be obtained by others. Even on most of these farms, however, there is considerable room for improvement. The number of sheep kept is usually not sufficient to affect materially the soil condition. To do this effectively it is necessary to keep large numbers of sheep on a comparatively small area, and thus the present stock-carrying capacity of these areas must be increased.

There are several ways in which this can be done, all of which will be dealt with in this article. They are:—

(1) The improvement of existing pasture species, and the encouragement of other and better species by the addition of fertiliser to the soil.

(2) The introduction by seeding of better species.

(3) The growing of cereal or other crops for grazing.

(4) Supplementing the pastures by the use of conserved fodders.

(5) Closer farm subdivision, and better reticulation of water supply.

CHEMICAL ANALYSIS OF PASTURE PLANTS WHICH MAY BE GROWN ON MALLEE FARMS.

In order to obtain a general idea of the relative feeding value of the various plants which may be used as pastures, specimens were obtained, and a chemical analysis made of 25 different species. These include the cereals, also pasture

plants which appear naturally after Mallee land is cleared, together with others which may be introduced with some hope of success.

Thanks are due to Mr. E. M. Hutton, B.Sc. (Agric.), Field Officer, for assistance in obtaining the specimens, and to the Department of Chemistry for the analytical work done.

The specimens were obtained at as near the same stage of growth as possible, the flowering stage being chosen for this purpose, although the wheat, oats, rye, barley, Wimmera rye grass, evening primrose, and lucerne had not quite reached this stage. It is realised that these analyses are only useful to give an approximate idea of the feeding value of each species of plant, and must be used in conjunction with such known facts as relative palatability, comparative growth, and suitability for the area. The different constituents into which the specimens of each species have been divided are:—

Water.

In all growing pasture plants a large percentage of the weight and bulk naturally consists of water. In the species under review the moisture content varies

Sandy soil which needs binding by pasture plants.

from 60 to 90 per cent., although the majority show between 70 to 85 per cent. of water. The water content of growing plants helps to make them succulent, palatable, and easily digested; it also keeps up the moisture content of the animal's body, and to this extent replaces drinking water.

Ash.

The ash is the mineral part of the plant—that which is left after burning. It consists of mixtures of many minerals, those usually present in the greatest quantity being common salt, lime and potash compounds, and phosphates. These minerals are very necessary to the health of farm animals, but only in small quantities, and on most soils are present in the plants grown in sufficient quantities. They are often supplemented, by careful stockowners, with the supply of mineral licks as an adjunct to the food of farm animals.

Several of the specimens analysed show an abnormally high percentage of mineral matter, and it is suggested that possibly the plants obtained included a quantity of earth in the form of fine dust. This, however, would not affect appreciably the value of the analyses.

Fibre.

This part of the plant gives bulk to the food—very necessary, particularly in the case of the ruminant animals, cattle and sheep. It consists of cellulose, and most of it is not digestible, although in reasonable quantities it helps to promote the digestion of the actual food constituents.

The amount of fibre increases as the plant approaches maturity, until in many cases the bulk of fibre left in the residues after the seed has been removed is such that the plant is not relished by stock, and the energy used in digestion is greater than the food value obtained. This is the case with wheaten straw, and probably also with the common grasses of the Mallee. An excess of fibre at any time is likely to make a plant unpalatable to livestock. In the analyses given the plant showing the greatest fibre content is Haresfoot Clover, which is known to be unpalatable. Next in order are Spear Grass, Silver Grass, Barley Grass, and the Brome Grasses, all of which are not relished by stock as they get near full maturity.

Protein.

This is the nutrient which is of most importance, and the one most likely to be deficient in ordinary Mallee pastures. It contains the nitrogen of the food, and as such is used to supply flesh, and all the nitrogenous parts of the body, replacing waste tissue, growing further tissue in young animals, developing the foetus in pregnant stock, stimulating milk secretion in the female after birth of the young, developing the wool of sheep, and when present in greater quantity than necessary for these purposes, providing energy also. Thus breeding and growing stock require a higher protein content in their food than other animals do. For this reason an essential part of good pasture management with stockbreeders is to obtain a mixture of species in the pasture which will provide sufficient protein.

Most grasses are somewhat low in protein content, whereas leguminous plants, as lucerne and the clovers, are relatively high, and therefore the well-balanced pasture should be a mixture of the two. In the building up of stock-carrying capacity on Mallee farms this is a most important point.

Carbohydrates.

These are the starches and sugars of the food, and are for the purpose of supplying heat and energy to the body. When present in greater quantity than is necessary for maintenance they also supply the body with fat. Carbohydrates are as essential as protein, and are necessary in much greater quantities, but are not so likely to be deficient in pasture mixtures in the lower rainfall areas as protein is.

Fats.

The fats are usually present in growing plants only in small percentages, but serve a very useful purpose. They are similar to the starches and sugars in the supply of heat, energy, and fat to the animal, but one unit of fat is considered equivalent to about 2¼ units of carbohydrate.

Only a proportion of the food constituents is actually digested, and the balance not utilized is voided by the animal. For this reason analyses such as these can give no more than an approximate comparison of food values. Where it is possible to ascertain the amount of digestible nutrients, the exact food value can be obtained by calculating all digestible material as starch equivalents, and the

nutrient ratio, showing the comparative value for growing or fattening stock ascertained by the relative proportion of proteins with other food constituents.

The digestible nutrient content can only be obtained by the actual feeding of stock with each food separately, and the amount of protein, carbohydrate, and fat voided by the animal ascertained and subtracted from the total consumed. This has been done elsewhere, though not to any extent in Australia, for most of the common farm foodstuffs, and the results obtained, set out in the form of tables, have usually been accepted here as fairly reliable. It has not been done with most of the pasture species during the growing period. The amount of work involved would be very great, and probably would not be justified by the value of the results obtained, as the majority of stockowners know sufficiently well, by experience, whether their pasture mixture is reasonably well balanced or otherwise.

The value of the present analyses to Mallee farmers mostly lies in demonstrating the fact that many of the species which are in the present natural pastures are deficient in some of the food constituents, chiefly protein; that the leguminous plants show a higher protein content than most others, and therefore that for the development of greater carrying capacity a balanced pasture mixture of legumes with the grass and other herbage is as essential as the provision of greater quantity.

In the early stages of growth nearly all pasture plants will provide a sufficient proportion of all necessary constituents provided enough is available; it is in the later stages that many become deficient.

Individual analyses will be referred to when dealing with the separate species.

Spear Grass (*Stipa variabilis*)

NATURAL PASTURES OF THE MALLEE.

In its natural state, before the scrub is cleared, most Mallee land has practically no stock-carrying capacity. On any belts of plain country, free of timber, species of Spear Grass are often present, and in the lower rainfall areas, in parts, Bluebush and some varieties of Saltbush can be found.

When Mallee scrub areas are leased for pastoral purposes some carrying capacity is obtained by periodical burning of the scrub, which allows further development of Spear Grass, and also makes available for stock the young growing shoots of various bushes. Even under such circumstances only a few sheep per square mile can be carried, and often then there is a definite phosphate deficiency, so that stock cannot safely remain on this country for any length of time.

With the clearing of the land for cultivation the position improves. There often appears to be sufficient Spear Grass seed in the soil to develop plants for a considerable amount of grazing. This persists for a time, but usually is killed right out eventually by cultivation practices. A shrub of the order *Compositae*, commonly called Yellow Daisy, frequently appears. This is a real cultivation weed, and gives considerable trouble to the farmer, until he commences to keep sheep. Sheep evidently relish the weed, and eat it out when young, so that it does not persist.

As cultivation continues, other pasture plants appear and spread, until pastures, at least in the Murray Mallee area, generally contain most of the following plants: Barley Grass, Silver Grass, Brome Grasses, Wild Mustard, Wild Oats, Geranium, Cape Dandelion, and various other species of comparatively minor importance. During the last five or six years another grass—Mediterranean Grass—has appeared, is spreading rapidly, and promises to be an important factor in pastures.

The advantages and disadvantages possessed by these common pasture plants are as follows:—

Spear Grass (*Stipa variabilis*).

This hardy, free-growing grass is common on new land. In the young growing stage it is relished by stock, and according to analysis should be quite a good maintenance and fattening food. As it approaches maturity it becomes tough, fibrous, and unpalatable, so that it provides no good food residue over the summer months. The seed, also, is sharp and spearlike, causing much trouble with sheep, affecting their eyes, and often penetrating wool and skin into the flesh. Spear Grass does not usually persist under ordinary Mallee farming methods, and so is seldom seen on old land.

Barley Grass (*Hordeum murinum*).

This is the most common grass on Mallee farms. It appears naturally, without any seeding, and spreads rapidly, until many of the pastures are practically all Barley Grass. It is quite definitely a cultivation weed, causing considerable trouble on land to be cropped, and usually persisting sufficiently well to form the main pasture again within two years after a cereal crop is grown. During its growing period it appears to provide a reasonably balanced ration, both young and mature stock thriving well on it; the chemical analysis also confirms this. After the flowering stage its period of utility is practically over. The seed is a real menace, causing sore mouths in all classes of livestock, as well as affecting the eyes and penetrating the skin of sheep. Barley Grass germinates quickly after autumn rains, gives good winter feed, but matures very early in the spring, so that the useful period is short. The straw residue, when the seed has shed, is of little food value, and is usually soon blown away after a few windy days, particularly if there should be a fall of rain.

[From "Grasses and Fodder Plants of N.S.W.," E. Breakwell.]

Left—Barley Grass (*Hordeum murinum*). Right—*Hordeum maritinum*. The bunch of flowers at the upper right-hand side of the plate is *H. maritinum*. Note that only the central flower is fully developed.

[From "Grasses and Fodder Plants of N S W," E Breakwell]

Great Brome (*Bromus villosus*) Note the large flowering glume.

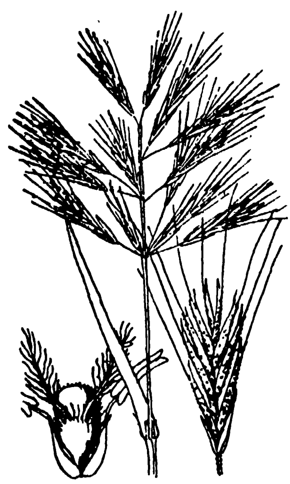
The chief disadvantage of Barley Grass is the fact that it is a common host for the fungus disease Takeall, which undoubtedly is one of the reasons why Takeall remains so serious a disease in wheat crops on Mallee farms. Any system of pasture improvement which will reduce or eliminate Barley Grass is therefore of extreme importance to the wheatgrower.

Silver Grass (*Festuca myuros*).

The majority of Barley Grass pastures contain also a certain amount of Silver Grass. Its season of germination and maturity is similar to that of Barley Grass. It is slender in flag and stem, never providing much bulk of fodder. Silver Grass has no very objectionable features; it may be a host to Takeall, but has never been considered important in this respect. Because of the short growing period, the lack of bulk, and the blowing away of residues after maturity of the plant, Silver Grass, although a good fattening feed for stock, will not be worth a place in improved pastures.

Brome Grasses.

The family of Brome Grasses contains some useful species, including Prairie Grass. Those which grow on Mallee farms in low rainfall country, however, are not so useful. They are the Great Brome (*Bromus villosus*) and Madrid Brome



[From "Black's Flora of S.A."]
Madrid Brome (*Bromus madritensis*).

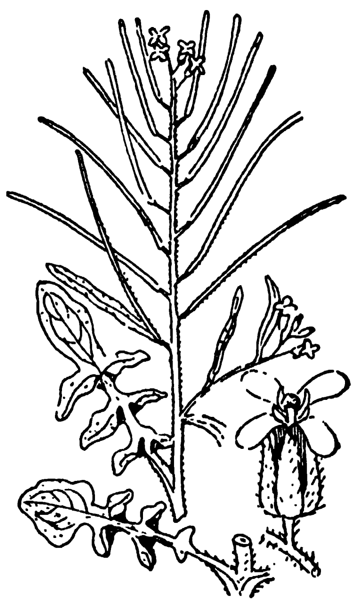
(*Bromus madritensis*). The second of these—Madrid Brome—is not very common It appears occasionally, never being a high percentage of the pasture, is a useful pasture grass during the growing period, but not of great importance so far as Mallee pastures are concerned.

A variation of the Great Brome, which is known as *Bromus rigidus*, is unfortunately becoming very common. Like the other common grasses, it provides reasonably good feed during the growing period, until flowering time. The seed develops on a panicle like the oat plant, and the seed itself is somewhat like an oat grain, but longer, harder, and with very sharp points. It is probably the most dangerous seed of all for damage to eyes, mouths, skin, and flesh of livestock. This grass also, is said to be a host to Takeall. Because of the very objectionable features of the seed of this plant, farmers should make an attempt to eliminate it if possible. This species is erroneously called "Mitchell Grass" by many farmers.

Wild Mustard (*Sisymbrium orientale*).

Wild Mustard is one of the chief cultivation weeds in the Murray Mallee District. It appears on practically all farms, and can be found to some extent in nearly all the cereal crops. It is called "Charlock" by most farmers, but the real Charlock is not at all common in this area.

The seed of Wild Mustard appears to remain in the ground sometimes for long periods without germinating. It is never possible to get a complete germination, successive crops often appearing after each fallow working during autumn months, so that, to the wheatgrower, it has nothing to commend it. From a pastoral point of view this plant is not objectionable. It provides quite good feed during the growing period. The chemical analysis shows a surprisingly high protein content, which would lead to the conclusion that this plant will provide a better balanced



Sisymbrium orientale. (L.) (Wild Mustard.)

ration for growing animals and for milking stock than most of the common pasture plants. This conclusion is confirmed—partially at least—by the experience of many farmers, who are very satisfied with Wild Mustard as a pasture plant. Some go so far as to say that they prefer their hay to contain a proportion of mustard, claiming that, apart from its food value, it acts as a tonic to livestock.

When mature, this plant provides more feed than many others. It is not greatly disturbed by wind or rain, and stock find the seedheads palatable. Probably the passing of mature seed through the livestock is the chief reason why Wild Mustard continues to grow almost everywhere on these Mallee farms.

The greatest disadvantage of Wild Mustard as a pasture is the strong characteristic odour. This gives an unpleasant flavour to milk, all dairy products, and to the flesh of animals killed for meat. The odour does not seem so volatile as some are, and it is difficult to remove from dairy products. If stock for slaughtering, however, are starved from 12 to 24 hours before killing the taint disappears.

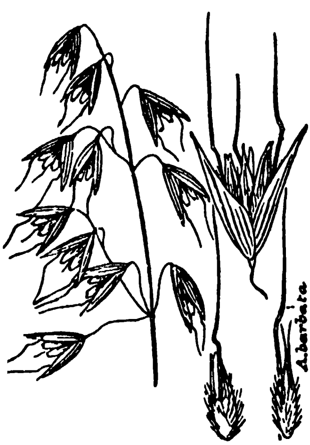
Wild Oats (*Avena fatua*).

This plant is not so common in the newer Mallee areas as in many other wheat-growing districts. It appears gradually, probably commencing when seed or hay is purchased which contains Wild Oat seed as an impurity. It prefers the higher rainfall areas, and in the Murray Mallee is often seen in crops grown in country with from 14in. to 17in. average annual rainfall.

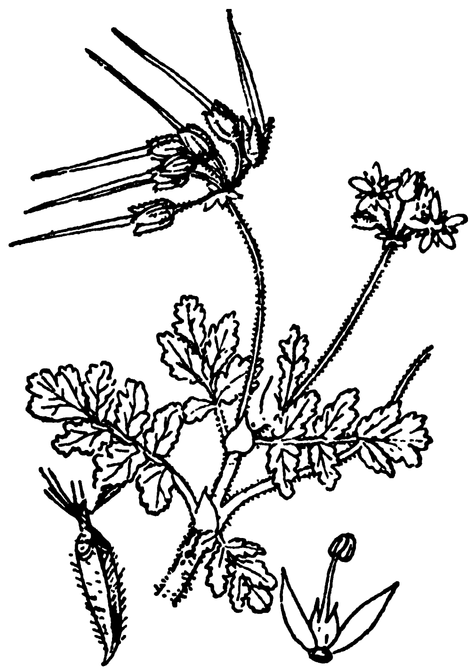
Like Wild Mustard, it is a difficult weed to eradicate on cultivation areas, owing to delayed germination of a proportion of the seed. It cannot be classed as a general pasture plant, as it does not persist on uncultivated areas, except usually for one or two years after a crop has been grown. It is quite a good feed, although more fattening than flesh or milk producing, is palatable to livestock at all stages of growth, and will also, when it grows as a self-sown crop, make good hay if it is cut soon after the flowering stage.

Geranium (*Erodium moschatum*).

Several species—usually called Geranium—grow among the pastures in this area. They are all very similar, and the one named above is the most common.



Wild Oats (*Avena fatua*).
[From "Black's Flora of S.A."]



Geranium (*Erodium moschatum*).

These plants appear usually after the land has been cleared for some time, and after some superphosphate dressings have been applied to cereal crops. With further fertilizer dressings, when leguminous plants are growing freely, the plants of this family become less numerous in the pasture mixture.

The analysis shows a high percentage of moisture, and comparatively low quantities of nutrients. This is confirmed by experience, as these plants are considered only moderately nutritious to stock. In some parts the common name of

Crowsfoot, or Stork's Bill, is given to them, because of the appearance of the seed heads. When the seed heads are mature they each contain several sharp-pointed seeds, attached to long spirally twisted awns. These seeds, with their awn attachments, are among the most dangerous to stock, freely penetrating the skin and piercing the flesh.

[From *Journal of Agriculture*, Western Australia.]

Cape Weed (*Cryptostemma calendulaceum*).
A—Portion of flowering plant. B—Leaf. C—Flower head. D—Ray flower centre of head. E—Flower from centre of head.

Cape Dandelion (*Cryptostemma calendulaceum*).

This weed is known to some farmers simply as Dandelion, and to others as Cape Weed. As another plant, from Europe, is also commonly known as the Dandelion, the name of Cape Dandelion is more suitable for this one, which came to Aus-

tralia in 1833 from South Africa. It is one of the chief cultivation weeds, and is very difficult to eradicate from fallow land unless destroyed when the plants are small seedlings, especially in wet seasons. The plant is very tenacious of life, and even when uprooted by the cultivator, will re-establish itself unless warm days or frosty nights kill it.

In areas with 14in. or more annual rainfall the Cape Dandelion destroys a considerable amount of cereal crop, as its habit of spreading over the ground tends to choke out all other growth. It germinates freely early in the autumn, and because of this often provides the first green pick for livestock, so that it is useful in this respect.

The analysis shows a higher percentage of moisture than for any other plant with very low percentages of all useful food constituents. This is confirmed by experience, Cape Dandelion being well known as a soft, watery food, of little value to livestock, except when in a mixture with better plants, and which also reaches maturity early in the spring, leaving no pasture residue. It persists on pasture land, unless methods are adopted to encourage the leguminous plants, when it can be reduced or eliminated. Cape Dandelion does not grow to any extent where rainfalls are less than 12in. to 13in. per annum.

Mediterranean Grass (*Schismus calycinus*).

Mediterranean Grass is a newcomer to the Murray Mallee area. It has been known for a considerable period in Central Australia, to which it was apparently introduced accidentally in the packing of camel saddles, brought by Afghans from the Mediterranean region, where it is a native grass.

It was first seen in the Murray Mallee about the year 1930, and the most reasonable theory is that the seed, which is very small and light, was wind-carried in duststorms during the drought periods of 1927 and 1929. Appearing first as single plants, it spread very rapidly, especially through the lower rainfall parts. It can now be found in all parts of the district, and over large areas of low rainfall country is rapidly replacing all other pasture plants, especially Barley Grass.

It has been stated that the grass is of low feeding value. This is not confirmed by either the chemical analysis or the experience of farmers. Although the sample obtained for analysis by the writer evidently included much dirt—shown by the ridiculously high ash percentage—there is a very satisfactory quantity of all plant nutrients, particularly of protein. The grass grows only a few inches in height stooling very freely, and stockowners state that it is palatable to all classes of livestock at all stages of growth.

It has no objectionable features, except as a cultivation weed on fallow, and although only an annual, maturing fairly early, the root system apparently remains alive for some time after the plant produces seed, and it will develop fresh growth if rains fall late in the spring. Although the residue after maturity is light, it is freely eaten by stock.

The chief plant being replaced by Mediterranean Grass is Barley Grass, and experience to date is that the replacement is beneficial, and will mean some increase in stock-carrying capacity, particularly in areas of low rainfall—from 9in. to 12in.—where any definite system of pasture improvement is difficult. Another common name given to this plant is Kelch Grass.

(*To be continued.*)

IMPORTANT WEEDS OF SOUTH AUSTRALIA.

[By G. H. Clarke, B.Sc., Botanist at the Roseworthy Agricultural College.]

No. 13—BUFFALO BURR.

Solanum rostratum, Dunal.

The name "Buffalo Burr" is probably due to the frequent occurrence of this plant, in former times, around the so-called "buffalo wallows" and other bare places on the western plains of North America, which is its native home. *Solanum rostratum* is a well-known plant in the United States, throughout which country it has gradually spread as a weed in an easterly direction, and from which it has been brought both to Europe and to Australia. The first record of its occurrence in this country was at Boggabri, New South Wales, in 1904, but it is now to be found in all States of the Commonwealth with the exception of Tasmania. It appears to follow the wheat belt and doubtless owes its introduction to impure seed wheat or other grain. Fortunately it is not very common in this State, only an occasional plant being found, here and there, in settled districts. Buffalo Burr has been declared noxious for the entire State, the main objections to it being its prickly nature and its free seeding qualities. For these reasons it should be destroyed wherever found, otherwise it is liable to contaminate seed, and thus to be spread extensively throughout agricultural lands.

In appearance Buffalo Burr is somewhat similar to the closely related Apple of Sodom (*S. sodomaeum*) which we have already described in this *Journal* (Vol. XXXVII., No. 8, p. 1015, March 1934). The resemblance is most marked in the form of the leaves and the distribution of the prickles. But it differs from the Apple of Sodom in a number of characters. Unlike the latter *Solanum rostratum* is annual, not perennial in its habit, and the flowers are yellow instead of purple or white. Moreover, the plant is of a greyish colour due to the presence of a felt-like covering of star-shaped hairs, and the berries are comparatively small and remain enclosed within the prickly calyces of the fruits.

Botanical Name and Classification.—The botanical name of the genus, and the characters, both of the genus *Solanum* and of the family *Solanaceae,* were dealt with in the article on the Apple of Sodom referred to above. The species named *rostratum* means "beaked," and is due to the fact that one of the five stamens of the flower is longer than the rest and has an incurved beak. Other characters which distinguish *S. rostratum* from other species of *Solanum* are the yellow flowers, the tomentum or felt-like covering of stellate hairs, and the enlarged prickly calyx which encloses the berry fruit.

Botanical Description.—An herbaceous annual, becoming woody when old, 8in. to 2ft. tall, the entire plant covered with a greyish stellate tomentum, the stems and branches bearing yellow prickles which become less numerous on the leaves; leaves ovate or oblong, stalked, 1in. to 3in. long, the blade irregularly pinnate or 1- to 3-pinnatifid, with obtuse undulate lobes. Inflorescence cymose but appearing racemose; cymes stalked; flowers yellow; calyx of five sepals, the lobes longer than the prickly tube, enlarging in the fruit and enclosing the globular berry, the prickles becoming very long and dense; corolla tomentose outside, about 1in. across, with long lanceolate lobes of which one is much longer than the others; stamens five, one anther longer than the other four, and with an incurved beak; berry globular, about ½in. in diameter, containing numerous dark minutely pitted seeds.

Properties.—Buffalo Burr is not a very common weed in this State, but it is an entirely useless plant and, in view of its prickly nature, is to be placed in the same category of undesirable weeds as the thistles and other plants causing injury to stock. These qualities, taken in conjunction with the readiness with which it forms large amounts of seed, justify its inclusion among the noxious weeds proclaimed for the entire State. It is a much wiser policy to regard a

[After J H Maiden, Some Weeds of New South Wales "]

Buffalo Burr (*Solanum rostratum Dunal*)

A—Imperfectly expanded flower, showing the beaked stamen to which the plant owes its specific name B and C—Two seeds, greatly enlarged. D—Flower, showing the cluster of prickles under the calyx.

new weed as being possibly harmful before it has secured a firm foothold, than to wait until it has become firmly established throughout the State before taking active measures against it. An ideal list of noxious weeds would be a list of very rare plants. While this, unfortunately, is very far from being the state of affairs with most of the weeds declared noxious in the State, there are at least a few which, like Buffalo Burr, do not appear to be of very frequent occurrence.

Dried specimen of Buffalo Burr Note prickles on stems, and the burr-like fruits.

Eradication.—Since the plant is an annual its eradication does not present serious difficulties. Prevention of seed formation being the essential method of dealing with weeds of this type, any plants that appear should be hoed out as soon as possible. Such active measures combined with regular and periodic inspection of all areas likely to harbour noxious weeds should be an effective means of preventing the growth and spread of Buffalo Burr.

A REVIEW OF THE TOBACCO GROWING INDUSTRY IN SOUTH AUSTRALIA.

[By R. E. Courthope Giles, Tobacco Instructor, Department of Agriculture, Adelaide.]

The past year has been a very trying one for tobacco growers throughout Australia. South Australia in common with the other States of the Commonwealth has suffered from unseasonable weather conditions and the most serious outbreak of Blue Mould disease that has ever been experienced.

Owing to the extreme heat and lengthy drought of the early part of last year, the crops reaped were particularly light.

Buying operations were conducted through the State during October and November last. In the South-Eastern areas, 277 bales of leaf were purchased from growers, the approximate total weight being 55,400lbs. Of this amount, 40,000lbs. were of the 1933-34 season's growth, and 15,400lbs. of reordered leaf, left over from the previous season.

Buyers rejected 137 bales of mouldy and inferior dark leaf, 90 of which had been carried over from previous years.

The quality of the leaf in the different localities varied considerably, the most satisfactory results being obtained in the Coonawarra and Comaum areas, where 3s. per lb. and over was obtained for the best grades, and as much as 3s. 5d. per lb. was paid for Bright Mahogany Leaf.

Throughout the South-East, the average price was only 1s. 9d. per lb. owing to the fact that a considerable quantity of short inferior light and Mahogany Leaf was purchased in the Penola area.

The Penola leaf suffered to a greater extent from the severe drought than was the case in other parts of the South-East. The rejected bales contained very inferior and immature leaf, for which there was no demand.

In the Adelaide Hills, 266 bales were purchased from growers, and the prices obtained were on a par with those ruling in the South-East, but the final results were not quite so satisfactory. A considerable quantity of the leaf offered had been roughly handled and broken, and in a number of cases insufficient care had been taken with the grading and preparation for sale.

Dark leaf grown in the vicinity of Mount Barker, and on patches of heavy ground in other parts of the Adelaide Hills proved to be unsaleable. In the past, during the tobacco boom period, quite a number of people grew leaf on soil totally unsuited for the production of the bright cigarette type, which is necessary to meet modern requirements.

The falling off in the demand for dark tobacco, and the consequent drop in prices has forced a number of growers to abandon tobacco growing entirely, or to transfer their activities to more suitable localities. To-day, with one or two minor exceptions, it can safely be said that growers are now established upon the right type of soil.

In areas where the rainfall is low—during the growing period of the plant, between November and February—some form of irrigation is necessary and growers have been advised accordingly.

EXPERIMENTAL WORK.

Plots were established with growers in the South-East, Adelaide Hills and Barmera and Berri districts in the Murray Irrigation Areas with the object of ascertaining the most suitable varieties for these districts. Clean seed of all the well known Virginian types was supplied to the State by the Council for Scientific and Industrial Research and tried out under constant supervision.

Unfortunately, Downy Mildew or Blue Mould disease has been particularly bad this season in the South-East and Adelaide Hills, and nullified a number of experiments from a purely varietal point of view, but from the disease resistance aspect, very satisfactory results were obtained. Dungowan and Spotted Gum appeared to be less susceptible to infection from mould, and made remarkable recovery in the field when control methods were adopted.

In the Murray Irrigation Areas, Hickory Pryor gave best results, but the majority of species did well where conditions were suitable, with proper cultiva-

Dungowan and Spotted Gum Varieties.—Grown by Messrs. Johnson Bros., Comaum.

tion, irrigation, and protection from the high winds that prevail in these localities. Seedlings grew remarkably well with but little attention and remained free from infection from Blue Mould even when taken to affected plantations in the Adelaide Hills, and they have since reached maturity.

In the South-East, in one instance, a grower lost his first planting of Hickory Pryor and White Stem Orinoco from Blue Mould. After thoroughly re-working his land, he planted for the second time, with the only healthy seedlings to be found in the district, namely: Dungowan and Spotted Gum. The crop was put out into the field at the end of November, and is yielding over 1,000lbs. of excellent leaf per acre.

Fertilizer trials were conducted upon the Experimental Plots, which proved conclusively the superiority of a complete manure for the production of bright tobacco upon the light soils in this State. The best results were obtained with the 3-8-3 mixture, containing Nitrogen, Phosphoric Acid, and Potash, plus 2 per cent. of Magnesia.

"BLUE MOULD."

The problem now facing tobacco growers in South Australia is that of the Blue Mould or Downy Mildew disease, which is undoubtedly the principal obstacle in the way of the establishment of a most promising industry.

The Commonwealth Council for Scientific and Industrial Research has been actively engaged in this matter for some considerable time, and it is hoped that some methods of prevention or cure will soon be discovered.

The disease made its appearance early in the current season—at the commencement of the field planting operations—with disastrous consequences to the crop in the South-East, particularly in the vicinity of Adelaide.

In the former locality, field control methods were more successfully carried out, and with the aid of clean seedlings obtained from outside sources, crops above the average quality are being cured.

Unfortunately, re-planting in the Adelaide Hills area was impossible, as adequate supplies of clean seedlings were unobtainable. For this reason, crops are very light, and in several cases, growers suffered a complete loss.

Every endeavour will be made by the Department of Agriculture to ensure a sufficiency of disease-free seedlings being available in the forthcoming season, by means of production in dry areas, and with the use of hot beds of the Bathurst type.

With the object of eradicating all known sources of infection from Blue Mould as far as possible, the Tobacco Industry Protection Act of 1934 was passed by the State Legislature in November last. Regulations under this Act have recently been gazetted, and growers will be well advised to note their contents, a precis of which is given hereunder:—

1. Every grower of tobacco who harvests seed for sale should notify the Director of Agriculture in Adelaide immediately, and prior to the harvesting of such seed.
2. Every person growing tobacco seedlings for sale must notify the Director within one calendar month of commencing to do so.
3. Any person who fails to notify the Director as laid down in Regulation No. 2 must give at least four days notice to the Director prior to any sale or disposal of seedlings being made.

A penalty not exceeding £5 can be imposed for a breach of these regulations.

Furthermore, the Act provides that old tobacco plants other than those portions which have been harvested must be destroyed by fire or burial before the 31st day of July in each year.

Owing to the prevalence of Blue Mould among tobacco crops during the current season, the last-mentioned provisions will be rigorously enforced, and proceedings will be instituted under the Act against offenders.

In conclusion, one can only hope that the endeavours of South Australian tobacco growers will be amply rewarded, as they deserve. They are pioneering a new industry in the State, in the face of considerable difficulties. This industry is of great financial benefit to the Commonwealth and supplies an avenue of employment, and a further source of income to owners of land, which could not be more profitably utilised, once the menace of Blue Mould has finally been disposed of.

VITAMINS.

[Their Practical Application to the Feeding of Livestock.]

Mr. Alan H. Robin, B.V.Sc., Government Veterinary Officer of the Stock and Brands Department, replying to the question, "What are Vitamins and their practical application to the feeding of livestock?" which was submitted at the South-Eastern Bureau Conference said:—Natural foodstuffs contain, in addition to proteins, carbohydrates, fats and mineral salts, minute amounts of certain substances or food factors which are essential for health and normal growth. These are known as Vitamins. Up to the present time, some 8 or 9 different ones are known and it is possible that as research work on them progresses, this number may be added to.

Unlike the better known constitutuents of foods, viz, proteins &c., Vitamins do not supply energy or constructive material for the formation of body tissue, but they exert an exceedingly tremendous influence on the nutritive processes of the body and a lack of them in the diet leads to general unthriftiness and definite symptoms of various "deficiency" diseases.

Our knowledge of the Vitamin requirements of farm stock is still rather incomplete, but investigational work that has so far been done in this connection indicates that Vitamin C (which prevents or cures Scurvy in human beings, monkeys and guinea pigs), is of no great practical importance to them—all classes appear to be able to get along quite well without it.

Cattle and sheep have been shown to suffer no ill effects from a shortage of the "B" group of Vitamins, lack of which causes Beri-Beri in man. Poultry are very susceptible to "Beri-Beri." I cannot find any records of any tests done on horses and pigs for these Vitamins. "B" group Vitamins are, however, so widely distributed in foodstuffs extensively used in farm stock feeding, *e.g.*, wheat offals, cereal grains, grasses, most hays, greenfeed, silage, milk, &c., that there is a very little likelihood of any shortage occurring in any ordinary ration that might be used.

Whether or not a deficiency of Vitamin "E" (which causes Sterility in rats), affects reproduction in farm stock is not known as no experiments have been carried out. This Vitamin also is widely distributed in foodstuffs, *e.g.*, grasses, wheat, bran, milk, so that under ordinary conditions a marked deficiency of it is unlikely to occur in farm stock rations.

Vitamin "A" which promotes growth and Vitamin "D" which controls the metabolism of calcium and phosphorous and promotes healthy growth of bone are of the greatest importance to farm stock, and a deficiency of them leads to disorders such as stunted growth, general unthriftiness, paralysis and rickets. Young pigs confined to sties and fed on cereals, young poultry kept on the intensive system without green feed, and calves, if kept in sheds and fed on artificial foods, are all very liable to suffer from these disorders, especially if the premises in which they are kept confined do not admit direct sunlight.

Two most potent sources of Vitamins "A" and "D" are green feed and good quality Cod Liver Oil and a supply of these in the rations of young stock being held in confinement is of very definite value in keeping them free of these diseases.

Direct sunlight is also a rich source of Vitamin "D" and exposure to it is often as valuable as feeding substances rich in this Vitamin.

Our present knowledge of Vitamins in relation to farm stock would therefore indicate that, so long as the stockowner exposes his stock to direct sunlight as much as possible and feeds them on a mixed and varied diet, including green feed, he need not concern himself much about the matter of Vitamins—the stock will get all they require of them.

With young stock being kept in confinement, especially if away from direct sunlight, consideration must be given to the matter ensuring them an adequacy of Vitamins "A" and "D" which can most readily be supplied in green feed and/or Cod Liver Oil. The dose of Cod Liver Oil is for large animals 1 dessertspoonful a day; (for poultry) 4ozs. for each 10lbs. of mash.

SULPHURING VINES.

[*"Is the effect of sulphur dusting during the ripening period of currant and wine grapes beneficial for early ripening and sugar content; if so, the best method to apply?"*]

Mr. A. G. Strickland, M.Sc. (Deputy Chief Horticultural Instructor), in replying to the above question, which was submitted at the Lower North Bureau Conference, said dusting with dry sulphur for the purpose of controlling the fungus disease, odium of the vine, seems to have been first proposed by an English gardener, named Kyle, in 1846. In the early fifties of the nineteenth century the use of sulphur as a specific against oidium was in general use throughout France, and right to the present day sulphuring has been regarded as standard treatment for oidium.

Under the climatic conditions which prevail in most of the vine-growing areas in South Australia, oidium has not constituted a major problem, and although it was customary to use sulphur as a routine vineyard practice in South Australian vineyards some 30 or 40 years ago, the practice is not nearly so general to-day.

In addition to its fungicidal action in controlling oidium, several authorities have claimed other advantages to accrue from regular sulphuring. In brief, sulphuring is claimed by these people to affect vegetation beneficially, increasing vigour, and imparting to the vine, darker green foliage, and generally more healthy appearance.

Furthermore, sulphuring whilst the vines are in bloom is claimed to lessen "coulure," or the tendency which certain varieties have of dropping their blooms without setting. Whether this is due to direct stimulation of the floral organs by sulphur, or due merely to the mechanical action of the draught caused during sulphuring and the impact of sulphur particles on blooms has never been worked out.

The third indirect advantage claimed to result from regular sulphuring is a hastening of ripening. A French writer, Mares, claimed vintages to have become some 12 days earlier under the influence of sulphuring, and in support of this contention gave a list of vintage dates from 1838-1863.

In spite of these generalised statements regarding the beneficial effects of sulphuring other than control of oidium, there is little or no direct experimental evidence to support the statements. Under dull, cloudy and sultry conditions, which favour the spread and development of oidium, there is no doubt of the benefits derived from sulphuring; but under conditions where oidium is not troublesome, it is doubtful whether the claims made for sulphur are always fully realised. In regard to the improved setting of grape varieties liable to faulty setting, claimed to result from sulphuring, it is interesting to note recent American work on the effect of sulphur fungicides applied during bloom on the set of apple fruits. Sulphur applied as a dust or lime-sulphur spray, either before pollination or shortly afterwards, definitely reduced the set of fruits. Admittedly, we cannot strictly compare the setting of grapes and the setting of apples, but it is, nevertheless, interesting to record this finding.

In regard to the claim of earlier ripening, we are again faced with a general statement without any supporting figures, other than those recorded by Mares from 1838-1863.

In the light of present knowledge, the matter may be summed up as follows:—

1. Where and when climatic conditions favour the spread and development of oidium, definite advantages should accrue from the application of sulphur to vines.

2. Where oidium is not a serious problem, there is a modicum of evidence that sulphuring may—

(a) Improve general health and vigour of vines.

(b) Improve setting in the case of vine sorts subject to "coulure."

(c) Result in slightly earlier maturity of the grapes.

Under different growing conditions, on different soils, and in different districts the above effects, (a), (b), and (c), may vary considerably in intensity, and in few instances would it seem that the cost of sulphuring would be justified, unless used as a specific against oidium.

In conclusion, it should be remarked that there is justification for careful experimentation, with a view to determining just how important sulphuring is in the matter of improving health of vines, improving setting, and advancing maturity of the fruit.

"KITCHEN" REMEDIES FOR COMMON AILMENTS OF THE HORSE.

The Hon. Secretary of the Pinkawillinie Branch of the Agricultural Bureau who asked for "Kitchen remedies for common ailments of the horse" has been supplied with the following information by Mr. Alan H. Robin, B.V.Sc., of the Stock and Brands Department:—

Sand in Horses.—Give a drench of 1 (one) pint of new milk, 1lb. of honey or treacle; or raw linseed oil 1½-2 pints, turpentine 4 (four) tablespoonfuls. Follow with drenches once or twice daily of 1 (one) quart of strong black coffee.

Blood Worms.—Starve animal for 24-30 hours and then give drench of raw linseed oil 1½-2 pints, turpentine 4 tablespoonfuls. Subsequently give 1 tablespoonful of Fowler's solution of arsenic in damped feed night and morning for a fortnight. Repeat the whole treatment after an interval of 3-4 weeks.

Colic (spasmodic and flatulent).—At outset give drench of raw linseed oil 1½-2 pints, turpentine 4 tablespoonfuls, scrubbing (or cloudy) ammonia 2 tablespoons. Subsequently, as necessary, give every two to three hours a drench of 1 tablespoon of scrubbing (or cloudy) ammonia in 1 quart of thin gruel. Supplement above medicinal treatment by giving enemas of warm soapy water. "Backrake" the animal first and then inject 3galls. to 4galls. of solution slowly through a short length (6ft.) of old hose or ½in. to ¾in. rubber tubing. Repeat the enemas every three or four hours.

Strangles.—Isolate animal in warm, airy quarters. Keep nostrils free of discharge by sponging out with tepid water every three to four hours. Give inhalations of steam medicated with a little eucalyptus or turpentine. Apply hot water foments frequently to swelling under jaw till abscess ripens. Then lance and subsequently irrigate out abscess cavity once or twice daily with weak antiseptic solution (2 per cent. to 3 per cent. lysol or "vetonza," etc.). Water animal from bucket and give 1oz. of ordinary photographer's "hypo" daily dissolved in the drinking water.

Simple Colds.—Isolate and treat as for strangles (excepting that there is no swelling under jaw to be treated).

OFFICIAL SINGLE TEST EGG-LAYING COMPETITION, 1935-36.

CONDUCTED AT PARAFIELD POULTRY STATION.

ONLY FIRST GRADE EGGS RECORDED.

FEEDING TESTS AT PARAFIELD POULTRY STATION.

[New Series of Tests by C. F. ANDERSON, Government Poultry Expert.]

In continuing the experimental feeding tests at Parafield Poultry Station, a new series of tests commenced on 1st April, 1935. Five tests each of 50 white Leghorn pullets were selected. The pullets were chosen as nearly even in age, type, and maturity as was possible.

In order to gain further information on the various methods of feeding, some of the tests are similar to the series which concluded on 31st March, 1935.

The following are the methods to be adopted, together with the results from 1st April to 30th April.

Feeding Tests commenced on 1st April, 1935.

1. Wet mash, composed of crushed barley and crushed wheat, with greenfeed and meatmeal; 2ozs. wheat per day.
2. Standard bran and pollard mash, with greenfeed and meatmeal; 1½ozs. wheat per day.
3. Bran and crushed wheat mash, with greenfeed and meatmeal; 2ozs. wheat per day.
4. Mash of crushed oats and crushed wheat with greenfeed and meatmeal; wheat, 2ozs. per day.
5. Commencing with a crushed barley and crushed wheat mash, greenfeed, meatmeal and then the feeding to be changed according to the season of the year.

Feeding test scores 1st April, 1935, *to 30th April,* 1935.

Test.	Eggs Laid.		Total.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on March 27th, there being present Messrs. R. H. Martin (Vice-Chairman), A. M. Dawkins, J. W. Sandford, S. Shepherd, H. N. Wicks, J. B. Murdoch, Hon. A. L. McEwin, M.L.C., Professor A. J. Perkins, Dr. A. E. V. Richardson, H. C. Pritchard (Secretary). Apologies were received from Messrs. A. J. Cooke, F. Coleman, and P. J. Baily.

Advisory Council of Education.—The Registrar of the Advisory Council of Education intimated that Professor Richardson (representing the Advisory Board) had been appointed as a Member of the Council for three years as from January 1st, 1935.

Sales Tax on Lubricating Oils, &c.—Eyre's Peninsula Conferences asked for the abolition of the sales tax on oils and greases when purchased for the production of farm power, or for use on agricultural machinery. The Prime Minister had informed the Premier that the claims had been listed for the consideration of the Government in connection with any sales tax remissions which the Government might be in a position to grant at some later date.

Wireless Talks.—Resolution of the Redhill Conference (Women's Branch)—"That this Conference after a lengthy discussion desires a broadcast talk once a month on the activity of Women's Branches, and on subjects of interest to the members in general." The Secretary was instructed to discuss the matter with the Director of Education.

Life Member.—The name of Mr. H. T. Martin, of the Inman Valley Branch, was added to the roll of Life Members of the Agricultural Bureau.

New Branches.—Approval was given to the formation of a Women's Branch at Tweedvale, with the following foundation members:—Mesdames C. Reuter, F. Schapel, O. Pfeiffer, E. Miller, — McHugh, R. Muster, J. T. Stevens, Misses R. Bretag, F. Stevens, M. and F. Erdman, M. and E. Pfeiffer, V. Muster, and W. Schapel.

Conditional approval was given for the formation of a Branch at Baroota.

New Members.—The following names were added to the rolls of existing Branches:—Mangalo Women's—Miss M. Klingberg; Balhannah Women's—Mrs. D. Kelsey; Petina—J. W. Smith; Buchanan—H. Marschall; Milang—R. Tuckwell, H. L. Morris; Monarto South Women's—Mrs. A. P. Braendler, Miss V. Hartmann; Wasleys Women's—Miss J. Siebert, Mrs. Congdon; Maltee—K. A. Talbot, M. J. Martin; Parilla Women's—Mrs. Mitchell, Mrs. C. O'Loughlin; Saddleworth—R. Robins, R. E. J. Miller; Inman Valley—R. C. Watson; Lipson—E. Treasure; Boor's Plains Women's—Mrs. H. Harris, Miss L. Harris, Miss G. Chynoweth; Balhannah Women's—Miss T. Peacock, Miss C. Pitt; Lone Gum and Monash—E. Docking; Wirrabara Women's—Mrs. W. Noblet, Mrs. C. H. Curnow; Wepowie—W. E. Koch; Tintinara—J. Murphy, R. H. Salmon, A. Prosser, R. Smith, D. Lang; Beetaloo Valley—L. McGinty; Arthurton—D. Henderson; Coonalpyn—W. Videon, J. Carswell, F. Quinton Watson; Monarto South—C. D. White; Kangarilla—Eric Gould; Wilmington Women's—Mrs. H. Carter (foundation member).

Mr. Shepherd gave an interesting talk on his recent trip overseas.

At the meeting held on April 24th there were present Messrs. A. M. Dawkins (Acting Chairman), P. J. Baily, F. Coleman, J. B. Murdoch, A. J. A. Koch, Hon. A. L. McEwin, M.L.C., Dr. A. E. V. Richardson, and H. C. Pritchard (Secretary). Apologies were received from Messrs. A. J. Cooke, R. H. Martin, and Professor Perkins.

Life Member.—The name of Mr. G. A. Stephens, of the Wilmington Branch, was added to the list of life members of the Agricultural Bureau.

New Branches.—Approval was given to the formation of Branches at Narridy (Women's) and Baroota, with the following foundation members:—*Narridy* (Women's)—Mesdames A. E. Klingner, M. Reynolds, J. Liddle, M. O. Smart, T. Welbourne, E. E. Richards, L. R. Nicolson, J. W. Eagle, W. J. Button, L. Baker, A. E.

and P. H. Smart, R. Darley, Misses F. Sandow, K. Mannix, O. and E. Sandow, S. and M. Price, M. Baker, M. Liddle, P. Jenkins, N. Darley, B. J. Reynolds; *Baroota*—Messrs. S. G. Stone, E. G. Mudge, O. T. Hobart, A. Baker, W. H. and J. E. Spencer, H. H. Jaffrey, H. V. Walter, C., C. R, and W. H. Mudge, W. J., F. J., and W. A. McDougall, E. W. Hulster, J. M. Hillam, E. B. Coe, W. Dahlenburg.

Conditional approval was given for the formation of Branches at Carey's Gully, Chapman's Bore, and Whitwarta.

Branches to be Closed.—It was decided to close the Everard East and Uraidla and Summertown Branches.

New Members.—The following names were added to the rolls of existing Branches:—Allandale East—E. L. Carlin, R. M. Hastings, jun.; Belalie Women's—Mrs. Walker, Mrs. S. B. Opie; Kybybolite Women's—Miss H. I. Rowe; Laura—A. Morgan; Maltee—T. Bassham, H. Box; Maltee Women's—Mrs. E. Cunningham, Mrs. R. Oswald; Mudamuckla—J. H. Martin, F. Heller; Murray Bridge—E. W. Mewett; Murraytown—G. Woolford; Penwortham—L. Wyman; Pinbong—W. Kempster; Pinnaroo Women's—Mrs. A. J. Dodman, Mrs. A. B. Chambers; Snowtown Women's—Mrs. A. H. White; Taplan Women's—Miss Ivy Moffatt, Miss G. Clark, Miss N. Condon; Tarlee—R. E. Clarke; Truro—T. E. Rosenzweig, R. K. Butler, O. W. Church; Wandearah—L. A. Jacobs; Warramboo—M. Dorward; Wasleys—O. A. Benger; Wilmington Women's—Mrs. A. J. Noll; Yundi—J. J. Guincy.

At both meetings several items were taken in committee.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

CONFERENCE AT MOUNT GAMBIER.

Mr. A. J. Hemming, Chairman of the Mount Gambier Branch of the Agricultural Bureau, presided at the Annual Conference which was held at Mount Gambier on 10th April. Delegates were present from Kybybolite, Kalangadoo, Tantanoola, Allandale East, Penola, Coonawarra, Kongorong, Millicent, and Mount Gambier.

Mr. S. Shepherd (member of the Advisory Board of Agriculture), Dr. A. R. Callaghan (Principal Roseworthy College), Messrs. R. C. Scott (Supervisor of Experimental Work), L. J. Cook (Manager Kybybolite Experimental Farm), C. A. Goddard (Assistant Wool Instructor, School of Mines), E. S. Alcock, W. H. Downes, A. L. Warren (District Agricultural Instructors), H. C. Pritchard (General Secretary), and F. C. Richards (Assistant Secretary) attended on behalf of the Department of Agriculture.

Conference discussed questions relating to pasture management, dairying, &c., and the following papers were read:—"Mineral Elements in the Diet of Livestock," Mr. A. C. McMillan (Mount Gambier); "Hints to Young Farmers," Mr. W. L. Barrows (Mount Gambier); "Rearing Fat Lambs for Export on Subterranean Clover Pastures," Mr. L. J. Cook (Kybybolite).

It was decided that the 1936 Conference should be held at Kybybolite. On the motion of Mr. J. Laslett (Allandale East), seconded by Mr. W. Griffin, it was resolved "That all resolutions carried at Conferences relating to subject matter for Congress be placed on the Congress agenda."

Mr. E. Gaffney (Coonawarra) moved and Mr. E. G. Allder (Coonawarra) seconded, "In view of the fact that the Minister of Agriculture has refused to appoint veterinary officers in country districts, the Department of Agriculture be asked to pay mileage to private practitioners pending other arrangements being made to appoint veterinary surgeons." The motion was carried.

At the evening session Dr. Callaghan delivered an address, illustrated by lantern slides, "The Conservation of Fodder."

There was a large attendance of Bureau members and their friends at the tour of inspection of Wood's Point, which was held in lieu of a Conference, on 21st February, by courtesy of Messrs. H. W. Morphett & Co., and under the auspices of the Jervois Branch. At various places of interest addresses on topical subjects were given by Messrs. R. C. Scott (Supervisor of Experimental Work), H. B. Barlow (Chief Dairy Instructor), C. F. Anderson (Poultry Expert), and H. C. Trumble (Waite Agricultural Research Institute). The above is a photo. of the party listening to the address by [illegible] Anderson, given through a microphone and amplifier. In the evening Mr. C. T. [illegible] (Stock and Brands Department) spoke in the Murray Bridge Institute on [illegible] of Stock."

THE STATE EXPERIMENT ORCHARD, COROMANDEL VALLEY, NEAR BLACKWOOD, SOUTH AUSTRALIA.

[By Geo. Quinn, Chief Horticultural Instructor.]

(*Continued from page* 1124.)

THE ROOT SYSTEMS OF VARIOUS ROOTSTOCKS FOR CHERRIES.

With a view to endeavouring to ascertain whether this stagnation and decline could in any way be attributable to root deficiencies, the root system of one typical tree of the same variety growing on each of the rootstocks was investigated in the following manner:—

An area of ground 10ft. x 8ft. 8in. was marked out on the downhill side of the tree. This extended 5ft. on each side of the centre of the tree trunk in the alignment of the row of trees growing on the rootstock in question. At this distance, it turned down the slope at right angles for 8ft. 8in.—equalling half the distance between the rows of trees. These two points were joined up with a line parallel to the first line, thus completing the rectangle, having an area of 26⅔ square feet.

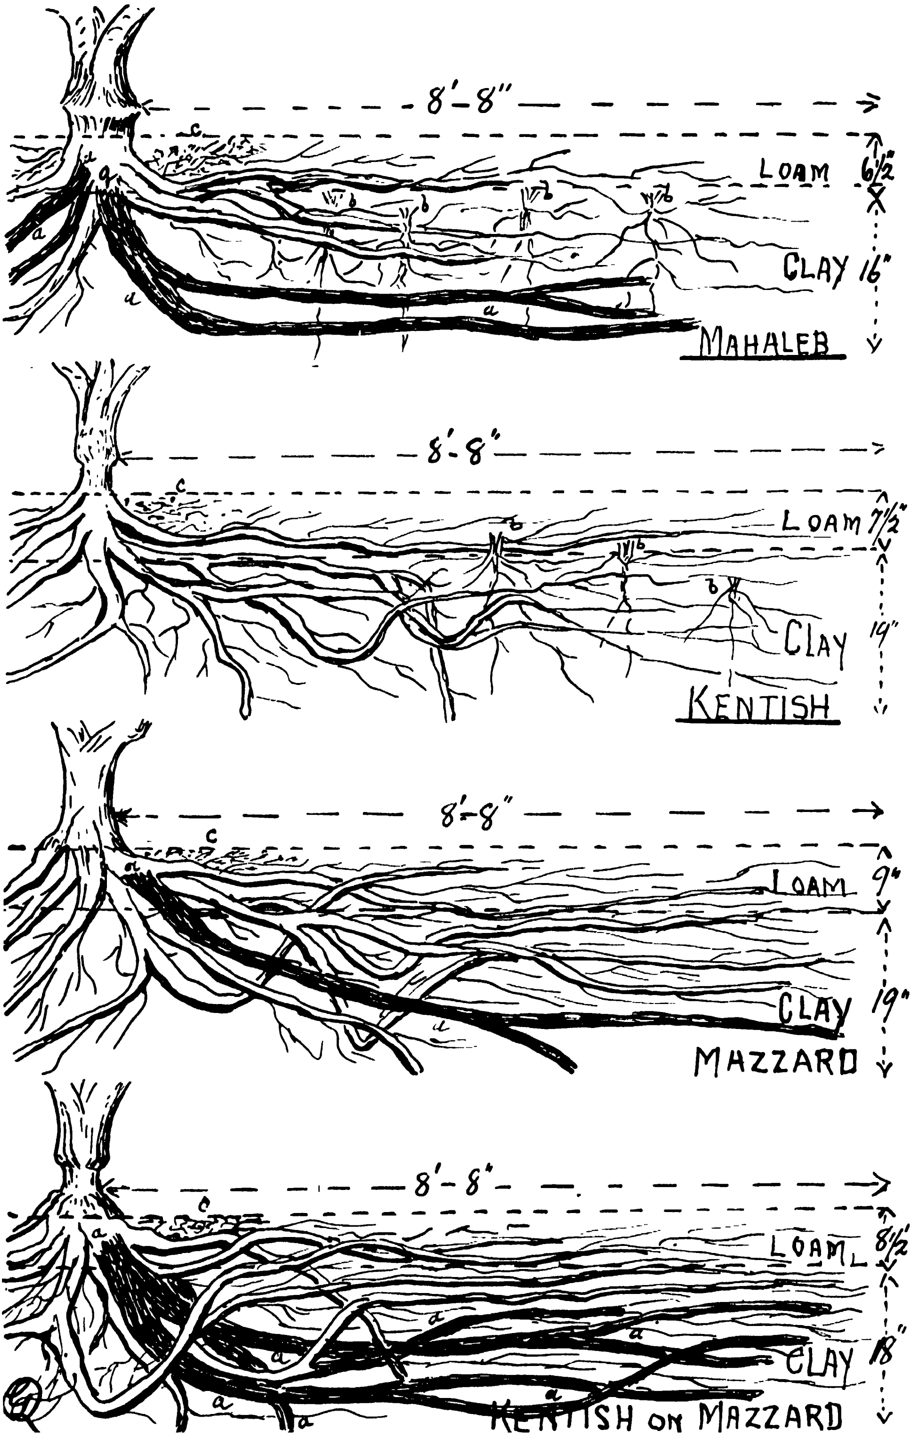
At the outer extremity of the area, a trench 18in. in width was opened until it had been sunk below evidences of root penetration. Any roots, if found coming from the trees in the next or lower row, were separated and cut away. A sketch was then made of the roots coming from within the area to be excavated and where they were more than about 1 cm.—⅜ths of an inch—in diameter, they were measured and a note made to that effect, and of the depth below ground surface at which they were traversing the soil, was also recorded. They were then cut away at the inner bark of the trench, and placed in the shade in groups separated out as:—

(1) Slender roots not over 3mm. in diameter, including fine fibres.
(2) All living roots above 3mm. thick.
(3) Roots of all sizes arising from the bases of suckers, and separate from the tree's root system.
(4) All dead roots.

The excavation was thus continued back towards the tree stem, taking 18in. widths in each step. This was continued up to the alignment of the centre of the tree's trunk. The roots were reasonably cleaned of soil, and then taken away to the work room, and weighed in their separate sections. The weather being cool and cloudy, without any perceptible wind, they did not appear to dry up to any serious extent.

The Mahaleb Root System.

It was found in excavating that the Mahaleb had at some time given rise to a fair number of suckers, which had been constantly held in subjection by the tillage operations, and though not showing above ground at all at the time of removal, were mostly still alive. They had formed a knotted centre from which roots had freely grown. Usually, the deepest and most directly descending fine roots were attached to these suckers and some went almost straight down for a depth of 29in. through the plastic clay layer into the fine marl or decomposed slate. The bark of the roots of the Mahaleb has a pale creamy brown colour, as if stained with clay. The tree on this stock had no large roots in the outer trenches of the area, but a fair number of long slender ones ramified the soil about 6in. or 7in. below the surface—just below the plough depth, but in the loamy surface soil. This class of root was found sparingly running in a horizontal direction about another 6in. deeper in the clay. Very few



Semi diagrammatic representations of the root systems of the various rootstocks in vertical section.

(a) Large dead roots (heavily shaded). (b) Suppressed suckers. (c) Massed fibrous roots.

roots of any kind had penetrated below approximately 16in. from the ground surface. About half-way across the excavated area several large dead roots were unearthed; these measured 3 cm.—1¼in.—in diameter, and were lying about 14in. deep. These had evidently been dead some years, as they were quite readily pulverised when handled. These were eventually traced back to the base of the tree stem, showing increased size as they were unearthed. Above where they joined the trunk, a new layer of large roots had emerged, evidently after the decease of the first lot. These large dead roots were presumably the original anchoring roots thrust down to the depth the land had been loosened and aerated during subsoiling operations. It is possible their decline was the cause of the trees failing to maintain their vigour of growth. As 1923 was the wettest and longest winter recorded at the Orchard, when even some peach trees were destroyed by soil stagnation on the same slope, it is, therefore, quite possible that these main roots of the cherry trees also perished about that time. The fact that similar types of main roots were found to have died on

[*E. W. Pritchard, Photo.*]

St. Margaret's on Mahaleb rootstock.

the Mazzard and combination rootstocks, lends some force to this contention.

An excavation made under the bole of the tree under description revealed the absence of deep descending large roots of any kind, and further tunnelling showed that the other large dead roots radiated from the bole on the uphill side of the tree stem.

The weights of roots excavated, as seen in Table C, and the sectional sketches in side elevation included herewith, show what a very poor root system this rootstock had maintained during recent years. Quite close to the junctions of the larger living roots with the stem, masses of almost wool-like fibrous roots were present in the undisturbed soil. This feature was also common to all of the other rootstocks which were excavated out in a similar manner.

It must be admitted that in excavating roots from a plastic, toughish clay, many of the ends of fine roots were broken off and retained in the small lumps of clay in spite of the workmen's efforts entirely to recover all roots. These are of greater importance to the plant than their insig-

nificant weights would imply, and consequently, some of the value attached to the weights of roots produced is stultified by their absence. At any rate, one may assume that as all the excavations were made in similar clay, and all visible roots and pieces of roots were collected, the losses may be taken to have approximated closely in respect of each kind of rootstock.

The Kentish Root System.

This root system displayed much greater development in proportion to the dimensions of the top growth of the variety it carried than could be attributed to the Mahaleb.

At the outer margin of the most distant trench opened, a good, even fringe of small slender roots was in evidence. These roots were mostly running in the base of the 7½in. depth of loam, and about 5in. below surface level. At 6ft. from the tree stem, practically no roots were found deeper than 14in. down, and these lower ones were traversing a stiff red clay. At

[*E. W. Pritchard, Photo.*]
Bigarreau Napoleon on Kentish rootstock.

4ft. from the tree, that part of the open trench showed a regular distribution of roots as thick as a small finger, and occasionally one dipped down through the clay to a depth of 27in. A little nearer, larger or main roots were met at depths from 13in. to 19in. These, with few exceptions, were running almost horizontally, but near to the tree bole several dipped steeply through the clay into the soft shale. These roots approximated between an inch and an inch and a half in diameter. No direct taproot nor vertically descending main roots were found beneath the bole of the tree. No dead roots of any appreciable size whatever were in evidence in this root system. It was extremely healthy, and shallowly, but evenly, distributed. Contrary to expectations, the evidences of suckering were not abundant and the tillage had evidently eliminated the host of suckers originally to be seen every year arising for some distance around the trees worked on this stock. With half the area given up to its root system excavated, this tree could be swayed or shaken indicating that on the uphill side its root grip in the soil was not equal to that which it had in the

excavated area. The colour of the outer bark of the roots of this stock is very dark—almost black when damp; beneath this epidermal skin a layer of almost bright crimson coloured inner bark is met. This was a most noticeable and distinguishing feature when cutting and separating the roots from those coming into the excavated area from trees on the other rootstocks.

The Mazzard Root System.

This root system as revealed in the tree grown directly on the Mazzard rootstock as well as that whereon the Kentish stem piece had been inserted between rootstock and scion is outstandingly strong and far reaching. At the outer margin of the excavated area—8ft. 8in. from the trunk—roots ranging from 15 mm. to 23 mm.—three-fifths to nine-tenths of an inch—

[*E. W. Pritchard, Photo.*]

Early Purple Guigne on Kentish rootstock.

in diameter were freely distributed along the 10ft. of trench. One of these was dead right back to the bole of the tree. This was apparently also one of the original main roots and it had travelled almost horizontally in the stiff clay at a depth of 16in. from the surface. The layer of surface loam is approximately 9in. thick here, and most of the very numerous smaller slender roots were found from 8in. to 10in. down, indicating that they relished the clay less. The larger roots, from 3 cm. to 7 cm.—approximately 1⅕in. to 2⅘in. in diameter—where they emerged from the bole were numerous, and well distributed.

Some of the smaller roots on this particular tree displayed peculiar bulbous enlargements, resembling the tuberous roots of the dahlia. These are not characteristic of the cherry tree root, and were evidently due to some specific, irritating organism in the soil. A glance at the sketches of these root systems will reveal a pecular characteristic displayed by the stronger roots of the Mazzard rootstock, in that whilst they appear to possess great penetrating power in so far as the stiff clay is concerned, there is a tendency on the part of these deep roots to turn and ascend nearer to the surface when the solidity or non-aerated character of the subsoil increases beyond those powers of penetration. The excavators repeatedly uncovered these knee-like root formations on this rootstock in such circumstances. The colour tone of the outer bark of the Mazzard roots is light brown, the sub-epidermal layer displaying a pale pinkish

shade. An excavation beneath the bole of this tree showed strong, healthy anchoring roots arising all around it, but no defined taproot. After the excavation had been completed, it gave no evidence of "rocking" when a strong workman tried to sway it.

The Mazzard root system of the Kentish-Mazzard combination stock resembled in its distribution and volume of roots the last-named rootstock.

At the extremity of the area, however, the face of the original trench revealed several large roots, having diameters from ¾in. to 1¼in., all quite dead and decayed. The subsequent excavating showed that these were in most, but not all instances, dead right back to the bole of the tree. Slightly above or between the points of attachment of these dead roots a lot of new main roots had developed from the stock. These measured between 2 cm. to 7 cm. (¾in. to 2¾in.) in diameter. This power of regeneration of its root system possessed by the Mazzard rootstock has evidently saved these trees from declining, and possibly dying, after the collapse of the original main roots took place. Most of these large living roots, after dipping down into the very dark-red and stiff clay, and turning up again, travelled through the loamy soil at about 7in. to 13in. below the surface of the land. Several dipped almost vertically and did not turn back. One of these was followed down 26in., and severed there, showing a diameter of 3½ cm., say, 1⅜in. thick. A vast number of thin long roots—under 2 mm. thick—spread away from the branches of these larger roots. These latter, when severed at the boundary of the excavation—5ft. from the trunk on either side—gauged from 2 cm. to 3½ cm. (¾in. to 1⅜in.) in diameter. No taproot was present beneath the bole of this tree, but large living roots had emerged from it on the uphill side, and it still retained an unshakable grip in the soil after being practically deprived of half of its root system. It will be seen from the figures in Table C showing the weights of roots excavated from an area measuring 10ft. x 8ft. 8in. situated on the lower side of each tree, growing on a different stock, that the greatest weight of dead roots was taken from a tree on the Kentish-Mazzard combination. Although this tree made a fine recovery, and never at any time, showed signs of actual distress, it would be of interest to know whether the insertion of the Kentish stem piece between the Mazzard root and the scion variety was in any manner conducive to the death of a larger proportion of the original main roots. From the fine healthy appearance displayed by this and all of the trees of the same and other varieties grown in this row—all of the stocks of which have been built up of the same component parts—one may express doubts as to holding the Kentish stem piece responsible.

INFLUENCE ON CROPPING AND QUALITY OF FRUIT.

The accompanying Table D indicates that the few first cherries borne by these trees were recorded in 1916—six years after the stocks were planted out "in dormant bud." These were collected from the Early Lyons and Early Purple Guigne varieties. It is pointed out that the greater proportion of this extremely small harvesting came from trees of these sorts worked on Mahaleb and Kentish rootstocks, but the trees budded on Mazzard, and the Kentish-Mazzard combination stocks also contributed some fruit from the Early Lyons variety. There is, however, no evidence that the use of the intervening piece of stem from the dwarfing (Kentish) cherry has been conducive to earlier cropping than where the scion variety has been joined directly on to the Mazzard rootstock.

In explanation of the somewhat patchy character of the yields recorded year by year from this plot of trees, it may be at once stated that the figures quoted in Table D do not represent anything approaching the total quantities of cherries borne by these trees. It was soon discovered when the trees began to crop that an unsuspected factor was destined to upset any attempt to show their full possibilities in this respect. The sheltering belts of large red gum trees, which lend such a picturesque effect to the

[*E. W. Pritchard, Photo.*]

Early Lyons on Kentish rootstock.

scenic beauties of this locality, are the refuge and home of hosts of fruit-eating birds. Principal amongst these in destructiveness to soft fruits generally, and cherries in particular, are the imported so-called English starling (*Sturnus vulgaris*) and the indigenous "larger Wattle Bird" (*Anthochaera corunculata*). The former is always present in destructive numbers in the orchards of Coromandel Valley during the fruit season, but the latter is more intermittent in its attacks, usually proving seriously pestiferous only in the earlier part of the season, apparently, when its natural food supply is scarce. It is then infinitely more persistent and daring than the starling.

In spite of mechanically operated and other bird scaring devices, combined with considerable slaughter by shot guns, these two pests succeed in destroying large quantities of cherries and other soft fruits in the State

Orchard. Notwithstanding the enhanced prices formerly received for their earlier ripening cherries, the commercial orchardists in this locality have, chiefly owing to this disability, abandoned cherry culture almost entirely. As a consequence, these pests concentrate early in the season on the cherry block in the State Orchard, where some 200 sorts of cherries are grown, and on the smaller plantings in certain trial plots where cherry trees are also included.

The figures in Table D may be taken as representing comparative proportions only of the annual yields of the different varieties grown in this trial when worked on the various rootstocks. This statement should perhaps be modified to the extent of saying that the loss of fruit due to bird pests has been proportionately higher from the two earlier ripening varieties, viz., Early Lyons and Early Purple Guigne. The latter variety has not cropped as well as the other varieties in this trial. As indicated previously, the failure to grow the trees of St. Margaret's on the Kentish and on the Kentish-Mazzard combination rootstocks has much reduced the total yields from this variety, whether harvested or destroyed by birds. It was unfortunate that during the years 1917 and 1918, when cropping had just begun, changes in the Orchard management caused a break in the records of this and some other trial plots in the Orchard.

Judging from the context, the yields from these cherry trees could not have been great during these seasons, and in the long run need not seriously affect the ultimate conclusions to be drawn relative to either the aggregate yields or those of the earlier years only.

In the year 1921, the cherry crop failed, and again in 1929. In the latter year, due to some undetermined factor, the blossoms were quite deformed or incompletely formed on all the varieties in this plot, excepting on the Florence. Hence, the absence of any fruit records. In respect to the influence exercised by the various kinds of rootstocks in inducing earlier crop production from the varieties worked upon them, the figures provided by this plot, as shown in Table E, may prove interesting. They certainly only represent the quantities secured from the birds during the first 12 years after planting, or from the seventh year onwards after fruit bearing had begun.

Had the average proportions of the crops been harvested during the seasons 1917, 1918, and 1921, it is quite possible that the total weights borne by the trees grafted on Mahaleb rootstock would have exceeded those produced on the trees worked on the Mazzard stocks up to 1921. At any

rate that would have been in accordance with results claimed to have been obtained by commercial growers of cherries who have used these two stocks. Pursuing the subject further it will be seen in Table F that during the 16 years between 1916 and 1933 in which the harvesting records were taken, that the trees of the five varieties in this trial, when worked on the Mazzard or on the Kentish-Mazzard combination stocks, were seemingly much more prolific than those grafted on either Mahaleb or Kentish rootstocks.

Whilst the different rootstocks did not appear to influence to any appreciable degree the periods of blossoming of the varieties under test, they do appear to exercise valuable effects on the time of ripening. In these tests the fruits on the varieties worked on the Kentish stock ripened first, those on Mahaleb following closely after. Those on the Mazzard followed a little later, and those on the Kentish-Mazzard combination were latest of all. It would certainly appear as if the intervention of the Kentish stem piece in the combination in some way delayed fruit maturity. There is no evidence that its presence induced earlier productiveness than noted in the trees worked directly on the Mazzard rootstock. Whether this delayed ripening would be borne out by trials made under the conditions found more suitable for cherry growing, or would have a commercial value if proved to be correct, remains for future testing to decide. The location or position in the plot occupied by this combination stock may be a factor in delaying the ripening. The row runs along the slope 52ft. distant from the topmost row, which is composed of trees on Mazzard stock. The fall

in the land is 8ft. between the positions occupied by these two rows. The differences detectable between the soils and subsoils appear negligible. Soil moisture in abundance in the root area is one of the greatest determining factors in delaying ripening of other stone fruits; but as cherry trees ripen their fruits before the moisture from winter rains becomes depleted to any serious degree, the possibility of the slightly lower position remaining much moister than that occupied by the other rootstocks is very remote.

The measurements of growth collected from this row of trees on the combination stock do not indicate up to the present that the reduced diameter of the intermediate Kentish stem piece has retarded their vitality to any serious extent. If it had, one might expect earlier ripening to eventuate, as is evident on the same sorts of cherries worked on Kentish

[*E. W. Pritchard, Photo.*]

Florence on Kentish rootstock.

rootstocks. It may be incidentally stated that the intermediate stem piece of Kentish—contrary to what Swarbrick and Roberts in the summary to Research Bulletin 78 of the Agricultural Experiment Station of University of Wisconsin, issued August, 1927, declares to occur in apple trees—has not apparently caused the Mazzard root system to assume the root character of the Kentish cherry.

In the environment under which these cherry trees have carried their crops, it has not been possible to form any definite conclusions relative to the comparative qualities of the fruits produced by the different varieties of the sweet cherry grown on the respective rootstocks. To secure even the proportion set out in the accompanying tables, the fruit was mostly gathered whilst still in a hard and relatively immature condition. Many of our growers of high-quality cherries claim that whilst the fruits borne by certain varieties grown on Mahaleb stocks are excellent, still, taken as a general average, the same variety yields fruits of superior quality, and certainly in increased quantities, when grafted on the Mazzard rootstocks.

It is claimed that the Mahaleb induces a super-abundance of blossoms resulting in a somewhat scattered setting of cherries. Trees on this rootstock crop well, and frequently in the "off" season for the cherry crop they show up to advantage. They are, however, declared to be comparatively short lived, tending to die back gradually from the upper limbs downwards.

The Kentish rootstock, when planted in rich, deep soils, is claimed by commercial cherrygrowers to suit the Black Tartarian variety well, inducing good growth and the production of good crops of average marketable quality. Bigarreau Twyford and Waterloo are only moderately successful on it, whilst Werder's and Knight's Black and Florence are said to be failures. St. Margaret's is stated to be over dwarfed on this stock. In this trial only the two last-named varieties were grown on this stock,

Bigarreau Napoleon on Kentish on Mazzard rootstock.

and a glance at Table F shows that the two white or light upright growing varieties—Bigarreau Napoleon and Florence—cropped reasonably well on Kentish, and produced fruit of fair average quality. As has been previously stated, the opinion generally held by the commercial growers of cherries in the Mount Lofty Ranges is that the Mazzard rootstock not only produces the healthiest and longest-lived trees of all varieties of the sweet cherry, but on it they also crop more heavily and longer, and on the whole, the fruit is of better uniform quality and size. This conviction is evidenced in the fact that of recent years *they have planted sweet cherry trees on no other stock.*

In so far as any evidence can be adduced from the cherry rootstock trial conducted at the State Orchard at Blackwood from 1910 to 1933, it tends to support the knowledge gained through experience by the two or three generations of commercial cherrygrowers in this State.

When all of the circumstances surrounding this trial are held up for consideration, the data collected of tree growth and crop production may be deemed incomplete and scrappy. When attempting to erect a comparison between the varying effects of these different rootstocks upon the

five varieties of sweet cherries worked upon them, there seems, in the writer's opinion, no more convincing evidence than that displayed in the present condition of these trees, after the lapse of 24 years when to prove profitable they should be at the zenith of productiveness. Of the 15 trees of the five varieties grown on the seedling Mazzard rootstocks, only one is giving signs of decline. This tree is located in a corner of the plot where two roadways cross at right angles. In this position, it receives the full brunt of the prevailing cold south-easterly winds coming directly down from the higher slopes of the ranges. When storm waters overflow the watertables, they erode away the looser and richer surface soil from much of the area occupied by its root system. In the writer's opinion, these have been the principal factors affecting its health. The remainder of the trees in this row are extremely healthy and robust—surprisingly

[*E. W. Pritchard, Photo.*]

Early Lyons on Kentish on Mazzard rootstock.

so, when the shallow and comparatively poor type of surface loam is taken into consideration.

As the accompanying photographs indicate, the affinity between the Mazzard rootstock and each of the five varieties worked thereon would seem very nearly perfect. So even has the growth around the point of union proved to be, that only after the closest scrutiny could it be clearly determined, in many instances, when the more recent stem measurements were being taken.

Of the 15 trees of the same five varieties grafted on Mahaleb rootstocks —and which originally grew so well—six are now dead. Two are rapidly declining, and will probably die during the coming summer, whilst the remaining seven are quite stagnant and each shows evidence of progressively dying back at the terminals of all limbs. In this trial, the Mahaleb stock did not appreciably, during the first 10 years, dwarf the trees worked on it, but since then it has most certainly hastened their decline. Some of

those already dead could, at the time of being removed, have been classed amongst the tallest trees in the plot. In every case, the distortion characteristic of the stem at the point of union of this rootsock with the scion variety was strongly in evidence. It stands out from the vertical alignment of rootstock and tree stem as distinctly as a prominently moulded cornice protrudes around a cylindrical column of a building.

The growth of the 12 trees of four varieties worked on the Kentish rootstock has been conspicuously dwarfed by its influence. As previously related, the trees of the fifth sort (St. Margaret's), having failed at the first planting, their successors did not seriously enter into the trial.

These 12 mature trees have maintained a fair standard of health. They appear, however, to have reached a stage of growth when the yearly vegeta-

[*E. W. Pritchard, Photo.*]

Early Purple Guigne on Kentish on Mazzard rootstock.

tive effort results only in extending at the points of the spurs sufficiently to produce each Spring a tuft of leaves and a small cluster of flowers. There is no evidence of branch extension having taken place of recent years. If it were not that identically similar effects may be seen on cherry trees of the same varieties growing on the Kentish stocks located under the most favourable conditions of soil and climate in the Mount Lofty Ranges, one might attribute much of this restriction of tree size to the shallowness and unsuitable nature of the soil in the Blackwood trial plot. Amongst the varieties under test the Early Lyons has shown the best tree development, but in crop yields it has not equalled those of Bigarreau Napoleon or Florence on the Kentish rootstock. The stem development or distortion typical of the effect of this rootstock on sweet cherry scion varieties takes the form assumed by the stem of a currant grape vine to which the annual cincture has been repeatedly applied to one position, or it may be likened to the rapidly growing stem of a young fruit tree around which a wire or label string has been allowed to remain unloosened,

In these cases, it is claimed that the prevention or retardation of the flow of elaborated sap back to the roots caused undue expansion of the area, owing to the excessive concentration of new tissue immediately above the point of restriction. In common terms, it may be stated that the effect of the Kentish rootstock is to induce a considerable enlargement of the stem of the sweet cherry tree immediately, and for some distance above, the line of its union with the scion variety. This gives the stem a top-heavy appearance. If the tree be grafted very low, or the line of union of stock and scion is buried when planting the tree into the orchard, this effect is hidden. In the accompanying illustration of the Early Lyons variety growing on this rootstock, the uncovered base of the butt of the tree is shown in the figure on the right hand side.

Florence on Kentish on Mazzard rootstock.

Of the 15 trees originally set out in the plot on the Kentish on Mazzard rootstock combination, two of the St. Margaret's variety perished in early years after an attack of Curculio Beetles, and one of the Florence died from some unknown cause whilst quite young. The 12 remaining mature trees consist of three trees each of three varieties, two trees of another, and one only of St. Margaret's variety. The use of this intermediate stem piece of Kentish cherry, although considerably restricting the expansion of that portion of the trunk, has not thus far, at any rate, had any apparent effect in the direction of retarding the development of the tree top generally.

The measurements of the Mazzard rootstocks below, and those of the actual tree stem above this inserted portion, have revealed an average expansion of a fairly normal character in both. The limbs and branches are exceedingly robust. The sketches and observations of the root system made during the progress of the excavation work indicate that the presence of this stem piece did not prevent the effective rehabilitation of the root

system of the tree examined when, from some unknown cause, a heavy mortality of the original main roots had taken place. That this recovery was not only effective, but had been rapidly achieved, is evidenced by the fact that until the excavating was recently carried out, the failure of these roots had not even been suspected, so well had the healthy condition of the tree been maintained. This power of recovery would appear to be a feature of the Mazzard root system, which, as far as our investigations reveal, is poorly developed in the Mahaleb, at any rate, when labouring under the unhappy union which it appears to make with a sweet cherry scion variety.

There would appear from the evidence found during this trial that a greater incompatability exists between the *Prunus Mahaleb* and the varieties of *Prunus avium*, than is found to exist between the varieties of *Prunus cerasus* and the sweet cherries. The dislocation of the physiological processes which is set up in the tisues at the line of union, or

[*E. W. Pritchard, Photo.*]

St. Margaret's on Kentish on Mazzard rootstock.

attempted fusion between the Mahaleb rootstock and the sweet cherry variety, is evidently more intensified and fundamental in character than is the case either where the Kentish rootstock is used alone, or the Kentish intermediate stem piece is inserted. The latter would appear to slow down the translocation or passage of the crude or the elaborated sap, or both, but apparently it does not break the continuity of the conducting vessels, as would seem to be the ultimate effect set up between the Mahaleb rootstock and the scion variety of sweet cherry worked upon it. It is claimed that the Kentish (*Prunus cerasus*) and the sweet cherry (*Prunus avium*) have been hybridised, resulting in the production of the so-called Duke type of cherry, the trees of which display certain of the morphological characters of the latter, and the fruits appear to possess some of the acidity of the former species. This quality of crossbreeding may imply a closer genetic relationship, and hint at a greater compatability for fusing into a more lasting union of stock and scion which is so essential to the success of this work.

In 1924, the writer carefully examined and recorded his observations on the points or lines of union on the trunks of 148 named varieties of cherry trees growing in the collection in the State Orchard at Blackwood, all of which had been worked on the same batch of seedling Mazzard rootstocks from which those used in the stock trial had been selected. These varieties had been planted out in the Orchard in 1911. Of this number, 110, or upwards of 74 per cent., were returned as having made perfect unions between stock and scion, and 38 noted as giving some indication of lack of compatability. Whilst a fair proportion of these 38 scion varieties were Kentish or sour cherries, quite a number of those *showing satisfactory unions were also varieties of Prunus cerasus.*

In this trial of rootstocks for sweet cherries, the plants used consisted of reputedly distinct species. In the cases of the Mazzard and Mahaleb, they were plants raised from seedlings, whilst those of the Kentish were suckers or accidental stools arising from the roots of orchard trees. As these latter were unlikely to have arisen around a single parent sour cherry tree, there are possible variations inherent to some of these plants, apart from anything due to extraneous conditions and attributable to causes which are not constant.

As each of the seedling Mazzard and Mahaleb stock plants are almost certain to have arisen from the fusion of genitive elements from two distinct parent plants, they also are likely to possess varying characteristics of growth and affinity in relation to the scion varieties worked upon them. These are possible factors in respect to which no attempt is made herein to estimate their comparative effects on the behaviour of the scion varieties as described in this trial. In so far as the seedling Mazzard stocks are concerned, the measurements and estimations of external manifestations in respect to the fusions or unions of the scions with these rootstocks give no outward evidence that any variability of a fixed nature exists amongst the rootstocks of the 15 trees, although they have been grafted on to five different varieties. Each rootstock has not only blended its tissues with those of the individual trees of the different varieties in an almost indistinguishable manner, but the growth, health, and general behaviour of the trees are such that up to the present no variable factor appears to be operating through the rootstock.

Although it would seem that by carefully culling the seedling Mazzard rootstocks in respect to their good health and general development, the raising of a tree of high average quality may be assured, the difficulty of obtaining such seeds or seedlings in Australia must ultimately force our nurserymen into the adoption of the use of vegetatively raised cherry rootstocks. The present method of digging up the accidental suckers or stools which arise in the orchards would seem to be a too precarious and haphazard means of supply, and leaves the way open for the introduction or continuance of an unknown degree of variability in such rootstocks.

In the nursery at Blackwood Orchard three types of rootstocks of *Prunus avium* (Mazzard) selected by the East Malling Research Station are being propagated by layering. These are provisionally labelled F 12/1, F 9/1, and F 2/1 by the selectors, but the writer is at present not conversant with their individual origins or merits. Whilst these should be tested for rootstock purposes, it would likewise be advisable for the Horticultural Branch to obtain a number of root cuttings, or of the volunteer stool suckers arising from authentic seedling Mazzard rootstocks on which healthy prolific and long lived sweet cherry trees are growing, and from these endeavour to establish a standard type or types of greater genetic purity for propagational purposes in the future.

[A further section of the report on the State Experiment Orchard will appear in the next issue.]

MEADOW HAY COMPETITION—HILLS DISTRICT.

Commenting on the winning entry, the judge said the stack entered by Mr. Peters consisted of a mixture of Yorkshire Fog, Subterranean Clover, Perennial Rye Grass, and a trace of White Clover; also a trace of Docks and Rib Grass. It was well protected in a closed-in shed, and exceptionally well cured, there being a high percentage of grasses of good quality. Three hundredweights of salt was sprinkled through the stack, and the hay presented splendid colour. It handled well, and was really excellent hay. All hay was carted within a week of cutting.

PAPERS READ AT CONFERENCES.

MID-NORTH BRANCHES, REDHILL, MARCH 14th.

SOME EXPERIMENTS WITH WHEAT AND OATS.

[F. J. PEDLER, Kooluuga.]

The following paper sets out a few observations on the yield and general behaviour of several varieties of wheat and oats which have been grown on my farm. It includes not only yield per acre, but resistance to disease, wind storms, &c.

Where grain yield only is considered, the most reliable variety has proved to be Ghurka, which I have grown for eleven years. This period includes three dry seasons, and two in which red rust was very prevalent, although a few spots of rust appeared on the flag these seasons.

In 1930 and 1932 no apparent damage was done to either the yield or quality of the grain, as Ghurka was the highest yielder in both seasons.

In addition to being rust-resistant, it appears almost immune to flag smut. It is also proof against damage caused by strong winds, the short stiff straw neither breaking off nor allowing the head to shed its grain. This variety is not suitable for hay—it is too short in the straw and is unpalatable. This also applies to the stubble, which even sheep do not care for.

Two other very reliable yielders are Sword and Ranee. Sword is the best all-round or dual-purpose wheat in this district, for, in addition to being a consistently good grain yielder, the variety is fairly resistant to rust and flag smut, and is an excellent hay wheat. Horses prefer it to many other kinds and it also gives good yields of hay per acre. The stubble is also favoured by stock, and makes useful covering for stacks, &c. Sword, however, has the tendency to shed its grain in rough weather. This average yield over seven years is high.

Ranee, first grown in 1928 and supplanted in 1931 by the later selection Ranee 4 H—which proved definitely better than the original—is perhaps a better grain yielder than Sword or even Ghurka, especially when the seasons are below average rainfall. Ranee 4 H is moderately resistant to rust, flag smut, and damage by storms, considering that it is easily threshed. It is perhaps more susceptible to damage by frost than many others. The hay is of poor quality, likewise the stubbles. Currawa, once a general favourite in this district, seems to have been superseded by the foregoing; its yield in the list of results for the last two years is near the bottom.

Quality is one of the early wheats which give fair returns, and is resistant to rust, and has never had a bad attack of flag smut. It sheds its grain very easily and cannot be safely grown in large acreages.

Of the new varieties—some only two years under test—Bencubbin and Dundee have given results which are very encouraging. Neither variety has shown any indication of flag smut, and both thresh easily, yet do not shatter readily. Bencubbin, however, has a tendency to lodge badly with heavy rains on it. As it is a fairly tall grower, it could be utilised for hay if necessary.

Dundee, somewhat resembling Federation, cannot be recommended for hay, its chief virtues being a good yielder and a good quality flour wheat. The yield—equal to that of Ranee in the last two seasons—coupled with its reputation in New South Wales, make it one that I have no hesitation in recommending.

Two selections from Ghurka—G.S. III. and G 2—have given very satisfactory results in both yield and disease resistance. Mogul, a variety which has a good record in certain parts of Victoria and gave fair yields in seasons 1931 to 1933, was last season' disappointing.

Two other varieties which have given fair returns are Calare and Collection. Both, however, are susceptible to a slight attack of flag smut.

[*Papers Read at Conferences.*]

Oats.

Out of a number of varieties of oats which I have grown I prefer the following three as best suited for my own use:—Calcutta Cape, Guyra, and Mulga. Calcutta, although slower growing than either of the other two, is still the best for quality hay in whatever stage it is cut. It is also a reliable grain yielder which is suitable for the manufacture of oatmeal and flaked oats.

Guyra is also a good variety for hay as well as a good yielder of plump grain. It stands up well and retains its grain better in rough weather than any other oat that I have grown.

Mulga is much earlier than either of the former, is very useful for grazing purposes, and stock show a marked partiality for it. It is also useful for hay, although perhaps not so bulky as the former two. As a grain yielder it is capable of big yields of grain with a soft, thin, white husk, and is in demand by racehorse owners. Unfortunately, Mulga sheds its grain very easily, often before it is ripe. Stock also clean up Mulga straw as if it were hay.

MIXED FARMING IN THE FOOTHILLS OF THE FLINDERS RANGE.

[P. Curtin, Beetaloo Valley.]

The occupation on a farm in these areas calls for a greater amount of study and forethought than for the lands on the open plain.

A farm of about 900 to 1,000 acres in the foothills is ideal for mixed farming. It should be securely fenced into convenient paddocks of about 80 acres in extent, or even larger or smaller, if creeks, stony reefs, or hills make them difficult to cultivate. For these reasons great care should be taken when erecting divisional fences. Try and make use of red and blue gum for fencing, but if posts have to be purchased, Myall is preferred.

A team of 11 horses is needed, so that one or two foals can be reared each year, and prevent the team from depreciating. Every care should be taken with their feeding and driving.

About 250 acres should be devoted to wheat on fallow, and about 100 acres of barley and oats could be sown early to avoid interfering with the sowing of the main crop. This could be sown on stubble ground, and, if a success, could be reaped or cut for feeding purposes. Crop every third year—fallow, wheat, grass; and by this method prevent the fallow from washing away into gutters. The ground is always in better

[*Papers Read at Conferences.*]

heart, and returns higher yields, with less workings, than if cropped every other year. There is not much difference in cultivated and ploughed fallow, but the latter in the hills is preferred, because the soil has not the same tendency to wash. Cultivating should be done while there is plenty of moisture in the ground. Avoid dry working if possible, but keep the fallow clean at all costs. The wheats most suitable for these parts are: for hay and grain, Sword, Waratah, Nabawa; and grain, Ranee and Currawa.

In conjunction with this amount of wheat grown each year 500 to 600 sheep could be kept. The plain-bodied Merino is the best sheep for farmers, keeping mostly wethers, as they can rough it better than ewes and lambs. Sheep do much better if changed frequently from one paddock to another. They do not require a great deal of attention, providing they are free from flies.

Dairying, at prices obtained for butter, will not pay on these areas, but it is advisable to keep two or three cows for the home requirements.

Along the ranges there are many choice spots which can be profitably adapted to almost any fruit. Wherever water is available and suitable for irrigation, a garden should be planted. Owing to the ravages of birds and other pests, citrus trees are favoured if suitable sandy soils are to be had. These will return (when in bearing) £2 to £3 a tree on prices obtained over the last few years.

One or two acres of garden peas can be sown every year. These do really well, and often a good price can be obtained. To make mixed farming a success, take on only what can be done well.

Care should be taken of all implements, harness, and tools, for without these being in good order, work cannot be done satisfactorily.

PIGS ON A MID-NORTHERN FARM.

[T. R. WELBOURNE, Narridy.]

It is not intended to discuss all breeds of pigs, but it would be an advantage to the industry if many of the breeds were wiped out. This would enable a more uniform type to be produced and help gain the confidence of the overseas buyer. This is most important, as the Abattoirs requirements are, roughly, 1,000 pigs a week, so that when this is exceeded—as it has been during the last couple of years—breeders must produce what the overseas buyer wants and insists on.

BREEDS.

The Berkshire is the bugbear of the industry. One of the greatest difficulties to-day is to get the man that has been breeding Berkshires to advance with the times and produce something more saleable, instead of putting pigs on the market that bring forth caustic remarks from the buyers. This pig is the wrong shape in almost every way, being too heavy in the head and too thick in the shoulder, carrying too much fat on the back, lacking in length of side, and having large hams which to-day are not in demand.

Recently the Canadian Berkshire has been imported into this State. This pig, crossed with the Large White, should revolutionise the baconers of this State, as it supplies the hams in which the Large White is deficient.

The Tamworth is a decidedly better pig; it shows superior length of side, lighter head and shoulder, and if a producer goes to the trouble of selecting pigs of this breed, he can produce a pig that will command a good price, especially from local buyers.

The Large White is the popular breed to-day. To breed pigs for export, it is most important to have a Large White sire, as the colour is white, and this is essential. This pig's main attraction is its length of loin. It is light in bone, shoulder, and head. Unless breeding for stud purposes, the breed is not recommended, because it falls away too much at the hams.

[*Papers Read at Conferences.*]

TYPES FOR EXPORT.

Remember when producing a pig for export that the loin is the greatest consideration. The longer the better, and the pig must show depth, head and shoulders light, bone fine. and hams shapely but not too heavy. Overfat pigs are not payable, and the best way to tell if a pig is fat enough is to press lightly on its back, and if the backbone can just be felt, it will have the correct amount of fat.

My best results have been obtained by mating the Large White boar with Tamworth and Tamworth-Berkshire sows. If entering pigs in the baconer class at shows, always choose females, as they are better shaped around the hams.

I do not advise anyone to set out breeding porkers for two reasons, one being that the cost of selling and railing to Abattoirs is out of proportion to the amount received, and if a few porkers are needed for home use, there is always a percentage of baconers that are short and fat, and these can be taken off at your convenience.

SELECTION OF BOAR.

Unless going in for stud breeding, there is only one sire for present-day requirements: the Large White, and farmers should ask the Department of Agriculture to inspect the boar. The care of the young boar is most important. Let it be assumed that 20 even suckers have been bred from three sows and your ambition is to top the Abattoirs market with baconers in 20 weeks from birth. I suggest the following hints:—

1. Take the three smallest pigs from each litter and sell them in the market, for these take six to eight weeks longer to fatten than the others.

2. Allow the pigs a large yard with a waterhole in it; this is very necessary, and keeps the pigs free from vermin.

3. At 12 weeks of age take off the six best and feed separately. At 15 weeks, if any of the balance are moving away, take them off and again pen separately. By this

method the first pen will be at the Abattoirs in from 19-20 weeks from birth, the seconds at 22, and the balance in 24 or a little more. If there are more than six pigs in a sty they do not move along so rapidly.

SELLING.

The only outlet for the baconer is the Abattoirs. The cost of selling is approximately 6s.—very high, but unavoidable when the breeder is 100 miles from the market. But there is room for complaint in the lack of information obtainable from the selling agents. Only recently my neighbour and I put pigs in a lorry to go to the railway, and we had to brand them to know them when we got there. In my opinion, the pigs would weigh the same; the only point in my favour was that my pigs showed a little more length, and when we received our statements I had received 57s. and my friend 41s. At present we have no way of finding out why there should be such a difference, and I think the time will soon come when we will need to have a man available to attend the Abattoirs and report on the pigs. It is not of any use experts telling us to produce a certain type of pig if we are unable to have our mistakes pointed out after trying to achieve the required type.

FEEDING.

The following is the method I adopt to put baconers on the market in 20 weeks. Feeding six pigs in a sty, they get 3 gallons of skim milk morning and evening, with as much soaked barley as they will comfortably clean up. Mid-day, soaked barley and a little meat-meal. When the pigs are 15 weeks old the meat-meal is increased to 5 per cent.

The cost of meat-meal is practically nil. The pigs fatten on 4½ bags of barley, whereas, without meat-meal, 5 bags are required. To-day half a bag of barley is worth 3s. 6d., and it would not cost that for meat-meal per pig.

In a Victorian test four pigs were put in a sty and fed on wheat. Four more were fed on barley two-thirds and wheat one-third, with free access to meat-meal. In 90 days the pigs fed on the mixture put on 100lbs. more than the pigs fed on wheat alone. The cost per pound of bacon was the same, as the mixture-fed pigs ate more, but to be able to increase the weight by 25lbs. per pig is a consideration worth noting.

The New Zealand experiment was with regard to Tamworth piglets running with the mother. One litter was kept shut up, while the other was allowed grazing. The closed pigs at eight weeks averaged 22lbs. and the grass-fed ones 35lbs.

FINANCIAL POINTS.

With regard to the financial side of pig breeding, the following figures are given. With six sows and a boar 100 bags of barley for a year will be needed. A sow eats a bag a month and a boar two. Should the sow average eight per litter, the price received per sucker will be the price obtained per bag for barley, so to-day one could reckon on 10s. per bag for barley, allowing that the milk was not accounted for.

If breeding baconers, allow 10s. for a sucker at eight weeks, and if you clear 50s. at 20 weeks, that will allow 40s. for the five bags the pig has eaten, showing a return of 8s. per bag.

Another point worthy of consideration is the number of litters a sow should have. I find that the first six litters are the most profitable. After that, the sow should be sold and replaced. I have three sows that came from the one litter. From the first six litters the average number of weaners was 9.2 and from the next four litters the average fell to 6.7, so it will be seen that these sows have been kept too long.

I desire to draw attention to the Export Competitions that are being held monthly and to which very little support has been given. This is a great mistake, for we have reached the stage when we must seek an outlet for our pigs. What is the use of breeding them if we do not look for a buyer?

[Papers Read at Conferences.]

This competition would obtain more entries if the number of pigs was reduced from 5 to 3. As the average farmer only has enough pigs to clean up the skim milk, five seems to eliminate them and leave the competition to the breeders of large numbers of pigs.

VETERINARY SERVICES FOR MIDDLE NORTHERN AREAS.

[R. J. Rose, Laura.]

At the request and on behalf of the Laura Branch of the Agricultural Bureau, the following resolution is submitted:—"That in the opinion of this Conference veterinary services should be provided for the area included in the Middle Northern Conference district, by the establishment of veterinary lodges, or other means."

State-wide Demand for Service.

At nine Agricultural Bureau Conferences during the last two years resolutions have been carried asking the Government to provide veterinary assistance in various parts of the State. These requests were considered by the Advisory Board, and a committee appointed made a recommendation that the present veterinary staff be strengthened, that the State be divided into five districts—Central, South-East, Murray Mallee, Eyre's Peninsula, and Northern—with a veterinary officer in charge at each centre to be decided upon, the staff to be under the control of the Chief Inspector of Stock, Adelaide. The committee further recommended that the duties of country veterinary surgeons should be to supervise the livestock of their districts, and to that end they should travel about their own districts over a definite itinerary. They should give advice, and if possible, practise as veterinary surgeons when required. For such veterinary work they should make a revenue charge on the basis of a fixed scale, it being understood that no charge for mileage shall be imposed upon those requiring their services.

This report was submitted to the Minister of Agriculture, and supported by a deputation which expressed the hope that action would be taken to give effect to the proposal.

[*Papers Read at Conferences.*]

The committee's report and recommendations were submitted to the Chief Inspector of Stock, who in his report to the Minister stressed the following points:—

That in his opinion there are few country districts within the State in which a qualified veterinary surgeon could not be induced to practise his profession if an organised effort was made by the stockowners themselves by means of a guarantee, or by the establishment of a veterinary lodge.

That the provision of veterinary services by the Government should be for the control of contagious stock diseases, the investigation of serious outbreaks of diseases in animals and for veterinary research.

That the requirements of the State in the above respects should be fully supplied before any consideration is given to an extension of the activities of the Department in the manner suggested.

The Minister informed the Advisory Board of Agriculture that he agreed wiht the opinion expressed by the Chief Inspector of Stock.

From the above summary of actions taken by the Advisory Board, the Chief Inspector's report, and the pronouncement by the Minister of Agriculture, it is evident that, while from stockowners' viewpoint it is desirable that veterinary services should be provided as a State instrumentality, from a general taxpayers' viewpoint it is not desirable. Factors that should be considered include the following:—

The cost to the State of carrying into effect the proposal to locate five qualified veterinary surgeons in country districts, for it must not be lost sight of that if such appointments are made, these officers of a necessity must be qualified veterinary surgeons, with recognised status, and not those who are usually termed "quacks."

In the Commonwealth there is only a limited number of University qualified veterinary surgeons, and consequently they can demand high salaries. It has been estimated that from £750 to £1,000 a year would be involved in the appointment, travelling expenses and other incidentals of a district veterinary surgeon, and in the scheme outlined by the Advisory Board committee the only setoff against it would be revenue from veterinary services.

VETERINARY LODGE SCHEME.

From a stockowner's point of view the appointment and maintenance from general revenue of district veterinary surgeons throughout the State may be regarded as a proposition worthy of wholehearted support, but from a general taxpayer's viewpoint it must be regarded as an impracticable proposal. The only proposal which is within the region of practicability is a co-operative scheme—possibly subsidised by the general taxpayer—such as those now functioning as Veterinary Lodges. Where established they have met with more or less success, which is determined by the principles upon which they are established and the management and administration.

Prior to a Veterinary Lodge being established unanimity must be arrived at on the subject of the qualification of the lodge officer. We are rightly or wrongly living in an age which demands specialisation. The trend of much of present-day legislation is in the direction of "one man, one job," the relegation to obscurity of the "quack," the individual who is jack of all professions or trades and a master or specialist of none. Among stockowners there is evidence of the growth of the opinion that as legislation requires a physician and surgeon who renders service to the human body, the dentist who extracts teeth and supplies artificial substitutes, the optician who supplies aids to defective vision, to possess certain definite qualifications, based on world-wide recognised standards—this should also be made to apply to individuals who practice veterinary science, for fee or reward.

While no serious objection may be raised to an individual or a company of individuals employing a blacksmith, carpenter, shop assistant, or a newspaper reporter to render veterinary service—irrespective of qualifications, real or imaginary—the Government as trustees of revenue derived from the general taxpayer, has a right to demand evidence of qualifications to render adequate service before subsidising payment for them.

Mr. Rose then referred at length to the activities of the Balaklava, Point Pass and Blyth Veterinary Lodges.

HOW TO MAKE SHEEP FARMING PROFITABLE.

[H. J. CROUCH (Red Hill).]

About 12 years ago the sheep and wool industry was much more profitable than it is at the present time, for the reason that formerly taxes, freight, wool handling charges, yard fees, costs, &c., were much lighter than they are now. Little science was required, and not so much judgment, nor was it necessary to be so particular regarding the type of sheep to be raised. It behoves every one now engaged in the industry, to give serious consideration to the many circumstances required to obtain the best results.

Sheep more than most animals, are most susceptible to improvement.

To be successful in a general way it is not necessary to commence with the highest class of sheep, but one should try and start with a useful flock of sheep, large framed, free from body and tail wrinkles, and covered with good wool. Under present conditions it does not pay to grow sheep for wool alone, the size of the carcass must be taken into consideration, and then when wool returns of the flock begin to deteriorate, sheep can be sold to the butcher. It is in the latter point that the present wrinkly Merino fails. It is nearly always necessary to keep them until they are full-mouthed, before they will fatten readily.

Every year the flock can be improved by careful culling, and making sure that the rejects are killed for rations or sold.

The aim of the sheep breeder is to make the flock profitable, and any revenue must be derived from the carcass and wool of the animal.

One of the heaviest losses in sheep raising is caused by blow flies. The sheep that are least susceptible to blow fly strike are those with a straight, square tail, free from tail and breech wrinkles. The progeny of the wrinkly Merino ewe mated with a Corriedale ram is remarkably free from fly strike. I prefer to shear the last week in October, and then crutch in March. The fly first strikes the wrinkly tail and breech, and until a type of sheep is bred with a clean, square tail, and wide rump and breech, trouble with the blow fly will continue.

CONFERENCE OF SOUTH-EASTERN BRANCHES, MUNDALLA, 20th MARCH, 1935.

SEEDING.

[G. D. BUTLER, Wolseley.]

OATS.

The first essential of successful farming is efficient and timely sowing of the seed, and the cornerstone of efficient seeding is adequate preparation for it. It is hard to say just when and where this preparation begins, but for wheat a lot of work on the fallows in the preceding winter and spring is needed. For oats sown on wheat stubble, it is necessary to start earlier, and see that the preceding wheat crop is as free as possible from weeds.

Oats seem to be dependent on frequent rains, and do not relish long spells of dry weather, but their worst enemies are weeds. If the preceding wheat crop is dirty, it is in most cases impossible to grow a satisfactory crop of oats after it. Partial success is sometimes obtained by the expenditure of an unreasonable amount of cultivation. There is not much difference between early and late sowing of oats, between mid-April and mid-June gives about the same results on an average, provided that in all cases, cultivation was sufficient.

To make oat-growing profitable, too much work cannot safely be put into cultivation: it appears that unless fair rains occur in March or April, oats must either be sown dry or combined in at the break of the season without prior cultivation. Often when

[*Papers Read at Conferences.*]

a priar cultivation is possible there is no difference between the crop grown thereon and that on the adjoining land simply combined in. Yet, as a factor in destroying weeds and conserving moisture—as far as possible—this prior cultivation should be done. The springtine combine is the best machine for this work. The work done by the discs and scarifiers looks better, but apparently is not fine enough to make a good home for weeds to germinate or for nitrifying bacteria to work in. There are times when only a scarifier or even a plough can be used, but so long as the combine will do the job this implement is preferred.

It is not advisable to sow on this cultivated land before or just after the next substantial rain that falls on it. Leave it for a fortnight or longer to mellow and for some weeds to grow. Heavy crops have been grown by leaving it until all other seeding was completed.

Superphosphate sown on the oat crop is wasted, it may give an advantage sometimes, but mostly it does not. On dirty land, it is detrimental, for it seems to stimulate the weeds unduly.

These methods are for dealing with the bulk of the soils in this district which have been under cultivation for many years. On new ground, or that which has been out to grass for a long time, oats usually do well, no matter how or when they are sown. During the last 20 years, the Department of Agriculture has imported and bred and tested many varieties of oats, but so far one cannot be recommended to supersede Algerians as a general purpose oat for an average cereal district. But there are many seasons when an earlier maturing oat will yield more grain than Algerian, and there is an occasional dry spring when one such will yield more hay. It is advisable, therefore, to sow at least one-third of the oat acreage with an earlier oat—Fulghum is perhaps the best. On the lighter soils, which ripen their crops earlier, this percentage might be increased. When seeding is delayed by climatic conditions and some oats have to be sown late, an early oat is preferable to Algerian. Farmers who habitually sow some early oats often have their hay carted before the wheat is ready to strip.

WHEAT.

As a rule wheat should be sown only on fallow. Occasionally crops succeed on non-fallow, but it is not profitable to practise a crop rotation wherein wheat is sown on non-fallow every year. On some of the lighter soils a short fallow is often better than a long fallow. For the actual sowing of wheat there is no better machine than the modern combine; but just when to use it puzzles the wisest. The second half of May is usually the best time for seeding in a normal season. After the first week in June it is often too wet. This means that the job has to be done in three weeks, not all fine weather. To sow wheat on heavier lands unless about 2in. of rain have fallen in the preceding four or five weeks, is to invite a partial failure from weeds and take-all. Thus, if May is rather dry, the time is shortened.

Experience has led me to sow as soon as the ground is right, but not before, and take the risk of being held up by a wet June. This risk can be minimised in several ways—(1) always include in the fallow at least a small area of well drained land and sow it last; (2) cultivate this area before weeds are too large; (3) use a rigid-tine combine when it is too wet for the spring-tine; (4) drain and level the land as much as possible. Cultivation is necessary, mainly to kill weeds. The earliest growth is the strongest, and if left unchecked would soon be too strong to be killed by one stroke of the combine. The weeds absorb too much of the most readily available plant food needed by the young wheat plant, and the binding action of the roots prevents that fine division of soil particles necessary for good crops. It is, of course, impossible to get on this cultivated land after the heavy rain that often spoils seeding, and often another rain occurs before it is workable. This second or third rain sets the soil so that a springtine combine does not work well, but the rigid-tine combine does first class work. Nearly always the last sown is the best crop, after allowing for the

better quality of land on which it grows. The alternatives to this procedure are—(1) to sow early and have a crop infested with thistles, wild oats, and take-all; or (2) maintain a plant quite out of proportion to the area sown; neither of which will appeal to good farmers.

A burning question every year is: "Shall the whole of the fallow be cultivated before combining in the seed?" The answer depends on the date and the amount of the opening rains, the density of weed infestation, the general condition of the fallow, the nature of the soil, the strength and plant available, the present weather and the look of what is coming, the probable price of wheat next harvest and the state of preparedness in which the farmer finds himself. As all these conditions are never uniform, either in themselves or in their respective relations to each other, the solution can only be left to the judgment of the farmer. It is advisable to work all heavy or safe land to kill the first crop of weeds, but do not take many risks with those areas most likely to be waterlogged. At least one autumn working is advocated to fill in the cracks made by the heat of summer. A good set of harrows will do this if autumn rains do not warrant a cultivation. Experiments at Longerenong show that prior to 1925 July seeding consistently gave better yields than May-June sowing; being continued until 1930, the May-June seeding consistently gave better results than the July seeding. It was explained that in the years after 1925 the fallows received much better spring and summer working than in the years 1918-25.

VARIETIES.

At present the whole question of varieties is unsettled, by the question of milling quality, but to fill the bags there is nothing better than Gallipoli for the earliest sowing. Ghurka will not compete with weeds so well, but for mid-season sowing it is as good as, or better than Gallipoli, and where a lot of straw is to be avoided it is preferable. For May and early June sowings, no other wheats compare with these. When the growing period is short, as it is when seeding is very late, they do not yield so well as an earlier maturing wheat. Of these early wheats, Ranee 4H is preferred.

Two or three varieties are enough on one farm. If seasons were more uniform, only one would be desirable. Gallipoli is not yet to be spurned, for in those seasons when oat crops are too short and scanty for hay, it will be better to cut than most other varieties. When saving seed, I keep on hand enough Gallipoli to sow one-fifth of the acreage, enough Ghurka for three-fifths, and enough Ranee for the other one-fifth. But in case the seeding may be later than usual, I keep a reserve of Ranee and give it to the fowls if it is not wanted. The seed should be well cleaned of all chaff, straw and other rubbish, particularly of cracked and broken grains. It was once thought settled that grading paid, that the plumpest grain must necessarily produce the best crop, but doubts have since arisen, and many samples of seed badly shrivelled by rust have been known to grow remarkably good crops. I prefer to be on the safe side and grade all wheat and barley, dusting the wheat with about 1oz. per bushel of copper oxychloride.

QUANTITIES.

Fifty to sixty lbs. of Gallipoli and Ranee and 45lbs. of Ghurka are sufficient to sow on my land. On lighter soils these quantities might be increased, but it must be remembered that these newer varieties have a much grater survival ratio than the older ones, and therefore the individual plants need more room. These quantities are not always enough to keep the weeds down, but it is preferable to allow a few weeds to grow rather than crowd the wheat. No drill will sow exactly what it is set to sow year in and year out; each machine should be tested by a weighed quantity of grain each year.

An application of superphosphate is necessary for profitable wheatgrowing: 56lbs. as a minimum and 112lbs. as a maximum for this district is suggested. It is a mistake to put a lot of super on poorly worked land, hoping that the extra super will make

up for the inadequate cultivation. The wheat plant, being unable to get its other food requirements in sufficient quantities is unable to use this extra phosphate. It stimulates wild oats, and so becomes worse than a dead loss. With star feeds, all grades are delivered in "blobs," but as the stars travel faster to sow the larger quantities of the lower grade, the "blobs" are not delivered so far apart. Stars should be set so that not one of them is dropping its "blob" exactly at the same time as its immediate neighbour.

The great point, however, is to be prepared. Many poor crops have been grown in this district because growers were not ready for action when the opening rains came. Have all the super in the shed by at least the middle of April, get the chaff shed full, go through all harness and tackling and repair or replace until it is in strong working order. Examine the combine carefully, get in an extra supply of combine shares, trim and shorten horses' tails, otherwise the long hair is always in the way when grooming and harnessing, chisel down any hoofs that are too long or splitting, on sticky ground remove all shoes, do not overwork the team, horses should be well fed and have moderate work in between harvest and seed time—after a long spell their muscles are soft, the straighter the machine is driven the easier it will be on the team, and the sooner the job will be done.

SOME DIGESTIVE DISEASES OF FARM ANIMALS.

With Suggestions for Treatment and Prevention.

[A. Ross, Mundalla.]

In country districts situated far from professional service, it is absolutely essential that farmers should have some knowledge of the ailments and diseases which are likely to affect their stock. In the majority of cases these people are thrown on their own resources, and in case of sickness among stock, have to depend on whatever knowledge they possess. The treatment of symptoms without a diagnosis is always unsatisfactory, but once an observant farmer has seen and understood a case of sickness in an animal he will generally recognise all similar cases in future. There should not exist in the farmers an implicit belief in drugs. The indiscriminate use of drugs is to be deprecated. Remember animals often recover not because of the treatment but in spite of it.

Diagnosis is the art of determining the nature, location and progress of disease. Without a correct diagnosis it is impossible intelligently to prescribe treatment, hence the importance of ascertaining what ails the animal before proceeding to treat it is apparent. Much more attention is now being given to the prevention and control of disease than in the past. Stockowners are beginning to realise that it is much more economical to keep animals free from disease than to wait until they get sick and then spend both time and money in attempting to restore them to health.

Treatment consists in removing the cause of the disease, and in supporting Nature in her endeavour to combat the malady. It is of no use treating the symptoms only, and allowing the cause to still operate.

MEDICINES.

The different forms in which medicine may be given by the mouth include drenches, balls, powders and pastes (electuaries). Most fluids are given as a drench and they require to be very carefully given. A beer bottle with about 8in. or 9in. of 1in. rubber hose slipped over the neck is good—even better than a drenching bit for this purpose. Only a little of the drench should be poured into the mouth at a time, and the animal allowed to swallow this before giving more. Swallowing can generally be induced by tickling the roof of the mouth. Never interfere with the tongue or pinch the throat or pour anything down the nostril, as this would be almost sure to cause a fatal pneumonia. The head should not be held too high and if the animal gives the slightest cough, the head should be lowered immediately. Cattle seldom receive medicine in any

[*Papers Read at Conferences.*]

other form than the drench, and as a rule, are easy to dose. Medicines are also given to horses in the form of a ball, and this is quite a convenient way, once one is used to it, especially if the horse is awkward to drench. Powders are a very convenient way also of giving medicine to animals, and are usually given in the feed, for which reason they should not contain substances having a disagreeable taste. The feed should be damped slightly and the powder thoroughly mixed with it to ensure the patient receives it all. Soluble substances with little or no taste can be given in the drinking water. Pastes are also a convenient way to administer medicines, more especially if it is dangerous to give it otherwise, or if a local effect is desired. The ingredients are mixed with treacle and smeared on the back of the tongue with a piece of flat board.

The majority of cases of sickness among the larger animals at any rate, appear to be connected with the digestive tract, and can generally be traced to some error in feeding, watering or management.

THE DIGESTIVE ORGANS OF THE HORSE AND COW.

In the cow, the stomach or paunch is so large that it fills up the whole of the left side of the abdominal cavity and a part of the right half. It is compound and consists of four compartments, viz., the paunch, the honeycomb, the bible, and the fourth or true stomach. The capacity of this great organ is up to 40galls.; the first compartment constituting about 80 per cent., except in very young milk fed calves, when the fourth compartment is the larger. The stomach of the horse, on the other hand, has a capacity of only 3 to 3½galls., but what the horse lacks in stomach, he makes up in bowels. Therefore, most of the digestive troubles of the horse occur in the bowels, whilst most of those of the cow occur in the stomach. The large bowels of the horse, known as the watergut and large colon, are often mistakenly called the paunch by the farmer—the horse has no paunch. Food swallowed by the horse passes to the stomach, where it remains only a short time, whilst being mixed with gastric juices. It then passes into the small intestines (about 72 feet), where it meets the bile from the liver and other juices, and the finer parts of the food are absorbed. The coarser parts pass on to the watergut and large colon, where the coarse or fibre parts (cellulose) are broken down by bacterial action and absorbed, the residue passing on to the rectum, where it is moulded into balls, and expelled. Little or no absorption takes place in the horse's stomach.

The cow, on the other hand, greedily swallows her food, which passes into the paunch, which acts as a kind of silo. Some little time after feeding, rumination commences, and the coarser material is returned to the mouth to be thoroughly chewed at leisure and mixed with saliva, when it is again swallowed. The rechewed material then passes to the bible, where all the moisture is squeezed out, and the food further triturated between the horny leaves of this organ, from where it passes to the fourth stomach, where true digestion commences.

[*Papers Read at Conferences.*]

When a cow develops some sudden digestive trouble, a good first-aid drench to give is mag. sulph. 1 to 1½lbs., ground ginger 1½ozs., ammonium carbonate 1oz., treacle ½ cup, water 2 pints. Follow with powdered nux vomica 1 teaspoonful, mixed with treacle and smeared on the tongue twice daily for a few days. For bloat or hoven 1 pint raw oil, 3 tablespoons oil of turpentine and half cup powdered charcoal is good, or a small teaspoon of Condy's crystals in a quart of warm water could be given. A wooden gag, such as a piece of broom handle placed in the mouth and tied to the horns to keep it in position is useful. In very severe cases a trocar and canula or clean pocket knife may be necessary to relieve the tension, but as a rule the gag would be effective; when the acute symptoms are relieved give the saline drench.

Traumatic indigestion often occurs in cattle, especially the family cow. This is due to swallowing foreign material, such as nails, tacks, pieces of wire, wood or bone. In some cases no harm accrues, the article being only discovered on butchering. In other cases the material finds its way to the honey comb stomach, where some of the sharp objects set up ulceration and gradually perforate the wall and work forward to the lungs or heart with fatal result. No treatment is of much use, but the provision of a good mineral lick or mixture will often prevent the trouble.

COLIC IN THE HORSE.

The disease of the horse that is most frequently met with is what is termed "colic," and many are the remedies that are reputed to be "sure cures" for this disease. The term "colic" is applied loosely to almost all diseases of the organs of the abdomen that are accompanied by pain, but in this paper it is intended to deal with diseases of the digestive canal only. Many horses die of bowel trouble while their owners are treating them for water trouble. A horse seldom has water trouble, and if farmers would treat their horses for bowel trouble, they would have far better results. If there is retention of water due to pain or pressure, an exploration by the greased hand will detect the distended bladder, which can generally be emptied by gentle pressure backwards. In any case, when the pain is relieved the horse will generally urinate freely. In the mare the finger inserted in the uretha will cause the water to pass. Never insert any irritating substance in the vagina for this purpose, although a slice of onion may be permissible.

Cases of true colic can be considered as follows:—(1) Spasmodic (gripes), (2) flatulent (wind), (3) impaction colic, (4) worm colic, (5) sand colic. It is unlikely that the average farmer will be able to distinguish one kind of colic from another with certainty, so treatment on general lines is recommended. For the first two the following would be good treatment:—1 to 1½ pints raw oil, 1oz. oil of turpentine, ½ to 1oz. chloral hydrate, and if evidence of much wind, 1 tablespoon of formalin added would retard fermentation. If the above remedies were not available, a nobbler of whisky or gin in a pint of water could be tried, and repeated in an hour, or baking soda and ginger in water followed by a pint of strong coffee might bring relief. In all cases, enemas of warm soapy water should be given every two hours—after back-raking. For impaction colic 1 to 1½ pints raw oil and 4 tablespoons of oil of turpentine well shaken up can be given, followed every two hours by sweet spirits of nitre 1oz., aromatic spirits of ammonia 1oz., treacle ½ cup, water 1 pint, until 3 doses have been given followed by enemas and backraking as before. Repeat whole treatment in 24 hours if no movement. Another word of warning here—never give laudanum when a movement of the bowels is desired, as this drug retards bowel movement.

For Sand.—1lb. honey in 1 pint new milk, followed in 5 hours by the treatment recommended for impaction. Follow up all cases with 1 teaspoon of powdered nux vomica on tongue twice daily for a few days.

For Diarrhoea (Scours).—It is generally conceded that the best treatment is to first remove the offending matter with a laxative drench, and then, if necessary, give astringents in gruel.

[Papers Read at Conferences.]

Inflammation of the Bowels.

In horses, this is a very serious and fatal disease, and generally occurs as a sequel to neglected cases of colic, damage to the bowel by intestinal parasites, bad food, irritant medicines, &c. The interior of the bowels normally swarm with germs of every variety, but so long as the mucous lining of the organ remains whole and uninfluenced by adverse conditions, these germs are of no consequence, and may even be helpful to intestinal digestion. But when anything occurs to damage or depress the cells composing this lining membrane, the germs at once become aggressive. They penetrate into the walls of the bowel, and set up a fatal colic, and permit the absorption of poisonous toxins, &c., into the general circulation. The symptoms are at first similar to colic, but later breathing becomes hurried, the pulse hard, fast and wiry, and the visible membranes become congested. Pressure applied to the abdomen causes pain. The dung has a bad odour, and is often covered with mucous. Such a case is a hopeless one to treat once the acute symptoms appear, but in the early stages might respond to careful nursing. Raw oil, 1 pint, and sweet spirits of nitre, 1oz., could be given, followed in 2 hours by ½oz. veterinary chlorodyne in thin gruel. Hot blankets applied to the belly give relief, but chill should be guarded against when changing. All cases of ordinary colic should be promptly treated in order to prevent this most serious disease.

Bots.

A good deal has been written and said about these "popular" parasites, and they at least furnish the horse-owner with a convenient method of accounting for the death of horses that have died from some unknown cause. Although it is claimed by most authorities that the bots do very little harm while in the horse's stomach, where they attach themselves to the lining of the organ by their hooked mouths and live on the inflammatory products of the small ulcers which they cause, they may cause death in odd cases by being present in such numbers so as to block up the opening into the small bowel (pylorus), and thereby cause a mechanical stoppage, or, in still rarer cases, may perforate the wall of the stomach. Owing to the nature of their attachment, and the toughness of their hides, they are very hard to treat, but carbon bi-sulphide (4 drams in a gelatine capsule) will expel many of them. This drug, however, is very dangerous, and may cause serious damage if unskilfully given; 2ozs. of turpentine in a pint of raw oil, well shaken up and given on an empty stomach, is far safer, but not so effective. Smearing the hair with a strong-smelling repellant or singeing the eggs is a preventive.

Wheat Gorge.

Hardly a year passes without some horses getting at wheat, and if farmers would make themselves acquainted with the treatment for this trouble, and avoid the valuable time lost while waiting for someone else to come, many fatalities would be avoided. As soon as it is discovered that the horse has got at wheat, give ½lb. bi-carbonate of soda in 2 pints of water. Repeat every 2 hours while necessary. Encourage the animal to drink as much water as possible. Three hours after the first drench give raw oil, 1½ pints, and turpentine 4 tablespoons, well shaken, or 1lb. magnesia sulphur. Next day give the soda drench morning and night. If founder threatens, lower the heels, and stand the animal in water all day, and put on soft standing at night. Bleeding at the jugular vein, 3 or 4 quarts, might be helpful.

While patent medicines are convenient, and may contain the drugs desired, they should be used with caution, especially in serious cases. Experience has demonstrated that it is better to treat each case on its own merits with the medicine especially indicated, and to treat the complications as they arise, than to give medicine containing a number of drugs, some of which are certain to be of no value, or even harmful. Besides, they are many times more expensive. The same applies to licks; those made up yourself from recommendations that will be gladly supplied by Government Veterinary Officers will generally give excellent results.

TOP DRESSING OF PASTURE LANDS.

[R. A. DINNING, Mundalla.]

Perhaps this short paper could have been better termed, "Our Experiences in Top-Dressing," as it is based solely upon our dealings with light, loamy soils, and may not apply too well to heavier land. The idea of top-dressing, although for more feed, and better feed, must necessarily be profitable; so the question, "Does top-dressing pay?" covers a wide scope. Referring to the land in its virgin state, the reply is certainly, "No." Then after the land has been cleared and broken up, a heavy dressing certainly makes a difference, but not a payable one. On our class of land, even after it has been under natural pasture for a number of years, the herbage is not dense enough to return the full advantage of the super. By dressing with a bag to the acre the first year, and half a bag afterwards, this land can be built up in 4 or 5 years to quite good pasture; but by sowing some better class of fodders and getting a bulk quicker, the benefit is so marked that it is very doubtful whether it pays to top-dress natural pasture at all.

Land that is sown with Subterranean clover, or, better, with Rye grass mixed with it, with a dressing of 45 per cent. super, at the rate of a bag to 2 acres, makes a wonderful pasture. This class of pasture shows improvement each year up to the fifth or sixth year, when it may be missed for one year, or, better still, be sown with a crop of oats, to get full value of the super used. Unless a paddock is dressed at least 3 times in succession, one does not get nearly the full value of labour. At the present time, super can be applied at less than 4s. per acre, and when put on sown pasture makes the improvement quite payable.

As for the methods to apply it, there is nothing equal to the drill or similar machines for even distribution, but for large areas in a short time a broadcaster on a motor lorry, and even on a light horse wagon is best; 40 acres can be dressed in a day. More than this could be done if the machine spread the distance advertised by the makers, but by driving too wide the area close to the machine is over-dressed, and where only the lumpy portion reaches there is not sufficient, and so leaves the growth very irregular. As for the time to apply, we start in February and continue through the autumn, to get the benefit of the super immediately the rains come, and in the early winter, when the feed is most necessary. We have dressed odd pieces much later, and they always show an improvement so long as there is plenty of moisture; but the earlier the better. As for the heavier classes of land, where cropping is carried on extensively, it is doubtful whether it pays to top-dress.

SIDE-LIGHTS AND SIDE-ISSUES OF PIG FARMING.

[J. T. RYAN, Mundalla.]

The purpose of this paper is to touch lightly a few of the lesser aspects of pig farming, points which in themselves are of little importance, but the sum total of which help a little in the better management of what can become an important sideline. The all-important factors of breeds, raising, feeding, housing and diseases of pigs have been purposely avoided.

"Figures talk" is no less true with stock raising than with banking. Apart from the owner's own interest and educational value, records of all costs and movements are essential when compiling statistics and income tax returns, and the time and worry of keeping such records is a hundredfold repaid for a few minutes spent each night, or twice weekly, recording the day's business.

Mr. Ryan's paper then continued in the form of a series of tables, compiled to show the methods adopted by him to keep a record of all business transactions connected with the breeding, feeding and marketing of pigs.

[*Papers Read at Conferences.*]

The first table, under the heading, "Census of Pigs," showed the number and type of pigs, such as boars, maiden sows, served sows, in-pig sows, dry sows, fattening sows, and pigs of various ages on either the first of the month or at weekly periods.

This was followed by a chart which gave details of the sale of pigs, and included the number sold, age, place and date of sale, agents, highest, lowest, and average prices, gross returns, average live weight, cost of freight and commission charges, yard fees, trucking, carting, insurance, feeding at abattoirs, total charges, and net returns.

The movements of the pigs for other than "sales" were also recorded by enumerating the dates of sales, and to whom sold. Described by Mr. Ryan as "a very essential chart" was a table which tabulated names, dates of service and farrowing, number in litter, and remarks. A simple chart followed. This described the breed and date of birth of the sow, its breeding, and the reason for its sale. A record which should prove of interest and help to breeders was one showing the litter records of the sows. This was plotted out to show the name and breed of the sow, the number of litter, and the number of pigs born and weaned in each litter.

Mr. Ryan considered that his next table, "the breeding summary and weight record of litters," was the most important record, even thought it necessitated the greatest amount of work. It made provision for the following details:—Name of sire and dam, age at service, number of litter, date of birth of same, number of pigs born, and mean and sexes, total weights, average weights, and the weights of weekly and average gains.

The paper then dealt very exhaustively with feeding, the writer setting out in additional tables the class of food, costs, &c., connected with this important aspect of pig raising. Referring to the value of various green fodders, Mr. Ryan gave the following information regarding crops he had grown for this purpose:—

Skinless barley and Berseem clover.—The finest quality, fastest growing early green feed possible to grow in this district.

Silver beet.—Too slow under other than garden conditions; not a success early or late sown.

Lucerne, sown in May.—Splendid germination and early growth, but checked by lucerne flea, and eventually overcome by weeds.

Phalaris and Cow grass.—More or less neglected, but both have possibilities.

Kale.—A hardy, fast grower, relished by pigs.

Pease and Cape Barley.—Splendid spring green feed, but later becoming too coarse. The best practice is to allow it to ripen, and then turn pigs on to it.

Sudan Grass, Imphee, Millets.—Poor germination through rain flooding, but then remarkable growth. Pigs preferred Sudan grass and millets.

[*Papers Read at Conferences.*]

Artichokes and Cattle Pumpkins.—Artichokes are the easiest sown and hardiest of all summer crops; best harvested by turning pigs on to them. Cattle pumpkins not a success under field conditions.

Lucerne, sown in October.—Splendid germination and growth, not worried by flea or weeds, outgrowing both. Recommend heavy spring sowings.

African Sorghum.—A very disappointing crop in early growth, but makes great headway in early winter, and lasts much longer into winter than other summer crops. Pigs like the succulent stalks, but dislike the leaves. This sorghum is extremely hardy, and has good possibilities on selected spots.

MAKESHIFT OR SUBSTITUTE APPLIANCES.

Weighing Scales.

Scales on a pig farm are as important as the measuring can in a dairy or the dairy scales, for unless one is an expert in estimating live-weight, one is only guessing, and when disapproving of prices received, unless one can state the exact weight, you will probably be forestalled by something of this sort, "Your pigs, though an attractive line, were over-weight. They should not be yarded dressing over 145lbs."

To be able to state that "the pigs weighed (live-weight) 180lbs., as compared with 185lbs. the previous week, and as they were the same line under same conditions and feeding, I am at a loss to understand the big difference in value," forces the agent to admit that the difference in price was caused by market fluctuations. Whilst this is not very satisfactory, it is certainly more substantial than to be told that the pigs were not this or that weight, leaving you with a doubtful mind as to whether they were or were not. Furthermore, if weight of litters, &c., food given, rate of growth, and other interesting data are to be kept, scales are an essential. Standard pig scales, however are fairly costly, and with the necessary building in, they are practically immovable, thereby necessitating the use of two sets of scales, for if all weighing is done upon the pig scales much inconvenience and double handling is caused. Therefore, the installation of proper pig scales is not advisable for a beginner.

An excellent makeshift, with most of the convenience of pig scales, plus the added value of being able to use them elsewhere, is found by placing ordinary wheat scales, as are used on most farms, in a race built of cyclone rail or stones. A crate measuring 3ft. high, 5ft. long, and 15in. wide, with three or four drop doors, is then placed upon the scales. Into this crate the pigs are driven, one or more at a time, depending upon the size or desire of the breeder. It is important to remember not to bolt the crate to the scales, otherwise the scales will soon be smashed. The scales are placed on blocks or a concrete bed. We estimate (conservatively) that over 2,000 pigs have been weighed on our scales, and although many were fighters and very rough, the scales are still in good order, and have been carted all over the farm.

Cook-house.

Where food is of doubtful quality it is always advisable to boil it. Raw foods, such as meat and potatoes, must be boiled. For large quantities—for instance, 5 or 6 sheep and a bag of barley—bucket boiling is out of the question. The installation of a boiler sufficiently large to accommodate the above quantity, plus the necessary building in and provision for the oven, makes the job fairly costly.

An excellent substitute is found by hanging several 40gall. drums in an old 2,000gall. tank. If the tank is in fair order it can be made both fly and fire-proof, and as the heat is more or less confined, this cook-house is reasonably economical on wood.

Water Troughs.

Water should never be withheld from pigs; therefore each yard or pen must have its own water trough.

[*Papers Read at Conferences.*]

To buy and instal water troughs is not inexpensive; to build concrete ones is costly, both for materials and time, and in most cases hard to keep clean.

A 40gall. drum cut in halves, or into three lengthways sections, makes ideal water troughs. Placed on four stubs in such a manner that they can be easily tipped up for cleaning purposes, and covered with hardwood, leaving only 2 8in. square openings for each section, they make troughs that in practice are second to none. Where upwards of 100 pigs, or even less, are running in a paddock the first section is provided with a ball-cock, and completely covered with wood; the other sections are connected by ¾in. or 1in. piping. In this case a tipping lid is made, so that the whole of the trough is exposed for cleaning purposes.

GATES.

Here is an item which, to the beginner, presents some costs. For size of opening provided, the cost of installation of factory-made pig gates is beyond all reason. The cheapest, easiest-opening and strongest gate is made from 3in. x 1in. hardwood, two pieces each end for uprights, the spacing for the 6 horizontal pieces being 2½, 3, 3½, 4, 6, and 6in. The spacing may be varied according to the height of the gate. The gate is strengthened with a cross piece. For hinges, 7-16in. or ½in. bolts (not pegs), with one end at right angles for 3in. bolted-through posts and fixed permanently with nuts have proved the best. A sheet steel box with an eye bolt through the centre is fixed to the gate in whatever position is handiest, and then the gate is simply dropped on to hinges. To prevent pigs from throwing the gate off its hinges, one of the right-angle bends is threaded so that a nut can be screwed on when the hinge is through the eye-bolt. This cannot be thrown off, no matter how determined the pig.

Where a large opening is wanted only occasionally, such as biennial thatching of the roof or the ploughing of the paddock, the cheapest and best gate is made by using Walker strainers on all 9 or 10 wires. A few minutes spent in undoing the strainers and throwing back the wire will make a large opening, which can be almost as quickly closed again.

In practice, on short strains of Cyclone the Walker strainers are essential, as short strains soon become very slack. They are quickly made taut again by this method.

It is evident that where other than very small numbers of pigs are kept any trouble not quickly checked might quickly develop into a serious problem.

PARASITES.

Apart from low prices, parasites, internal and external, present no small obstacle. The only internal parasite that caused us any real concern was the long round worm (*Ascarius suis*). After many experiments, oil of chenopodium proved the most effective remedy.

Weekly Application.—The external parasites which for some time caused most trouble and worry were fleas, mange and tick, in that order. For the purpose of this article the procedure has been reversed.

Although tick or lice are easy to kill with any oily mixture, mineral oils are by far the most satisfactory and economical, old sump oil from a car or tractor being 100 per cent. effective. In many piggeries tick continue to exist simply because the oil is not applied regularly enough.

A weekly application of sump oil for a few months will completely kill out this pest. However, our experience has been that sump oil, or any waste oil for that matter, has little or no curative effect upon mange, and does not even inconvenience the flea.

Mange, in many cases, is more unsightly than actually detrimental to the growth of the pig. Those lightly affected apparently receive no set-back, nor does the trouble always spread rapidly, although it may be of the sarcoptic type.

[*Papers Read at Conferences.*]

A mixture of raw linseed oil, good phenyle, and flowers of sulphur will always cure mange, and also kill any tick, and drive fleas off the animal, but it had no power of eradication of the fleas elsewhere than on the pigs. Furthermore, the mixture, although effective against mange and tick, is rather expensive when used extensively.

The flea is the greatest insect curse in a piggery. For a long time a losing fight was waged against this scourge. While many things would kill fleas or drive them off the pigs, it was a long time before anything was found to rid the pens or pig-houses of them.

Even such drastic agents as straw fires and boiling water, which would kill the adults by hundreds, were useless against the covered eggs and larvae, and the sheds were quickly re-stocked by the parasite. Cleanliness could not get rid of them any more than a clean paddock will rid one of rabbits. They and their breeding burrows must be directly attacked, and so it is with the flea.

So serious did the flea problem become that we seriously thought of abandoning this sideline. At that time the fleas were breeding in the sand in the open, and the position seemed hopeless.

After much experimenting and the use of different powders and mixtures it was found that a strong mixture of phenyle and rain water was as good as anything as a temporary measure of relief. This at its best merely would hold the enemy even.

With the idea of substituting crude oil for the more expensive raw linseed oil as an experiment upon mange, we mixed the crude oil and phenyle and omitted the flowers of sulphur. This we knew would kill the tick. The mixture proved successful upon the mange. It was remarkably more effective against the flea than anything else we had used, regardless of its expense.

A badly-infested shed was quickly and completely rid of fleas, and remained so for weeks. An accident to the phenyle tin temporarily forced us to use crude oil on its own, and, to our surprise, it proved a splendid remedy. Used through a force spray pump, crude oil is cheap, practical and remarkably effective against fleas, mange and tick.

That contention is best borne out by the fact that in our piggery of nearly 300 pigs there is not one tick, flea, or a sign of mange or any other skin trouble, and crude oil solely has been used for the past 18 months. A dry, clean dirt floor is preferred by pigs to any other, including well-strawed wooden floors.

While dirt floors are easily kept dry, it is not always so easy to maintain them in clean condition, free from vermin. We regarded that task as almost impossible, but crude oil solved the difficulty. All pens, houses and pigs are sprayed every three weeks.

This frequent treatment might appear expensive, quite apart from the results obtained. With any other method of application but a spray pump it certainly would be. Under test by this method 200 baconers were effectively covered with 2galls. of oil at a cost of 1d. for 7 pigs. We now use considerably less oil, as its spreading properties are remarkable, and it is effective in minute quantities. While crude oil improves the appearance of a coloured pig, it certainly does not add to that of the whites. Where desired, however, the oil is easily washed out with warm suds, leaving the skin and hair very white and clean. Crude oil, too, is harmless to pigs, except when it penetrates their ears under force, thereby causing them some inconvenience or slight suffering, but only for a few hours at the most.

Litters under 7 days have been sprayed without any harmful effects. We are decidedly of opinion that the spraying of a sow with crude oil prior to farrowing is as effective in the control of worms as is washing her with warm suds or an emulsion, and certainly it is ten times as practical.

We are using crude oil in the piggery for several other purposes, with apparently good results. Any reader doubting the ability of crude oil to kill fleas—for that matter, any insect—should smear a little upon them and see the result. We would like to emphasise, in conclusion, that crude oil is not waste or sump oil.

[*Papers Read at Conferences.*]

LOWER NORTH, BLYTH, 28th MARCH, 1935.

MARKETING OF FARM PRODUCTS.

[E. H. LANYON, Blyth.]

Although much time has been devoted to discussing methods of increasing production of the various classes of produce handled by farmers, a little attention could be given to the improvement in methods of marketing. Manufacturers of foodstuffs are compelled by law to guarantee the purity of their products under the Pure Foods Act, and the farmer must realise that the wheat he markets is to be the food of the people.

A great deal of work is put into preparing the land and treating the seed, but many farmers consider that so long as the wheat is in the bags it is fit for market. There is a tendency to-day to put wheat in second-hand bags that are far from attractive. Apart from the appearance of the sacks, the condition is so poor that they will barely stand handling and some are leaking wheat from badly repaired holes. Then there are farmers who do not consider the harm they are doing to their own market by allowing barley, turnip, or Star Thistle to be reaped with their wheat. It will be said that these are at times unavoidable, but it is not good policy to allow this to occur a second time without some steps being taken to eliminate foreign matter from other people's food. The farmer who allows loose earth and sometimes stones to be picked up and bagged with spilled wheat is gaining very little and doing a vast amount of harm to his future sales.

The weather at harvest time is not always what the farmer would desire, but with a little foresight the delivering of bags with wet and mouldy bottoms could be avoided. It is false economy to allow hundreds of bags of wheat to stand unsown in the paddocks waiting for a cool day to sow them. If labour is engaged to sow the wheat and also stack it off the ground, then the carting can be delayed indefinitely, but the quantity of wheat that is spoiled each time there is a heavy rain is much greater than one realises. There is also a danger of white ants attacking the bottoms of the sacks if left standing for any length of time in the paddocks. Careless harvesting can also spoil a good sample of wheat, either by cracking of grain, by improper thrashing, or leaving chaff in the wheat and so spoiling what would be an otherwise good sample.

It should not be necessary to mention bunt or smut, but unfortunately there are still farmers who neglect the proper pickling of seed and so deliver smutty wheat to market, and expect full price for it.

Should a farmer have the misfortune to have his crop pinched by rust or frost, he should be prepared to accept a reduced price, as the shipping of pinched wheat as f.a.q. will only damage future markets.

The Blyth Bureau has conducted Seed Wheat Competitions for about 10 years, the members submitting samples of seed which are judged on a system of points for freedom from weeds, dirt, chaff, and visible admixture; freedom from injury in harvesting; and for plumpness and evenness of grains. There has been a noticeable improvement in the wheat marketed in the Blyth district since the inception of these Competitions and the Branch is to be commended for their inauguration.

WOOL.

The second product of importance in this district is wool, and much could be said for the classifying of farmers clips of wool. If it pays the large pastoralists to engage experts to class their wool from thousands of sheep of an even line, it should also pay farmers to give more time to the classing of their clips.

The farmer who sells wool usually raises lambs for export market, and here again a little more care in the handling of the lambs could be exercised. It may be that the farmer himself is careful at home when picking out a line of lambs for trucking and then sends an inexperienced boy to the station with the lambs, where they are roughly handled in loading, which results in the carcasses being rejected.

[*Papers Read at Conferences.*]

In the Mid-North districts it is hard to keep suitable pasture for cows and so the maintaining of first grade cream or butter is a difficult matter, but it is possible to market the produce more often than is generally done and so obtain better returns.

The handling of eggs could also receive a little more care. The condition in which eggs and butter have been marketed in the past is the reason for the low prices offering for these products to-day, and if more care is given to these matters the results should be more satisfactory to all.

THE STATE'S PROBLEM OF LOW QUALITY WHEATS.

[W. J. MARSHMAN, Owen.]

From time to time in the press, warnings have been issued against the production of low quality wheats, and to the observant mind, these warnings are not to be taken lightly.

The Minister of Agriculture has spoken in no uncertain strain upon this matter, and his opinion has been backed up by the Director, the Principal of Roseworthy College, and by all members of the Agricultural Department. Besides the opinions of our agricultural heads in this and other States, there are the very strong views of the best millers, and even bank managers have become interested in the subject.

One very prominent bank manager of Melbourne has made the following statement in regard to the position in Victoria. He says:—"We are up against trouble with wheat quality following denouncement by the millers of 'Free Gallipoli' wheat for milling purposes. The matter is really a serious one and millers next year may decline to buy 'Free Gallipoli' or may pay 6d. per bushel below normal for it."

Recently at Canberra, the President of the Federal Millers' Association of the Victorian Wheatgrowers' Corporation Ltd., complained bitterly to one of the State Agricultural Directors of the low quality of some of the Australian wheat. They said it was really unsaleable in the British market, and was seriously handicapping millers in one State, both in regard to domestic and export production.

The Advisory Committee mentioned, even went so far as to approach the Federal Government with a request that steps be taken to prevent the cultivation of low quality wheats for inclusion in the f.a.q. standard.

The object of this article is not to create a panic amongst wheatgrowers, but to try and get them see the true perspective and with this idea in mind, seek the views of exporters and British millers. They too, have made most unfavourable comments regarding the inclusion of low quality wheat. One exporter states that he has a quantity of last season's f.a.q. wheat on hand, which contained a large percentage of Gallipoli. There is, he says, no sale for it in Great Britain, because it was below the standard of Australian quality, and because of the danger of weevil infestation, he was selling it in the Oriental market at reduced rates, other than bread making. This action, he says, tends to lower the value of all other Australian wheats.

The second exporter produced letters in Canberra from the manager of his London organization and managers of two of the leading British milling firms. These were all to the same effect, namely, that the wheat is below the recognised standard of Australian wheat and is not required even for fillers. Country millers will not touch it. It is not a question of price; they simply do not want it. Some has been sold for stock feed.

A similar position has arisen in the Argentine and Hungary. Very drastic legislative steps have been taken in these countries to raise the standard, and correct the trouble which has arisen as the result of the production of inferior quality, but high yielding wheats. Twenty-four varieties in Argentine have been suggested as unfit for milling. Prior to the Great War, Hungary produced wheats that were among the strongest in the World.

[*Papers Read at Conferences.*]

During the War, greater stress was laid upon quantity production, and quality was brushed aside for the soft wheat types with the big yellow kernels, with a high starch content, and a big wheat yield.

At the end of the War—when American hard wheats were again imported by the central European States—Hungary found itself in a difficult position, with large quantities of soft wheats on its hands, which nobody wanted in Europe, since every country in Europe produces enough soft wheat for its own requirements.

THE POSITION IN THE ARGENTINE.

In the Argentine a National Wheat Commission has been created which (1) controls the entire trade in grains; (2) shall establish certain wheat types for the various districts in accordance with the wheat production of those districts, and shall lay down the zones in which the different wheat types are to be produced; (3) the breeding stations may not distribute new grain varieties before the express permission of the Ministry of Agriculture has been obtained. The Ministry will then decide if, and in which districts of the country, the particular varieties may be cultivated; (4) the Ministry of Agriculture will permit the cultivation of new varieties only in those cases where the latter promises a decided improvement over existing types.

An Argentine report, dated 1st February, 1934, has reached Australia and extracts state that the position is extremely serious, and no longer can we assume that Australian wheat is required on the European market solely because of its colour, bloom and dryness.

The Director of Agriculture in Western Australia states:—"In the past the Departmental policy has been not to place any restrictions upon the varieties which farmers shall grow and shall be included in the f.a.q. standard. In future, owing to the position which has arisen, I feel that in Western Austsralia—and indeed throughout Australia—this policy cannot be pursued without injury to the wheat industry. Western Australia has grown thousands of acres of Gluclub, of about the same test and quality as Gallipoli, and the Department is doing all it can to discourage farmers from continuing with it. Last year the area under Gluclub was 316,830 acres.

In an article dated Adelaide, 7th January, the Minister for Agriculture said that at a conference of Ministers at Canberra it had been decided to advocate growing of higher quality varieties. All Agricultural Officers are much concerned about the position and are doing valuable educational work in this regard, and the Chemistry Department is testing wheat for milling quality.

Under the heading "Effort to Improve Quality of Victorian Wheat," Melbourne, 27th February, 1935, appears the following:—Declaring that it was a matter of vital importance to the community, the Premier (Sir Stanley Argyle) said to-day that he intended to have an immediate investigation made into the quality of Vctorian wheat. "I am strongly of opinion," he says, "that salvation for all producers lies in maintaining quality." "We have," he says, "produced the highest quality wool, and magnificent types of sheep, and have tried to build up the flocks and herds, and it is reasonable that we should see that the great importance of the wheat industry is not allowed to be affected by the breeding of an unsuitable quality of wheat."

Dr. Callaghan, Principal of Roseworthy College, says:—"From my personal contact with most of the millers of this State, I am perfectly satisfied that they are very sincere in their desire to obtain varieties of higher baking quality. It is evident, therefore, that there is a happy future for a variety or varieties of wheat possessing good quality provided they have yielding ability sufficient at least to compete with high yielding varieties of poorer quality."

Mr. A. R. Hickinbotham, Lecturer in Chemical and Physical Sciences, of Roseworthy College, says:—"The important constituent in bread making is the gluten, and each variety of wheat tends to have a characteristsic amount of gluten of a good or bad

[*Papers Read at Conferences.*]

quality. A large amount of good gluten allows the dough to absorb more water, and therefore makes more loaves for each bag of flour. It enables the loaf to stand up well, and hold more of the gas formed by the yeast, so that the loaf is larger and looks better, and it confers on the bread a more silky texture and resilient crumb.''

At present in the laboratories, the Department of Agriculture is testing thousands of varieties by the Pelshenke system, which is as follows:—A small amount of grain is ground into wholemeal, and to 5 grams of the meal 2.5 per cent. of a 10 per cent. solution of yeast is added. This is mixed and kneaded with the meal, and rolled into a ball, and placed in a vessel or beaker containing water held at 31°C. The ball sinks, but, as gas is evolved by the action of the yeast, it rises and expands, and finally ruptures and falls to the bottom. The time from when the ball is placed in the beaker to when it breaks is given as the Pelshenke test figure. The higher the figure, the better the quality.

Taking Gallipoli grown in South Australia and Victoria, and Gluclub in Western Australia, the tests of these varieties are very low indeed, ranging from 23 to 27. The popular Nabawa also shows a very poor test from 31 to 41 according to rainfall and soil conditions. Gluyas Early, another poor quality wheat, as low as 26 in the Laura district and about 35 at Roseworthy; King's White, about 37.

In the writer's opinion, it might be well for us to seek for varieties of a higher milling quality, such as Dundee, with a test of 60; Aussie, 117; Crostam, 65; Ford, 60 to 80; Ranee 4H averages between 50 and 60; Sword very irregular, but some tests according to selection showing as high as 58 and 60.

It is difficult to lay down a hard and fast rule as to what should be the minimum as regards test. Personally I would say about 50, and in seeking to remedy the difficulties confronting us, whatever courses we adopt, the improvement of our f.a.q. qualities can only be gradual.

The Remedy.

Firstly, let us cut out altogether growing those varieties of very low gluten content that have placed us in the present difficult position.

Secondly, let us seek amongst those varieties that do show better milling qualities (and there are quite a number of them) for wheats suited to the various districts that will tend to raises the present f.a.q. standard.

In the third place, let no new variety be issued by the Department of Agriculture that does not come up to the desired standard as set by the Minister or Director of Agriculture for general cultivation.

Whatever standard might be fixed for home consumption, let us see to it that a genuine and earnest effort is made to improve on the present low quality of many of the Australian types of wheat for export overseas.

MIXED FARMING.

[H. Bradley, Owen.]

With wheat at such a low price the present-day farmer is at a loss to know what to do for the best. A short time ago the Premier said ''Grow more wheat,'' and at that time the G.P.O. stamp had this wording. Farmers grew more wheat, and the result was by no means satisfactory.

It is necessary to go further back to discover the fault which was made by an overseas country. By holding back their wheat exorbitant prices resulted. European countries commenced wheat growing in order to keep their people, and so brought about over-production. Prices which only about 10 years ago were in the vicinity of 5s. 6d. per bushel (Australian quotation) have now come down below normal, and farmers must do something different in order to bring about a lower wheat production. We can grow more oats and barley. These have proved fairly satisfactory methods. One

[*Papers Read at Conferences.*]

thing in their flavour is the very high yield which can be obtained, but only through thorough working operations. With wheat at 2s. 6d. per bushel it can be grown with profit, providing, of course, that the land be freehold.

In almost every district farmers are being sold up, either by misfortune or bad management. However, there are quite a number who have not given up in despair. They have adopted another method, namely, mixed farming. These last few years the farmer who has adopted mixed farming is doing the best thing. Certainly, there is not much to be had from the sidelines, but every little helps.

Wheat Growing.

Take, for instance, a man who has a holding of 600 acres. He could have 150 acres under wheat, 150 fallow, leaving 300 acres for oats and barley. In this district, where the average yield is around 15bush. per acre, the crop on 150 acres would turn in 750 bags; take 75 bags out of this for seed and 25 for fowls, the farmer could sell 650 bags, which at 2s. 6d. a bushel would be worth £243 15s. 6d. Out of this amount must be taken the cost of 8 tons of superphosphate £32, cornsacks £22. For the power farmer, £35 for fuel, working expenses, interest on capital and depreciation on plant should not be more than £130, leaving the farmer with £24 15s. approximately.

The best practice is to plough a piece of ground for the cereal crops. Most farmers have a tendency to slum this part of their work, and about seven out of ten farmers in this district drill oats and barley on land which has been previously cropped with wheat. This is not sound, and more than once it has been a complete failure. For instance, a farmer, after burning off the wheat stubble, waited for a rain and drilled with oats. When harvest came they were hardly worth reaping, the yield being about 2 to 3 bushels.

Another sowed oats on fallow. They yielded 30bush. per acre. There are, of course, exceptions. I have seen 30bush. oat crops on stubble, but it is unusual in this district. It is suggested that a farmer plough up 100 acres with the first rains, then harrow and drill oats, sowing 60lbs. seed and 90 to 120lbs. super. Fifty acres of oats are all that is required for hay for cows, and some to reap for seed.

Barley in its turn is another source of income, and on the remaining 50 acres of early fallow sow malting barley. This, sown at the rate of 40-60lbs. per acre and formalin-pickled should, under average conditions, yield from 21 to 50bush. per acre. Ninety pounds of super are necesary for good results. After reaping, put 150 bags in the barn; 25 bags are enough for seed for the next crop, leaving 125 for pigs, and carry over if necessary. This should leave the farmer with 100 bags to sell. Two hundred acres are left on which to run sheep and cows, having, of course, 150 acres of fallow for the forthcoming crop. With 200 acres left the farmer can comfortably feed 8 cows and 50 ewes.

[*Papers Read at Conferences.*]

SHEEP.

Large-framed plain-bodied Merinos are the best breed for fat lamb raising. If possible, the selection should be made from a flock of 100 or more, for by so doing the desired type could be picked. It would pay for the trouble, even if the seller wanted 2s. a head more. This class of ewe, mated with the Dorset, Lincoln, or Southdown ram, will give excellent results. Moreover, the lambs by these rams out of the Merino plain-bodied ewe will not be wrinkly, and if fed properly on good grazing land, will turn in a price exceeding by far that for the pure Merino lamb.

To illustrate the importance of fat lamb raising, I give the following account of my experience. In January, 1934, I bought a line of 50 Merino ewes out of a flock of 150. They had been mated to Dorset and Suffolk rams. On arriving home with them I breeched them and turned them on the stubble, where they stayed until lambing. Owing to late rains I was unable to paddock them for about a fortnight, so fed them on chaff. At the end of four months lambs averaged £1 0s. 3d. a head at the Abattoirs. I kept the ewes on grass until shearing. They were shorn in September, and at one of the early wool sales the fleece wool was sold at 8½d. lb. Here again I would advise farmers not to put woolly or shorn sheep on fallow. It is not sound practice. Before shearing, if sheep have been turned on fallow, they are always full of dust, and after shearing the wool is coated with dust. If farmers want a good price for their wool they must take care of it and not neglect the sheep.

If lamb raising and wool growing are to be carried out with success every effort on the farmer's part should be made to secure good prices. I suggest that the 2, 4, and 6-tooth ewes be kept for the purpose of lamb raising and wool growing, and as they rise "full mouth" sell them and buy young ewes to take their place. It is a good plan to shear before barley grass seeds fall. This seed in particular is bad for the sheep.

Two years ago sheep which had been grazing on barley grass until the seeds fell were shorn. They were crippled and in some instances the seeds had pierced under the flap in the sheeps' eyes which temporarily blinded them.

In the last few years flies have been a menace to sheep. If possible, it is a good plan to breech twice a year. This eliminates the pest considerably. After shearing, flies seem to be at their worst, and the only thing to do is to keep them as clean as possible, and use good fly oil. Cooper's milk fluid is a very effective disinfectant.

PIGS.

I favour the Large White for breeding. A pure-bred boar crossed with sows of the same breed or half-bred sows are very successful crosses, and if the sows are not too weighty, they have a better chance of rearing big litters. Pigs which do not have milk as part of their diet lack bloom. Here is the only place where cows are a little profit to the farmer. They do not pay for the food they eat, apart from providing milk for pigs. Four breeding sows are enough for the farmer to care for, and they should average two litters a year each. A fortnight before a sow farrows it should be fed mostly on milk and other slop foods, and when a sow has farrowed, feed on 1½ to 2galls. of skim milk mixed with two double handsful of bran and just a little barley for each feed. Feed three times a day. When suckers are three to seven weeks old they look for feed apart from the sow, and milk and soaked barley is their main diet. At eight weeks they are fit to sell, and at present prices should be worth 12s. to 18s. each.

POULTRY.

Lately egg prices are a little firmer, and if eggs are cheap, a certain amount of profit can be made. The average farmer feeds his fowls on wheat all the year round, whereas if he went to a little more trouble and fed them on a pollard and green feed mash in the morning and wheat at night he would gather more eggs at the end of the day. The White Leghorn seems to be the most popular breed; 100 laying hens is quite a handy number in conjunction with the other sidelines.

(*To be continued.*)

DAIRY AND FARM PRODUCE MARKETS.

MESSRS. A. W. SANDFORD & Co. reported on 1st May, 1935, as follows:—

BUTTER.—The beneficial rains during April very much improved the outlook for dairying in this State, and in most areas the feed is showing up nicely. As a result, production is moving upward and the cream supplies to the factories have not only improved in quantity, but also in quality. There is now sufficient local choicest butter for trade requirements and a surplus of first and second grades, so that increasing quantities will be exported from this outlet. Values have continued steady in the Adelaide markets, but there was a slight improvement in London rates. Present local values are:—Choicest creamery fresh butter, in bulk, 1s. 4½d.; prints and delivery extra. (This price is for local sale only and, under the quota system, the equalised price manufacturers will receive will be 11.875d. per lb., on which basis payments to cream suppliers will be calculated. Separator lines, from 9d. to 1s. 1d. for choicest; stores, 6d. to 8d. per lb. (These prices are subject to equalisation levies.)

CHEESE.—In the South-East conditions are very favourable and the minimum of production was reached last month, and milk supplies are now increasing. Rates have continued steady and good clearances were effected from week to week. Values are:—Large and medium, from 8½d. per lb.; loaf, from 9d. per lb., at store door, delivery extra; semi matured and matured, 10d. to 10½d per lb.

EGGS.—As is usual at this time of the year supplies are very short, but they are more than sufficient for local needs so that shipments have been made to Sydney fairly regularly. As in most areas the moulting of the birds took place early it is expected that an increase in production will result earlier than usual this year. Present rates are:—Ordinary country eggs, fair average quality, 11d. per doz. net; long distance rail or shipping eggs, lower; selected new laid clean eggs, 1⅞ozs. and over, to 1s. 2½d. per doz. net.

BACON.—All consignments met with steady turnover throughout the month and consumption has improved. Rates remain unaltered at:—Best quality sides, 9½d. to 9¾d. per lb.; middles, 10½d. to 11d.; heavy middles, 9d. to 9½d.; rolls, 9d. to 9½d.; hams, 1s. 1d. to 1s. 2d.; cooked, 1s. 3d. to 1s. 4d. per lb.

ALMONDS.—Heavy supplies were marketed throughout April, but interstate and local trade readily absorbed all that were offering and demand still continues satisfactory at:—Softshells and Brandis, 8½d. to 9½d. per lb.; hardshells, 5d. to 5½d. per lb.; kernels, 1s. 10d. to 1s. 11d. per lb.

HONEY.—The stocks on hand from last season are still heavy and market is somewhat dull. Sales have hardly kept pace with the incoming consignments and values are without change, being:—Prime quality clear extracted, 2½d. to 3d. per lb.; lower grades, 1d. to 2d. per lb.

BEESWAX.—Met with ready sale at quotations:—1s. 4d. to 1s. 4½d. per lb., according to quality.

LIVE POULTRY.—Sales are held every Tuesday, Wednesday, Thursday, and Friday and our sale rooms are the best equipped in South Australia. Clearing sales arranged in any part of the State. As is usual after the Easter sales, supplies fall back and values for some lines improve. Much heavier quantities could be placed satisfactorily and, therefore, we advise consigning. Crates loaned free on application. The following are prices realised:—Prime roosters, 3s. to 4s.; nice conditioned cockerels, 2s. 6d. to 2s. 11d.; fair conditioned cockerels, 1s. 9d. to 2s. 5d.; chickens, lower; heavy weight hens, 2s. 6d. to 3s. 3d.; medium hens, 2s. 1d. to 2s. 5d.; light hens, 1s. 9d. to 2s.; couple of pens of weedy sorts, lower; prime young Muscovy drakes, 3s. to 4s.; young Muscovy ducks, 2s. to 2s. 9d.; ordinary ducks, 1s. to 2s.; ducklings, lower; geese, 2s. 6d. to 3s. 6d.; goslings, lower; turkeys, good to prime condition, 8d. to 10½d. per lb. live weight; turkeys, fair condition, 6d. to 7½d. per lb. live weight; turkeys, poor and crooked breasts, lower; pigeons, 2½d. to 3½d. each.

POTATOES.—New season's, 7s. 6d. per cwt.

ONIONS.—New season's, 8s. 6d. per cwt.

INDEX TO BUREAU REPORTS—*continued.*

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator *v.* Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

ROTATION OF CROPS.

[*Paper read by Mr. D. Telfer at a meeting of the Dudley Branch held on March 19th.*]

Attendance: 12.

There is scarcely a text-book on agriculture, no matter in what country it was written, which does not devote a chapter to this important subject. It is regarded by the writers, be they English, Americans, New Zealanders, or Australians, as quite as important a part of agricultural practice as fallowing or manuring. They do not all advocate the same rotations, but they all agree on several points, and it is worth while to consider them.

First, they observe that when land is first opened up no attempt is usually made at any rotation, while in older countries fairly complex rotations are very strictly adhered to. Some indeed go so far as to say that the state of development of agricultural practice in any State or district is indicated by the complexity of the rotation generally adopted. In other words, they say that if no rotation was practised, it is a sign that the farming methods were primitive.

There are several reasons why rotations are important, but some of these certainly do not apply here. In England, for instance, the rotation is turnips, barley, clover, wheat, and one of its main virtues is that barley and wheat take their nutriment and moisture from fairly deep down, while turnips and clover feed only in the surface layers of the soil, and thus the soil is used up more evenly. But here we are restricted to winter growing crops and for the most part to cereals, and so we cannot avoid feeding fairly constantly on the same layers of soil.

Again, it is said that by growing a variety of crops work is more evenly distributed throughout the year. In rich, irrigated areas, such as parts of the South-East, where summer crops can be grown, this is certainly so but under our conditions the thing which more than any other, makes it difficult to follow a definite rotation is that we do not always get good early rains to enable us to work up stubble land.

Again, where such crops as sugar beet or potatoes can be grown, the frequent cultivation which they must receive during the growing period is a great advantage in cleaning the land of weeds, but we cannot grow any crops which require inter-tilling on a field scale, and so this advantage, too, is nullified. There are reasons, however, why rotational cropping is worthy of consideration. One is that it facilitates the control of certain diseases, notably take-all and flag smut. Wheat is our main revenue crop, and the rest of our farming practice must be adapted to the needs of the wheat crop. It is well-known that take-all and flag smut cannot be controlled, much less eliminated by pickling. They must be starved out of the soil. A clean fallow before the wheat crop is essential, but take-all cannot be starved out in one year. If the land is left out to pasture, barley-grass will almost certainly appear and serve as quite a good host for takeall spores. And so it is essential to introduce a crop of oats before the fallow, and if the oats are preceded by a crop of peas, they will benefit greatly from the accumulated nitrogen, and there will be no host for the disease for three consecutive years.

The other most important aspect of the question is the maintenance of soil fertility. I believe it is a common experience locally that the land is much tighter and harder to work than it was 15 or 20 years ago, and this is due almost entirely to the rapid exhaustion of supplies of organic matter in the soil. Apart from making ploughing a heavier and more costly job, this has a direct influence on the effectiveness of fallow. It is well known that during a period of fallow, nitrogen is added to the soil, but perhaps not quite so well-known that the tiny organisms which take the nitrogen from the air and convert it to a form available to the plants

actually live on the organic matter of the soil. They must eat if they are to live and work, and their food is humus-decaying organic matter.

By working the soil, we admit air from which the nitrogen is drawn, but if the amount of food available for the bacteria is steadily reduced, their numbers and their vigour must also be reduced, and there must be a corresponding reduction in the amount of nitrogen available for the crop. We must feed the bacteria so that they can feed the crop. The practice of alternating wheat and bare fallow is very exhausting for the supply of organic matter.

Another practice which is fairly common is the adoption of a three-course rotation, fallow, wheat, pasture. From the point of view of the wheat crop and the soil this is, of course, far better than the alternation of fallow and wheat, but it has its drawbacks. The most obvious is that it provides only one revenue crop in three years. This is a small point in light mallee land, and the practice might well be carried out there, but where land is £12 or £15 an acre it places a heavy burden on the wheat crop which must pay for the bulk of three years' rental of the land.

Moreover, we cannot expect a good growth of high quality forage on our land following a wheat crop. On a recent visit to Roseworthy Agricultural College we saw that there, in a good season at any rate, a really wonderful growth of fodder may be developed. Whether a heavier application of superphosphate would make a difference here is a matter requiring experimentation, but as a rule the returns from a paddock left out to pasture are rather meagre and so it is necessary to charge nearly three years' interest to the wheat crop. Moreover, the benefit to the soil resulting from the droppings of sheep and cattle can only be proportionate to the amount of feed grown. The maintenance of soil fertility is very largely dependent on keeping as many stock as possible.

The sowing of fodder crops is then necessary if we are to keep on farming our land successfully. At the present time there is no more profitable sideline than raising fat lambs and there is no better forage crop which we can grow here for them than field peas. Peas not only leave the soil richer in nitrogen, but, if grazed, supply a surprising amount of fodder, and besides raising first-class meat and wool, the land is greatly enriched in organic matter by the droppings of the sheep. The inclusion of peas in the rotation thus provides a record revenue crop immediately following the wheat, besides maintaining soil fertility. The chief drawback is a tendency to foul the land with wild oats. If wheat is to be grown after peas, cultivation is generally necessary to secure a clean crop. It is probably better to sow oats, which may be expected to yield heavily and may well be cut for hay or ensilage. If left for grain, they should provide a fair revenue crop or form excellent reserve of concentrated fodder. Barley might be grown instead of oats, but as it is subject to take-all and flag smut, oats are more beneficial.

In the fifth year the land may be left out for grazing, which one would expect to be fairly good following oats or barley, especially if dressings of super in previous years have been fairly liberal. An alternative would be to grow wheat after peas and follow the wheat with oats, which should be grazed, or again the oats might be cut or reaped and the land left out in the sixth year.

Stockraising must play a very important part in agriculture if the fertility of our soils is to be maintained and wheatgrowing is to be permanent. One thing is very plain. A man cannot adopt a five or six course rotation if he has only two or three paddocks. Subdivision of areas must go hand in hand with the development of a more complex rotation. Temporary fences are worthy of consideration at the present time when capital is scarce. It is all a question of economy, but a rotation on somewhat similar lines to those indicated will eventually prove most profitable in this district. Such a system would maintain the fertility of the soil at a fairly high level and should thus be permanently profitable.

YORKE PENINSULA DISTRICT.

ARTHURTON (Average annual rainfall, 16in. to 17in.).

February 7th.—Attendance: 14.

HARVEST REPORTS.—Mr. S. Henderson reported that his crop had been disappointing. His best fallow had not yielded as well as poorly prepared fallow. Of the wheats grown, Aussie proved best, with a yield of 10 bags to the acre. Barley also was below average. Mr. S. Brine said in the Port Clinton district crops did not finish well. Up to a certain stage they appeared fair for the season, but failed to maintain the earlier promise. Merriden wheat returned 20bush.; other varieties were lower. All wheats except Early Gluyas shed badly; Gluyas lodged badly. Barley averaged 17bush., and was A1 sample. Mr. R. W. Burns said Ford on land fallowed with the combine gave best results. Barley returned 7½ bags per acre, while other on good soil away from the coast returned 2 bags per acre less. Both samples were A grade. Mr. P. Roads reported fair crops, Dan variety being the best. Wheat and barley averaged about 7 bags per acre. Mr. C. Hicks considered the season ideal for barley in sandy soils; his best crop yielded 13 bags per acre. Wheat returned 6 to 7 bags. Ranee was the best variety. Mr. L. Clasohm reported fair crops, considering the dry spell during seeding time. He had to use a culti-packer to get the land fine enough for seeding. Sword was the best wheat. Mr. E. Clasohm said Sword and Ranee proved his best wheats. He considered it was a mistake to grow more than two or three varieties of wheat each year. Barley returned 7 bags per acre. Mr. Noble said Arthurton had sent in some of the finest samples of wheat seen in the wheat yards. One sample weighed 65lbs. per bushel. A bulk sample taken from the district averaged 62½lbs. per bushel. (Secretary, T. Howlett, Moonta.)

Harvesting operations, Messrs. T. Rodda & Sons, Yorke Peninsula.

FIRE FIGHTING.

[Paper read by Mr. R. BURNS of the Arthurton Branch of the February Meeting of the Boor's Plains Branch.]

A historic review of fire reveals the fact that primitive man regarded it as something evil, malevolently supernatural, something that would endanger his life or destroy his environment. But gradually man learned the art of kindling and using fire, and to-day fire plays an important part in life's affairs.

Fire under control is essential to man's comfort. In almost everything we do we depend on fire in some way or other. Fire is essential in the cooking of meals, the lighting of cities, streets, homes and motor cars, the warming of rooms, etc., and every internal combustion engine requires fire to enable it to function. We depend on fire to consume rubbish and all unnecessary straw, grass, and wood in our paddocks, etc. The debt civilisation owes to fire is incalculable, for without it modern civilisation would not have been possible. Wonderful as fire is when under control, it is invariably a menace and a source of tremendous danger when out of control. Fire is a good

servant but a bad master. In our own State extensive damage and ruin is wrought by fire. Nearly every year uncontrollable fires rage in the Mt. Lofty Ranges. These bush fires often destroy valuable farms and homes are burnt and completely destroyed, rendering the unfortunate homeless, and not infrequently, human lives are sacrificed.

If a fire breaks out in a wheat growing district at the beginning of harvest a farmer may lose all and receive nothing for his labours, consequently he may thus be ruined. So it is necessary for the sake of all to take every conceivable precaution and exercise every preventive measure to ensure safety at all times.

The causes of these ruinous fires are a subject for very serious thought. There are many different ways in which a fire may commence. One authority has affirmed that 95 per cent. of fires are due to human agency. Of this percentage 90 per cent. is attributable to ignorance and carelessness.

Some tractor operators are guilty of working their engines without effective spark arrestors. Most up-to-date tractors are easily fitted up in this direction, and if so equipped the risk of fire will be eliminated. Frequently outbreaks of fires are caused through smokers carelessly tossing out lighted cigarette and cigar butts into dry grass. In December last a tree was struck by lightning and the surrounding crops were in danger of being destroyed, but the efforts of the Fire Fighting Association proved successful in extinguishing the outbreak before serious damage was done.

Fires are often caused by the carelessness of people burning grass and rubbish too near haystacks and crops, etc. The most serious and offensive cause of fire is that which is done intentionally. Such cases as these should be followed up and the offenders severely punished. It is foolish for a man to say he will never have a fire on his property because he is always so careful with everything connected with fire. Fires sometimes originate from the most unexpected quarters.

The old saying that prevention is better than cure surely applies to this subject. Firebreaks are an imperative necessity. Before attempting to burn a paddock, a good clean break should be made. No hard and fast rule can be laid down concerning the width of breaks. These must be determined by local conditions. A 12ft. break is generally considered adequate in these districts, so long as care is taken in every other direction. Before using the mouldboard plough—which is the implement usually used for this class of work—the break should be thoroughly cleared of all inflammable material. When intending to burn a paddock, a man should notify adjoining farmers. Suitable weather should be selected for unfavourable weather conditions sometimes prove disastrous. Under ordinary circumstances 3 or 4 men should be on the spot at the time of lighting. Holiday makers and campers should only light a fire to boil the billy on a prepared spot, and should see that the fire is thoroughly extinguished before leaving that spot.

Many districts can boast of an organised fire prevention and fire fighting committee. Bush fire legislation, the most recent being the "Bush Fires Act, 1933," provides for the legal constitution of such bodies. Under this Act, Fire Control Officers up to 15 in number from residents of the area in which they may exercise their powers, with an additional 15 from adjacent areas under conditions defined, may be appointed. Only men of representative character capable of leadership should be selected, the utmost care on the appointment of such officers being essential. It will be found that volunteer fire fighters will work willingly under leaders in whom they have confidence.

A member of the fire committee should be appointed to receive notice of a fire outbreak. It is his duty to telephone all controllers within a reasonable distance of the outbreak, notify landholders and do everything possible to hurriedly organise parties of men to hasten to the point of danger. Co-ordination between Intelligence Officers, Telephone Exchanges and Broadcasting Stations is a factor which makes for success. Spades or shovels and rakes and plenty of water should be taken to the scene of the fire.

Shovelling sand on to the fire is a good method of extinguishing the flames. Once at the fire, the local Controller immediately takes charge. Knowing the lay of the country he would decide on a plan of action. If the outbreak be on a large scale, a

system of breaks may be decided upon. This plan must be worked so that no overlapping takes place. Visiting Controllers would be wise to follow the advice of the Local Controllers and all volunteers on arrival should immediately place themselves under the control and direction of Fire Controllers. If a fire breaks out where there is no firefighting organisation, once the alarm is given—so long as it is not a false one—people should rush to the scene with the necessary equipment with all possible speed and do all in their power to suppress it.

However, people are not generally lax in this direction, and it behoves all who have anything to do with fires at all to take every possible precaution to prevent disasters and thus save the public of the terrible and strenuous ordeal of firefighting.

[By Mr. T. H. HOWLETT, Arthurton Branch.]

One might truly say that many of the most disastrous fires which exhausted the last ounce of strength and energy of fire-fighters, destroyed valuable properties, animals and bird life, and even human life originated from lack of knowledge concerning the danger of fire. It seems almost hopeless when men past middle age who possess more than average intelligence calmly light a pipe or cigarette, or throw cigar or cigarette butts still burning on to the roadside during summer. In his own home, such a person may be most careful and well alive to the danger of fire. Why then is one unable to impress on those old enough to use matches, the need for the same care at all times as that exercised in their own home? At a meeting of Fire Fighting Committee held recently, one speaker made a statement to the effect that the majority of the fires that got out of control in the Adelaide hills last year were caused by careless picnickers, who had neglected to put out the fire used by them before leaving the picnic grounds. Scoutmasters, Tourist Bureaux, the Postal Department and Automobile Societies are each endeavouring to keep the dangers of fire before the public, yet sterner measures appear to be necessary.

In farming districts, if each farmer made a practice of ploughing a fire break in winter about 8ft. wide around all grass paddocks and treated it as fallow during Spring it would minimise the danger of burning grass paddocks. A few hints on fire fighting:—The first thought should be what weapons do we intend to use against the fire. The leather fire beater (a piece of soft leather attached to a suitable handle) is used by many and appears efficient. Others prefer a wet sack or the top of a mallee bough. I prefer a shovel, provided loose soil is available. It enables one to stand some distance from the fire thus avoiding heat and smoke, and next to water earth seems the best for quenching fire. A substitute for the shovel should be provided in case hard ground is encountered. A pick or grubbing axe oft times proves helpful in providing loose earth for removing smouldering butts of grass and herbage. All such tools should have the owner's initials and some private mark stamped on them; this precaution often saves confusion later on. A water bag and harvest can of water should be carried if possible.

For the small cost of the articles mentioned every farmer could afford to keep a set for the purpose of fire fighting. The knapsack for fire fighting (which consists of a can holding four gallons of water strapped to the user's back and operated by a spray pump) is also very efficient and can be operated in close places, but a constant supply of water is needed. In organised districts, the usual practice is to have 40gall. drums or iron tanks with a semi-rotary pump and hose attached in readiness for outbreaks of fire. I favour the use of water when obtainable, for there is less danger of the fire gaining a fresh hold when extinguished with water.

In harvesting months when burning is prohibited, keep a careful lookout for accidental fires. Remember that quick action is necessary, as a few minutes may mean all the difference in damage a fire out of control will do. On arriving on the spot, endeavour to take in the full situation of the position and determine whether or not there is a chance to burn a break to check the fire front. If not, work from the rear and prevent if possible the side spread of the fire. Always have one or two men following the main workers to prevent minor outbreaks which quickly undo the work of the leaders.

Never put earth over smouldering heaps of manure, &c. In windy weather such embers will often smoulder for hours and may then be carried by the wind and restart the fire. It is far better if possible to scatter such matter about as it will then soon burn out. Much of the hard work of fire fighters is often undone by a change of wind, therefore, use judgment as to whether a change of wind is likely and try to be well protected on the side that could with a change of wind become a long fire front. In a case of fire out of control try and keep as cool as the fire and weather conditions will allow, a large fire out of control on a very hot day has a tendency to unnerve the stoutest heart. It is equally true that over excitement and eagerness have been the cause of many disastrous actions. It is often very noticeable in fire fighting the amount of effective work a quiet worker will accomplish while others who have become flurried have exhausted their strength and also have a tendency to do the wrong thing. Moreover, such workers often rush to a fire without a weapon of any kind and this is one of the reasons why all farmers should give some thought to fire fighting before the actual outbreak.

EASTERN DISTRICT.
THE GORDO IN RAMCO.

[*Paper read by Mr. F. Lewis at the March meeting of the Ramco Branch.*]

As this district has the reputation of growing Lexias of a quality equal to anything in Australia it may be of interest to describe the methods practised by local growers to get this desirable result.

There are four contributing factors—suitable soil, age of vines, method of pruning, and drying. Practically all the Gordos in Ramco that are producing quality fruit are grown on a fairly steep, loose, sandy northern slope, originally big pine and mallee country with a natural drainage. They were planted in the early days of irrigation on the Murray and are about 30 years old. For some years they were pruned on the Gooseberry Bush system, which produced quality, but not quantity, and later, after becoming well established, were trellised by forming a rod on each side of the "crown" on a low trellis, Espalier style, and gradually cutting out the old spurs on each side of the row. This, of course, left a lot of large wounds which have never healed over and are now riddled with white ants, but this does not seem to affect the vigour of the vines.

When pruned, most of them appear to be black, distorted, ant-eaten old stumps, and anyone used to younger vines would naturally feel inclined to prune them below the ground level with an axe. One of the chief causes of inferior Lexias is the modern method of training the vine to a comparatively high trellis with long, thin arms which do not grow enough foliage to properly shade the fruit, with the result that the exposed berries are small and hard.

As a general rule, for Gordos, the nearer the butt the better the fruit. Provided the drainage is good enough, Gordos will stand any amount of water, and unlike Currants and Sultanas the more vigorous the vine, the better the fruit, both in quality and quantity. Unfortunately, Gordos ripen rather late and growers with other varieties leave them until their racks are cleared of Currants and Sultanas and they show a high Baume test.

When Gordos are just right for the distillery, they are too ripe to make good Lexias, as a fair proportion are already dark Raisins or else have turned a blue colour.

Gordos are practically all dipped in the old style boiling caustic; any other method tried so far is too slow in drying so late in the season. They should be dried in the

open to get as much sunlight as possible; in fact I have seen first class fruit dried on racks that had no provision whatever for covering from rain or dew.

Much of the sugaring trouble is caused through rack drying, especially if the grower has not sufficient plant and is compelled to shake down the fruit while the skin is still tight and finishing the drying on hessian. I have always dried as much as possible on trays, and for the past three years this tray-dried fruit has been kept separate and marketed in London as a distinct line. The colour is not very attractive, but buyers evidently appreciate the keeping qualities as they have sold readily. These were packed at the end of the run, and, of course, missed the early markets. Another cause of sugaring is close stemming. With the stemmer set close enough to take off all "tails" and the fruit is a little too dry, it knocks the skin about badly and when moistened up overseas it becomes sticky and sugary. If a fairly large parcel of Lexias with the tails left on was tried out on the London market, prices realised would justify the experiment.

I have had very little experience in manuring Gordos and in 28 years have applied fertiliser only twice; once with Bone Super and once with Complete Vine Manure, and in neither case did the returns show any improvement, but wherever Stable Manure was used there was a distinct improvement. About three years ago a lot of the vines "went back" so I gave them an application of Sulphate of Ammonia at the rate of 1cwt. to the acre and the same amount the following year. This brought the vines back to normal and I am now harvesting a record crop.

SOUTH AND HILLS DISTRICT.

ECHUNGA.

March 6th.—Attendance: 26.

POULTRY.—Paper read by Mr. T. Sando.

Systems of Poultry Keeping.—In the more commonly accepted classification there are 5 systems:—(1) Free range; (2) colony; (3) semi-intensive; (4) breeding pen; (5) intensive.

Comparative Value of the Systems.—The free range system is only suitable for those who have a considerable area of land at their disposal. For farmers and some small holders this system offers very great advantages. Many commercial egg farmers also rear their birds on this system. Whenever possible, growing stock should be given their entire liberty. The colony system is perhaps more suited to small holders than any other class of poultry keeper. The semi-intensive system is one to be recommended where there is sufficient room available for the erection of the necessary runs. For small holders, pedigree stock breeders, and the like this system is eminently suitable. The intensive system is only to be recommended for those whose space is very restricted. On reviewing these systems it would appear that the semi-intensive scheme would prove most suitable to local conditions. Under this scheme a scratching house and outside run would be provided. The area allowed is approximately 3 to 4 sq. ft. per bird in the scratching house, and about 20 sq. ft. per bird in the run. Therefore, a house 17ft. x 20ft. with a run attached, measuring 100ft. x 20ft., would be sufficient to accommodate 100 to 120 birds.

Breeds.—From experiments carried out by private individuals and Government departments extending over a period of many years, it has been proved that the breeds most suitable to our conditions are the White Leghorn and the Black Orpington.

Feeding.—There are two methods in common use—(1) wet mash and grain; and (2) dry mash and grain. Wet mash.—The usual practice is to give wet mash in the morning, green feed mid-day, and grain in the afternoon. A good mixture is equal parts by measure of bran, pollard and wheat meal, which constitutes 50 per cent. of the mixture and the other 50 per cent. consisting of chaffed green feed. A hot soup made from 2lb. of meat meal to every 100 birds is also added, and then thoroughly mixed, as much is fed as the birds will clean up in 25 to 30 minutes. Dry mash.—This is fed in hoppers, and although this method entails less work tests have shown that the egg production is not as high as when wet mash is used.

Cleanliness.—This is as important as feeding. All drinking and feeding utensils should be kept perfectly clean, and sleeping quarters should be kept free from accumulations of filth. Perches should be frequently scrubbed to keep down parasites. With proper housing (which means there must be no draughts or leaky roofs or damp floors), regular feeding, and attention to cleanliness, good results should be obtained, provided that a good type of the breed is used.

Marketing of Eggs.—To meet the requirements of the market careful attention should be paid to the manner in which eggs are despatched to the marketing centres. During summer eggs should be collected from the nests at least 3 times a day and immediately stored in a cool place until despatched to the packing floors. All eggs should be perfectly clean, and it will be found that if those that are stained and dirty are cleaned immediately they have been collected the cleaning can be carried out more effectively and much more quickly than if left for two or three days. The time has arrived when only eggs that are spotlessly clean, fresh, and of good quality will command prices that will return the poultry keepers a margin of profit, and that to market eggs in an indifferent condition will certainly mean failure. (Secretary, L. Walters.)

CONFERENCE AT MOUNT GAMBIER.

Delegates from Women's Branches in the South-East met in conference at Mount Gambier on 10th April. Mrs. Altschwager (Millicent) presided over an excellent attendance of delegates from the Coonawarra, Penola, Kalangadoo, Tantanoola, Rendelsham, Kongorong and Millicent Branches, the opening address being delivered by Mr. H. C. Pritchard (General Secretary of the Agricultural Bureau). The following papers were read and discussed:—

FIRST AID HINTS UNTIL THE DOCTOR ARRIVES.

[Miss K. Hutchesson, Millicent.]

A few reasons why you should learn First Aid and Home Nursing:—Because one then has the knowledge to relieve suffering and possibly save human life. Because knowledge will be gained of what to avoid, and thus prevent further injury and suffering. Because the knowledge rightly applied assists the doctor and lessens the period of suffering for the patient. Because everyone should acquire knowledge of a subject which has proved of inestimable value in all walks of life. Because the means of obtaining this knowledge is within reach of all.

The doctor cannot always come at once when needed. He may be attending another case and while waiting him, it may be advisable to administer First Aid.

A first aid outfit should consist of the following:—Dry cotton wool, sterilised gauze and bandages, boracic lint, adhesive tape, a pair of small scissors, a bottle

of tincture of iodine, ammonia for insect stings and inhaling in the case of fainting.

The following hints will be helpful but the doctor should always be called as quickly as possible, especially in the case of accidents.

Fainting.—Lay the patient on his back with the head turned on one side and if the face is pale lower the head and raise the feet. Undo all tight clothing Ensure an abundance of fresh air. Sprinkle the face with hot or cold water alternately. Apply warmth to the pit of the stomach and the heart. Do not give fluids or food while insensible.

Nose Bleeding.—Place the patient in a sitting position before an open window with the head thrown slightly back and the hands raised above the head. Loosen tight clothing. Apply a piece of ice or something cold over the nose and at the back of the neck. Place the feet in hot water and induce the patient to keep the mouth open to avoid breathing through the nose. Do not allow him to blow through the nose.

Haemorrhage (Bleeding).—Haemorrhage is of three kinds. *Arterial*: blood from an artery, which is bright red. The blood spurts out in jets. *Capillary*: the blood is red. It may flow briskly or merely ooze from all parts of the wound. *Venous*: the blood is dark red, flowing in a steady continuous stream. Place the patient in a suitable position, remembering that blood escapes with less force when the patient sits and still less when he lies down. Expose the wound removing whatever clothing may be necessary. Immediately apply pressure with the thumb or fingers directly on the bleeding spot. Maintain direct pressure between the heart and the wound by applying a firm pad on the pressure point. Encircle the limb by a narrow bandage or strap with its centre over the pad and tie the ends of a half knot on the opposite side. Insert a short strong stick and tie it firmly to the bandage. Twist the stick to tighten the bandage which will press the pad upon the artery and arrest the flow of blood. Tie the end of the stick to the limb so that it will not slip and release the pressure. Bleeding of the oozing type is controlled by pressure on the dressing and firm bandages.

Fractures.—When a bone is broken a fracture is said to have occurred. Give immediate attention, observing the following rules. First attend to fracture on the spot. Restrain bleeding when present. Cover the wound with a clean dressing. Always steady, and support the injured part. Try with great care and without using force to place the limb in a natural position. Use bandages, splints and slings when necessary and practicable. Remove a patient suffering with a fractured spine, thigh, or pelvis in a recumbent position. Every doubtful case treat as a fracture. Send for or take the patient to a doctor.

Splints must be firm, long and broad enough to keep the joints immediately above and below the fractured bone at rest and should if possible be padded to fit accurately to the limb. A splint may be improvised from a walking stick, umbrella, broom handle, flat piece of wood, cardboard or anything that is firm, long and wide enough to support the fractured bone. Bandages must be applied firmly over the splints, but not so tightly as to constrict the circulation of blood in the limb.

No case of head injury should be regarded lightly. Place the patient at rest in a quiet room on a low pillow and apply warmth. Apply ice or cold water to the head continuously. Do not give stimulants, and obtain medical assistance as soon as possible.

Sprains.—Are due to a sudden wrench or twist. Support the limb in the most comfortable position well raised. Apply cold dressings to the joint. If this does not give relief, apply towels wrung out in hot water. For a sprained ankle if out of doors apply a figure 8 bandage tightly over the boot. Keep the bandage wet after application, thereby tightening it. If the patient is indoors first remove the boot and stocking and treat as above.

Drowning.—Do not lose time. People have been saved even though they have ceased to breathe and are apparently dead. Apply artificial respiration. Send for a doctor at once. Carry out the following directions proceeding systematically and do not give up till the doctor pronounces the case hopeless. Remove weeds, sand, etc., from the mouth and keep the air passages free. Loosen clothing at neck, chest, waist, and see that breathing is possible. Lay the patient face downwards, turn head to one side, arms forward and palms down, perform artificial respira tion. Kneel astride the patient facing his head, place the hands flat over the lower part of the back, lean forward keeping the arms stiff and firm, press steadily and firmly. This action forces air and water from the lungs. Draw back the body and relax the pressure but do not remove the hands. This permits the chest to expand and draws air into the lungs. Repeat these movements regularly but not too frequently—16 times a minute is a good average. Time the movements with the aid of a watch. Do not be hurried or flurried in striving to restore the patient, but be persistent. When the patient commences to breath normally assist natural circulation of the blood by briskly rubbing the body and limbs towards the heart.

Electric Shock.—If the patient is still in contact with electric current *do not touch* him, unless you are insulated. Rubber gloves or a pad made of any rubber material will afford effective insulation. If these are not obtainable, push the patient away with a piece of dry wood. Lay the patient on his back, loosen all tight clothing, allow a sufficiency of air. If breathing has ceased or is feeble, apply artificial respiration as described under drowning.

HOUSEHOLD HINTS.

[Miss I. E. Fensom, Millicent.]

Testing Oven Heat.—To judge the heat of an oven, try it with a piece of white paper, leave it for about 3 minutes and if too hot the paper will blacken. When the paper becomes dark-brown the oven is fit for small pastry and scones. When light-brown it is ready for tarts and when dark-yellow it is right for bread, pound cakes or large meat pies. When just tinged it will be ready for sponge cakes or any other light cooking.

To Clean a Vacuum Flask.—Put some crushed egg shells in it with a little vinegar, shake well, then half fill with water and stand for a time. Shake again, then rinse thoroughly. Invert the flask in a jug, and when dry, put away—do not replace the cork, as this is liable to make the flask musty.

To Remove Tar.—Scrape off as much as possible, then rub on any clean mutton fat or lard and let remain for 24 hours; if linen or cotton, wash the article out in strong warm soapsuds; if woollen or silk, take out the grease with ether or methylated spirits.

To Remove Motor Grease or Tar.—Get a good brand of eucalyptus and rub the spots with a clean cloth dipped in eucalyptus, change the cloths as they get soiled. Hang out in the air when finished and then the smell will disappear. It is also good for cleaning collars of men's suits.

Uses for Sugar Bags.—To save the wear of tea towels, cut a piece of sugar bag the size of the tray and bind round with cretonne or bias binding. Place this on the tray before putting wet crockery on it. This will not get half so wet as they do without it. There are many useful things to make such as peg aprons, kettle holders, and aprons for gardening, scrubbing and all outdoor work. Very nice cushions for verandah or garden seats can also be made by dyeing the bags any colour you wish and either stencilling a design on it or cut out any figure from cretonne and button holing it on. They will also make sleep-out bed covers, seats for deck chairs, duster or string bags.

Uses of Borax.—Borax is an antiseptic. It is an arrester of decay, and as such is useful in the preservation of meat, butter, milk and all articles of animal food. It softens water for cooking, bathing, washing, and all household purposes. It is a good cleaner for all paint work. Put a tablespoon to a gallon of water, it will not leave any white marks. It whitens linens and cleanses them better than soda. It cleanses and heals ulcers, festering wounds and sore throats. When powdered borax is sprinkled about places infested with ants, the pests soon disappear. It can be used in cooking green vegetables in place of bicarb. soda, preserves the colour and makes them tender. Limp salad vegetables regain their crispness if soaked in water with a little borax added to it. When washing, add ½lb. borax to 10galls. water, soak white clothes in this, and soap will be saved. An ounce of borax dissolved in 1 pint of hot water and then allowed to cool, will kill aphis on roses and other plants.

Cleaning Fireplaces.—Fireplace bricks can be cleaned, even if very sooty and dirty, by brushing them first with a stiff broom and then applying a mixture made from ½ pint of strong household ammonia, ½lb. of powdered pumice and 1 quart of soft soap. Apply with a brush, leave for at least 1 hour before rubbing it well into the surface with a scrubbing brush, and rinsing it thoroughly with clear water.

Stains on Linen.—Most stains that are freshly made on table linen can be removed by placing a cloth over a dish and pouring boiling water on to the stain. Coffee, tea and various fruit stains yield to this treatment.

Grass Stain.—To remove grass stains from white flannel garments, rub on a mixture of equal parts of pure glycerine and yolk of egg. Allow to dry on, then wash the stains on the garment in the usual way after a few hours.

Scorched Marks on Linen.—If the scorch is not an absolute burn, it may be removed by boiling the fabric in milk, turpentine and soap. To ½gall. milk, use ½lb. soap and ½ a teacup of turpentine. Be careful about exposing the turpentine to the fire.

To Remove a Top from Salt or Pepper Shakers.—If the top of a cut-glass salt or pepper shaker becomes stuck place a collar of tightly wound wool around it and saturate the wool with olive oil. Stand it upside down in a warm place for a few hours then unscrew, anti-clockwise.

LITERATURE IN THE HOME.

[Mrs. W. Varcoe, Millicent.]

In many homes one finds rooms beautifully and comfortably furnished, and the meals served to members of the family are regular and nourishing, but to feed the mind no thought has been given.

Children's school books and a daily or weekly newspaper are all the reading that can be found in some homes, and in more than one the children are not allowed to read the newspapers. One thing to be thankful for is that these conditions are not so common to-day as they were thirty or forty years ago.

A carefully chosen library is a necessity in any home where there are children. It is as important for a child to have access to at least a few good books as it is that he be given the correct food to build up the growing strength of his body.

A young mind needs the right kind of literary food to help it develop in the right directions. A reader of the best kinds of literature is never ignorant and is usually more kindly in his actions toward others, and also to dumb creatures around him. He is usually more broadminded and tolerant in his views, as the more he reads the more he knows and also the more he knows, the more he realises what a lot there is which he does not know.

Good books are one of humanity's best friends; they are good and cheerful education and also pleasant, ever-ready companions with whom to while away one's

spare time. They are particularly good companions by the fireside on a wet day or winter evening.

BOOKS.

"Who would dare to limit or assess
Their influence in times of doubt and stress,
In deep perplexity, in sorrow's hour,
We turn to books, and find in them the power
To aid and bless, we of the lonely bush.

"Earning our bread by constant toil and rush,
The sport of fickle Nature's varying mood,
Battling with drought, with pestilence and flood—
Snatch a brief respite, greater minds to meet,
And find in books companions doubly sweet."

Country boys and girls have a wonderful opportunity to improve their minds and broaden their outlook by means of good books. They are not hemmed in by a round of pleasures as are city young people. Country people have to depend more upon themselves than upon others for their amusements, and there is no more profitable and restful entertainment than the reading of good books.

One can sit at home and travel the world by reading books written by those who have travelled in far countries. One can explore new countries and learn of the many strange customs and habits of the inhabitants of those countries, or read interesting books of history, fiction, or humour. Almost every book has in it something that will benefit the reader, some line that will broaden the mind or improve one's vocabulary. In starting a small library for the home, two of the first books necessary should be the Bible and a good standard dictionary. No library is complete without a good dictionary.

For the benefit of the children there should be a copy of "Lamb's Tales of Shakespeare," the "History of England," "History of Australia," Daniel Defoe's "Robinson Crusoe," and R. L. Stevenson's "Treasure Island," as well as others of his writings, "Pickwick Papers," by Charles Dickens, "Innocents Abroad," by Mark Twain, poetical works of John Masefield, and Bunyan's "Pilgrims Progress." Some of Ethel Turner's books and those of Mary Grant Bruce, as well as books by other popular writers of fiction for children should be chosen.

H. V. Morton's three books—"In Search of England, Ireland and Scotland" deserve a place in every library, also poems of Longfellow, Robert Burns, Tennyson, "Ben Hur," by Wallace, "Uncle Tom's Cabin," by Mrs. Beecher Stow, "Les Miserables," by Victor Hugo, "The Three Musketeers," by Dumas, Complete Edition of Kipling's Verse, John Galsworthy's "Forsythe Saga," "Eugene Aram" by Lord Lytton and as many of Shakespeare's and Charles Dickens' works as one can afford, also Mark Twain's, "Ultima Thule," by Henry Richardson and "Karanga," by Hibble are two good books, "Singing Gold," by Dorothy Cottrell and as many more good books of all kinds as one's financial means will permit. "Freckles" and "The Harvester" by Gene Stratton Porter are two most interesting books and another two favourite American writers are O. Henry and Jack London.

NEW GUINEA BUTTER BEAN PICKLE AND EASY WAYS TO COOK A RABBIT.

[Mrs. F. Todd, Rendelsham.]

The much despised rabbit is often a godsend to the farmer, and in country districts also to those who must eat white meat. The rabbit is best hung for a day in cooler weather; choose rabbits three parts grown. Wash, or better still, wipe with a cloth wrung out in warm water. The rabbit needs plenty of herbs, seasoning, bacon, pork, etc., to make it appetising.

Stuffed Rabbit.—A large cup of bread crumbs, ½ cup chopped suet, parsley, thyme and seasoning to taste. Bind with a beaten egg, fill the body of rabbit with stuffing and sew up with strong white cotton. Press hind legs towards head, and fore legs towards back, place slice of bacon on loin; skewer all and tie with string; baste well. Mashed potatoes, green peas, and brown gravy make an appetising dinner. Also 4 sausages can be placed inside of rabbit and one served to each person. Instead of an egg to bind stuffing, a piece of butter and a little milk can be added, and is not quite so dry.

Boiled or Steamed Rabbit.—Place rabbit in saucepan with a little water, dripping or butter, pepper and salt. Cook until tender, place on dish and pour over parsley or onion sauce. Mashed potatoes and cauliflower are nice with this dish.

Braised Rabbit.—Joint a rabbit, dry well on cloth, roll in flour, fry until brown in boiling fat, place in saucepan, fry onions in fat left from frying rabbit and add to rabbit in saucepan and stew gently.

Irish Stew.—Place alternate layers of rabbit, potatoes, onions, etc., in baking tin, season each layer and sprinkle with dried mint and flour. Small pieces of bacon, pork or ham can be added. Nearly cover with water, place another tin on top and cook in hot oven for 2 hours.

Rabbit Pie.—Cut rabbit into small pieces, and place in alternate layers, tomatoes, onions, carrots, etc., into pie dish. Add seasoning, place in oven and cook till tender, about ½ hour. Before dinner, place on short or flaky crust. Add a little water or thicken a little before placing pie crust on.

Cold in Sandwiches.—Men folk are fond of a rabbit's leg sprinkled with salt and placed between bread and butter for dinner in the paddock. Also a couple of rabbits are nice cooked or roasted with a piece of pork and apple sauce.

Rissoles.—Put rabbit through mincer with ham and mince, also a green apple, a few bread crumbs, and cold potato. Add 2 or 3 eggs. Make into rissoles and fry in hot fat.

NEW GUINEA BUTTER BEAN PICKLE.

The butter bean is like the marrow and cucumber in habit and growth. To use as a vegetable it must be cut young whilst the skin is still tender, also for pickling. When young, the skin can be used. Later the skin becomes hard and must be peeled. Scoop out the inside and cut into pieces, place in pan in layers with onions, cucumber, green tomatoes and apples. Sprinkle each layer with salt. Cover with water and stand all night. Next morning drain, place in pan, cover with vinegar, 2 or 3lbs. of sugar according to size of pan and quantity of vegetables, 2 tablespoons of ground allspice, and cook until tender. A nice pickle can be made if white vinegar is used with a little cornflour and mustard to thicken.

HINTS ON PERSONAL APPEARANCE.

[MRS. Z. A. BIGNELL, Rendelsham.]

The right care and culture of the human body is a duty incumbent on every woman. It may not be within the reach of all to enjoy the charm of perfect features, but it certainly is within the range of possibilities for almost everyone to take the necessary care of the hair, skin, etc., and thus ensure the possession of some of the many features of beauty. It is interesting to remember that there is a loveliness about all little children—their baby heads sunning over with curls, the delicate rosiness of their little fat cheecks, and the rounded curves of their chubby arms. No matter what the features, it is the age which makes the beauty, but in going among groups of adults, the impressions gathered are quite different, and one wonders why it should not be possible for a far more generous average of good looking people to be seen than is visible in cities. Surely with due thought and cultivation, there might be almost universal beauty of maturity as there is of youth.

The answer is not far to seek. In all too many instances the wear and tear, the rush and turmoil of life have blotted out all but the daily round of duties, and people have forgotten that they could with just a little care have retained much of the brightness of younger days, and attained the true beauty that belongs to every age as truly as it belongs to spring, summer, autumn and winter.

Moderation is the key note of the situation—too much care results in artificiality. Every one has had the experience of the girl who has overdone it, and who in her effort to look her best has lost the charm of natural girlishness, so each one must judge for herself the amount of care and the right means necessary to use in order to express in face and form all the beauty of which they are capable. To have a fresh clear skin and the delight of growing health, the daily bath is an absolute necessity.

The pores of the skin must be thoroughly cleansed, in order that the blood shall be able to do its duty to the frame through which it flows. The softer the water the better for the skin; a very refreshing bath is made by the addition of vinegar, which can be scented by soaking in a few drops of rosemary, camphor, sage, mint, or lavender.

Clean clothes should be worn as frequently as possible, fresh air is another aid to beauty, also exercise. Food and sleep play a most vital part in the beautifying and development of the appearance and in both these directions some people need more than others. 10 p.m. to 6 a.m. are the regular hours for sleep. It is impossible to begin too early to the care of the hair; a dirty brush should never be put near the hair. Brushes should be washed often and a good way to dry a brush is to hang it by a piece of tape before the open window. Ammonia added to the water cleans brushes thoroughly; the comb can be scrubbed with a nail brush.

Face Creams.—It is a great mistake to be careless about the buying of creams for the complexion—only the purest and best should be used. Olive oil rubbed lightly into the skin and then wiped with a clean piece of cloth is very good. Almond oil is an excellent grease to use on the skin under powder.

Chamois leather makes the best puff, and a little powder may be used carefully and evenly by this means. Only the best powder should be used. It is cheapest after all, for it lasts longer and imparts a finer and softer finish to the skin.

A final hint, never eat anything that disagrees with you—if it is desired to keep a good complexion. Indigestion is one of the greatest enemies of the skin, and for this reason the simpler the food, the better. Fruit, either fresh or cooked, and green vegetables should form a part of the daily diet.

A sallow complexion can be brightened by the application of cucumber milk. Mennaline makes eyelashes and eyebrows longer and can be applied to the lashes and brows at night. Cleminite can be used instead of powder and can be procured from a chemist by the ounce, and just enough water to dissolve it and applied to the face in the usual way. The effect of this preparation is retained all day under the most trying weather conditions.

Mr. A. L. Warren, R.D.A. (District Horticultural Instructor) delivered an address "The Home Garden."

FANCY WORK.

[Mrs. Stafford, Tantanoola]

How to Choose Material and Design.—Before commencing a piece of work it is well to consider the purpose and use to which the finished article is to be put Much good work may be spoilt and time wasted by working with unsuitable materials and inappropriate designs.

If the article to be worked is to be in constant use and likely to receive hard wear, the foundation material chosen should be of firm durable texture, and the working thread, a well-twisted silk or a reliable mercerized cotton, and, if it is

to be frequently laundered, fast colours should be specially selected. Conventional subjects are more easily treated than natural ones in most cases, as they can be worked in any colouring to match the general scheme of the room, of which the article is to form a part. If floral designs are preferred, however, be sure to work them in natural colouring, and in stitchery to represent as nearly as possible the actual form of each flower.

Broadly speaking, there are four points which should be borne in mind:—

(1) Choice of material.
(2) Appropriate design.
(3) The colour scheme.
(4) Suitable stitches.

Each of these points should be decided by its suitability to the purpose in hand. For example, fire-screens may receive different treatment from cushions; more expensive material and floss silk may be chosen for a screen, as there is practically no wear; the design should be chosen with the idea in mind that it will be seen in an upright position, the colouring should be bright, as the object of a fire-screen is to hide the barren look of an empty grate, and to provide an attractive object for the eye in lieu of a fire, which is always the centre of attraction in a room.

For cushions, the material should be of rather firmer texture as it has to stand hard wear; the working thread should be twisted, and stitches chosen which keep the working thread firm and taut so that it is not liable to fray. When selecting a design for a table cover or a cushion for general use, remember that the cover will be seen from all sides of the room, and should look equally well seen from any point of view. With regard to the cushion which is in constant use, a symmetrical design is best so that it can be turned about in any way and still look right.

For curtains, borders or sprigs may be chosen, but always remember that floral sprays should grow upwards.

Bedspread designs are often very varied, but they should give the idea of restfulness, either a dainty little spray repeated over the whole surface, the monotony relieved by varying the colours of alternate sprays, or the stitches in white work; or a large design of hops, poppies, etc., which are very suggestive of sleep.

If many colours are selected for the embroidery, the stitches chosen should be few, thus showing off the shades to the best advantage; while for all white work a variety of fancy stitches and fillings may be used, as the one colour enhances the beauty of the actual stitchery.

The Blending of Colours.—When embroidering in coloured work, the heaviest portion of the design should be worked in the darkest shade.

With the majority of flowers and leaves this tone is at the centre, ranging to the lightest on the outside. Always remember that a full blown flower is paler than the bud, and also has far less shadings.

Competitions always tend to increase efficiency in the standard of work, irrespective of what industry or hobby it might be.

Evenness is absolutely essential in needlework, as this improves the standard of the work and also increases the marks awarded to the competitor who follows this out.

Fineness is another strong point, as often in embroidery it is harder to work finely along a narrow design line than it is to overcast it coarsely along the same length.

ITEMS OF INTEREST FOR CHILDREN.

[Paper read by MISS P. FOALE at a recent meeting of the Parilla Branch.]

A child's mind is always working, therefore must be doing something, so if a child has nothing to play with and is at a loss to know what to do next, nine times out of ten he will get into mischief; this will worry mother and then he will have to be spanked for it, whereas if he had something to occupy his mind it would be better for both mother and child. But it is often a mother's problem to know how to cope with the wants of the young and active brain of a growing child. Bright coloured picture books are interesting to most children, but books of any size are rather expensive so the following is suggested:—Take a book with a nice firm cover. Leave every third page, taking care that those cut out are not cut too close to the centre, to prevent the corresponding page in the other half of the book becoming loose. The cutting of the pages out is to prevent the book becoming too bulky for the cover when finished, as the pictures will be pasted on both sides of the pages. This will bring the book back to the original size. Where the pictures do not cover the print, the little ones can fill in with water paints or crayons. Cover the book with wall paper or a pretty coloured material and it will be just as attractive as any that can be purchased. Any black and white pictures can be coloured with pencils.

Any small toy a child makes for himself, he values more than most other things in his play box. Get the children to do some modelling with odds and other things in his play box. Get the children to do some modelling with odds and ends such as cardboard, match boxes, dead matches, scraps of fine wire, transparent paper and animals cut from old books. This play, besides being clean, not only teaches the children to be resourceful, but will keep them inside on cold and wet days.

This illustration shows a model farm and homestead. This I made without spending a penny on it. The whole thing is laid out on a large piece of beaver board, it measured about 6ft. long and 4ft. wide. If only small pieces are available they can be joined at the back by pasting on sheets of paper, the joints do not matter so long as they are fairly close. The next thing is to draw with a hard stick and pencil the lines for fences, paddocks, stables, yards, drive, house grounds, etc. This done, take a punch or hammer and nail and punch holes at

equal distances apart for posts; also punch holes for trees in paddocks and garden and for horses and cows. One hole for each animal. Now make a little thick boiled starch and paint with a brush a small portion of the board and sprinkle with dark coloured sand. Let it stand for a few minutes then tip the board on end and all the surplus sand will drop off. Then do another portion the same and so on until all but the drive and garden paths are covered with sand. This gives it a natural appearance. If all the board is painted at once, the first part will be too dry for the sand to stick to by the time the last piece is finished painting. Paint the drive and garden paths and sprinkle with a very clean white sand to give it the appearance of being gravel. Put dead matches in all holes where posts are wanted and outline the drive with sprigs of fine green such as young tips of wild pine trees; also for a few trees in the paddocks. In the left hand corner, right to the front of the picture are small paper horses, two with riders, two with foals, and two or three others. These are pictures cut out of farm papers. Attach these to matches by means of a strip of stamp paper across the back, then stand the match in a hole between the trees. In the right hand corner at the far back, are cows cut out similar to the horses. If the drive is followed past the front and down the side of the house and then where it turns to go along the back of the house, the front of the garage will be noticed. This, and the shed further to the left, are cut out of thin cardboard. The house is made from a square box with a black pencil mark on the outside to make it look like bricks, then colour with red ink. The roof is cut like a bungalow and also coloured with red ink. Holes are cut for the windows, then paste some transparent paper over them from the outside, dip a finger in water and wet the transparent paper from the outside, and although it will go soft and stretch in a few minutes it will dry and pull tight then it will have the appearance of glass. Do not put it too near fire to dry quickly, or the heat will split the paper. Now hang little pieces of bright coloured material inside for curtains.

In the left hand corner of the garden can be seen a little round summer house. Make the bottom with cardboard and a roof of frayed binder-twine. This looks like a thatched roof. Also cut from thin cardboard the front gate and arch in one. The little white mark which appears to be right under the arch is a tiny white elephant standing in the centre of a pond made out of a small lid. This is half-way between the house and gate. The lawns and garden may be coloured with pencils. The windmill is made of wire and cardboard. One very small table, two chairs, and one garden seat which cannot be seen in the picture are on the front lawn. These are made of very fine white cardboard. With a red roof for the house and darker red for the garage and shed, the green trees and little animals, the whole plantation is sure to be pleasing to the children. Give the children an outline of the whole thing and then let them go ahead and build it as they would like it to be.

WIRRABARA (Average annual rainfall, 19.29in.).

January 17th.—Attendance: 21.

Mrs. G. Krantz exhibited specimens of bush carpentry, which included a work box, lunch basket, &c. She also demonstrated how to make containers in which to bake small cakes, using for this purpose the tops of jam and preserving tins.

HOUSEHOLD HINTS.—The following were supplied by Mrs. Krantz:—*Stoves, when Burnt Red.*—1oz. each of blacklead and bluestone. Cover with water and allow to stand for 24 hours or until dissolved. Pour into a large-mouthed bottle or earthenware jar. Paint on the stove whilst the latter is hot. Two coats may sometimes be required, and if too thick more water can be added. *Stove Polish.*—2ozs. blacklead, 1 cup each methylated spirits and furniture polish. Put in a Mason jar and screw down with a rubber ring to prevent evaporation. Put on a cold stove with a swab, allow it to dry, and

polish with a soft cloth. A handy swab can be made with a piece of sheepskin bound on to the end of a stick, the wool on the skin being clipped to the desired length. *To Use Up Stale Cake.*—Crumble the cake (or steam pudding), and add sultanas or any other fruit. Mix with eggs, according to quantity of crumbs, to a soft consistency. Jam may be added. Make some short pastry, roll thinly, and place on an oven slide. Spread on cake mixture, and place the remaining pastry on top. Roll lightly with a rolling pin to make firm, and place slide in the bottom of the oven. *Kitchen Cleanser.*—1 large packet extract of soap, 1 block of sandsoap, 2 tablespoons borax, 2 cups finely sifted ashes, 1 cup whiting, 4 cups boiling water. Slice the sandsoap and roll with a rolling pin. Add dry ingredients, and mix well. Finally add the boiling water and stir at intervals until it forms an even thickness. Stand for 1 hour, then place in a tin, or preferably a large-mouthed bottle or jar. *To Clean Aluminium Saucepans when Burnt.*—Pour a little water in the saucepan and put in an onion, boil for a little while, and the burn will rise off. *To Clean a Discoloured Aluminium Saucepan.*—Put in lemon skins, and fill the saucepan to the top. Rhubarb peelings and leaves will act in a like manner. *To Roll a Shoulder of Ham.*—When cooking the ham tie a string in a similar manner to that when tying a parcel, so that the ham can be lifted out when cooked. When cooking the shoulder to roll it must be boiled until very tender and the flesh commences to leave the bone. Lift out and skin in the usual way. Then cut out the bones, place a strong piece of calico on the side dish. Lie the ham near one side of the cloth, and place on it all loose pieces of meat from where the bone has been removed. Roll all as tightly as possible, the same as for a roly-poly pudding. Twist up the end of the roll, and tie tightly by twisting the cloth and cord similar to a roll of bacon. Leave until quite cold before undoing. *To Salt Meat.*—To half a kerosene tin of water add 2lbs. of salt, 1 cup of vinegar, and 1 dessertspoon of saltpetre. Boil until all is dissolved. Put in meat and boil for 5 to 10 minutes. Leave in brine until required, preferably in an earthenware or wooden vessel. (Secretary, Mrs. A. Curtis.)

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences—1935.

Upper North, at Booleroo Centre, Wednesday, July 17th (Wepowie Branch, E. C. Roocke, Secretary, Booleroo Centre).

Hills, at Lenswood, Thursday, August 22nd (B. F. Lawrance, Secretary).

Murray Lands (East), at Alawoona, Thursday, October 3rd (A. J. Pengilly, Secretary).

Fruit (Non-irrigated), at Lyndoch, Tuesday, November 5th (J. S. Hammat, Secretary, Williamstown).

Each Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda of the Conference in their respective districts.

Pruning Competitions.

McLaren Flat, June 22nd; River Murray—Berri, June 25th; Barmera, June 26th; Moorook, June 27th; Cadell, July 2nd; Waikerie, July 3rd; Moorook (Championship), July 4th; Light's Pass, June 24th; Lyndoch, June 26th; Lone Pine, June 28th; Koonunga, July 1st; Greenock, July 3rd; Williamstown, July 5th; Watervale, July 8th; Williamstown (Championship), July 17th.

Toxaemia of Pregnancy.—Death of Breeding Ewes.

The Secretary of the Lipson Branch of the Agricultural Bureau reports the death of 35 breeding ewes. The ewes died very suddenly and apart from the fact that they were lying down and a slight discharge from the mouth was visible, they otherwise appeared to be in good health. This question was referred to Mr. R. H. F. Macindoe, B.V.Sc., M.R.C.V.S. (Deputy Chief Inspector of Stock) who says the name of the disease is Toxaemia of Pregnancy, and as the name implies, it is thought to be due to the absorptions of toxins (poisons) from the liver or bowels, but the specific cause is not known. The symptoms of illness appear about the last month of pregnancy. The affected sheep are always fat and generally running on good pasture or being given supplementary rations, and they are very often carrying twin lambs. Briefly, the salient features of the disease are:—

1. Ewes are in an advanced stage of pregnancy.
2. Nearly all are carrying twin lambs.
3. Are in high condition.
4. Running on good feed or being given supplementary feed.
5. Livers of affected sheep are pale, enlarged and fatty.

Symptoms.—Generally the owner's attention is drawn by the fact that affected sheep are apart from the flock. The affected ewe appears listless and if forced to move, walks aimlessly and with a staggering gait. The sight is often impaired and there is a grinding of the teeth. There is no appetite and the animal appears stupid. A twitching of the muscles about the head is often noticeable. As the disease progresses, some partial collapse occurs and when raised, the sick ewe may stand for a while, but will eventually fall and be unable to rise or use the legs even if supported. Death may occur in a few hours or even take several days, but it always occurs unless the ewe happens to lamb, when recovery will take place.

Treatment.—There is no effective treatment which will cure the disease, but 2ozs. of Epsom Salts dissolved in ½ pint of water to which half a cup of treacle is added, may be administered and, if possible, the sick sheep made to exercise. Recovery, however, is very rare.

The disease, however, can be prevented by seeing that the pregnant ewes are kept in good store condition and not allowed to become fat. If ewes are fat, place them on paddocks where the feed is not too abundant and where, in order to get sufficient, they have to exercise. Do not feed concentrates until the ewes have lambed. Where pasture is abundant, it will be necessary to exercise the sheep for a mile or two daily until they lamb.

It is emphasised again that high condition is the predisposing cause of the disease.

Is Inhaling Copper Carbonate Injurious?

Statements have recently been made to the Director of Agriculture (Professor A. J. Perkins) that farmers have been seriously injured by the inhalation of copper carbonate used in the dry pickling process as a precaution against bunt in wheat. The matter was referred to the Chairman of the Central Board of Health (Dr. A. R. Southwood) for an opinion, and he states that the effects on the human subject following the entry of copper or its salts into the body may be summarised briefly. If large doses are taken by the mouth, vomiting generally occurs promptly; harm may arise from the caustic action of the substances on the gastro-intestinal lining. Apart from such acute cases of copper poisoning, there is little evidence of injury to health. Men constantly engaged in the mining and smelting of copper, or in brass-founding and other industries where copper is used, are not appreciably affected in health thereby, and do not appear to suffer from symptoms indicative of chronic copper poisoning.

It is unlikely that the occasional handling of copper carbonate in the dry pickling process of wheat will cause harm to the health of persons engaged in the work. The inhalation of large amounts of the carbonate dust might irritate the throat, and perhaps cause attacks of bronchitis, but no serious danger is likely. Ample protection to workers would be secured by observing the following points:—

1. The process should be conducted in the open air or in well-ventilated sheds.
2. Workers should as far as possible stand to windward of the apparatus being used.
3. A simple mask or respirator might be used if any irritation was found to occur. Protecting the mouth and nose with a simple mask of a few layers of gauze would suffice.

Wheat Crop Competitions.—Offer of Prizes by Millers.

The Millers Produce Company of South Australia, Limited., has informed the Minister of Agriculture (Hon. A. P. Blesing, M.L.C.) that for this year the Millers would make a donation of £5 to each of the districts conducting a crop competition under the direction of the Department of Agriculture, subject to the Minister's approval of the Millers linking a prize with the Government grant for the competitions and also subject to a small modification of the competition conditions. This modification is that the five following varieties of wheat be not eligible for the prizes represented by the Millers' donation, viz:—Gallipoli, Free Gallipoli, Ghurka, Waratah and Nabawa. The reason for the exclusion of these varieties is that in the opinion of Millers they are "weak" wheats and not of the quality which will enhance the standard of Australian wheats. In judging for the Millers' prize, the existing conditions upon which competitions are judged will be followed and if, under those conditions, the winning crop should happen to be either Gallipoli, Free Gallipoli, Ghurka, Waratah or Nabawa, the nearest crop (not including one of the ineligible varieties) to the winning crop will be adjudged the winner of the prize. Each District Committee will decide if the amount of the donation will be used for "First," or divided into "First" and "Second" prizes.

When accepting this offer the Minister intimated that it will be clearly set out that the prize money will be subject to the conditions laid down by the Millers and that the prizes will be donated only to districts conducting wheat crop competitions controlled by the Department of Agriculture for the Championship Shield of the Royal Agricultural and Horticultural Society.

Entry forms for the competitions are obtainable from the Secretaries of the respective districts throughout the State.

Quality in Wheat.

The Argentine correspondent of the Empire Marketing Board (Mr. W. J. Jackman) recently reported that the National Wheat Board has determined the varieties of wheat most suitable for the six zones into which the cereal region of the Republic has been divided for the purpose. Pending the passage of the Grain Bill now before Congress, there was no power to enforce the Board's recommendations, but the Board's action was looked upon as valuable preparatory work, looking to the future. In classifying the various wheats, the Board kept in mind, first the industrial qualities and, second, the vegetative characteristics, as, for instance, winter and spring wheats. On the basis of quality three groups have been established—strong wheats, fillers, and soft wheats—the first two for the European market and the last purely for the domestic and Brazilian markets. Most of the leading railway companies, which maintain experimental farms, have lent their assistance to the Commission, as have also private experimentalists, and much valuable educational work should result. As illustrating the interest taken by the railway companies in the improvement of seed grain, one of them (the Central Argentine) has sent out for the eighth year its large cleaning machines, which are placed at the disposal of farmers for the cleaning and selection of their seed grain, free of charge, at the local stations.

Reports received from England with regard to the quality of shipments of wheat already received there were very satisfactory. Although the weight of the grain was low, the gluten strength was comparatively high, according to tests made by the British millers. A high percentage of this year's shipments were from the south of Buenos Aires and the Pampa, whose wheats for the last three or four years have been leading the Republic in regard to strength, and it was not to be expected that the standard would be maintained throughout the year.

Almond Growing at Black Springs.

Replying to a correspondent who asked whether the Black Springs district was suitable for almond growing, Mr. J. B. Harris, the District Horticultural Instructor, states that as the average annual rainfall is approximately 19in., and as the almond, generally speaking, thrives well in the middle north areas of South Australia, it should be possible to grow almonds satisfactorily at Black Springs. Occasional irrigation during the growing season would be advantageous in most years, and particularly in dry seasons. Almonds will not thrive where the soil is subject to waterlogging. Protection from frosts and cold winds during blooming time are very important. At least two varieties blooming at approximately the same time should be grown to permit of cross-pollination. The varieties recommended are IXL, Brandis, Hatch's Nonpariel, Ne Plus Ultra, and Peerless.

Woolly Aphis Parasite.

Replying to the Secretary of the Beetaloo Valley Branch of the Agricultural Bureau who asked for particulars concerning the introduction of the parasite (*Aphelinus mali*), the Deputy Chief Horticultural Instructor, Mr. A. G. Strickland, says the insect is best introduced in late winter or early spring. The Department of Agriculture will provide twigs bearing parasitised aphis at the cost of 6d., which includes postage, to *bona fide* growers who make formal application.

Subterranean Clover for the Waitpinga District.

"Is any advantage to be gained by sowing grasses with Subterranean Clover in the Waitpinga district?" This question—asked by a subscriber to the *Journal of Agriculture*—was referred to Mr. R. Hill, District Agricultural Instructor, who says that on freshly cleared land the only grass considered advisable to sow with Subterranean Clover is Yorkshire Fog. Sown at the rate of 2lb. per acre, it has given very satisfactory results. Other grasses should not be sown until the clover has been grown for about four years, when the soil fertility will be much improved. Grasses suitable to grow following that clover period are *Perennial Rye Grass* on the heavier soils and

Wimmera Rye Grass on the light soils, at the rate of 6lb. per acre. The seeding of pastures should be completed in the Waitpinga district not later than early in May to obtain the best results. The use of 1 and 1 superphosphate is not recommended where clover is to be encouraged, because of the detrimental effect that nitrogenous fertilizers in any great quantity have on leguminous plants. However, the use of a very light application of nitrogenous fertilizer with Subterranean Clover on freshly cleared land to provide nitrogen for the plant until it can establish its root system and harbour bacteria is at present being investigated by the Waite Research Institute, but until more definite results are obtained the process cannot be generally recommended. Superphosphate at the rate of 2cwt. per acre is recommended.

Wild Lavender.

The plant known as Wild Lavender (*Lavandula stoechas*) has been gazetted as a noxious weed within the boundaries of the District Council of Port Elliot. Wild Lavender is a garden escape, and appears to be spreading over a large area, and while it is not found on cultivated ground, it is quite thick on pasture land in some parts of the district. It is not difficult to destroy by tillage or hoeing, although attention for about three seasons would be necessary for its eradication.

Construction of Cement Concrete Walls.

In reply to several questions from a subscriber to the *Journal of Agriculture,* Mr. T. A. Macadam, Lecturer in Building Construction at the School of Mines says a fair width for a concrete wall of a building 10ft. high, when the wall is reinforced with steel roads ⅜in. laid 18in. apart horizontally and 3ft. apart vertically would be 6in. for the domestic type of building. If the wall is of considerable length without any re-entering walls assisting to support it, the thickness would be increased. To hold the building boards in position some form of timber support is necessary, and this is best provided by vertical posts at sufficient intervals to keep the boards in position, the posts being supported by struts secured to pegs driven into the ground. The feet of the posts could be bolted to the foundation or to another peg in the ground. The distance apart of the posts will depend on the size of the boards which are used, but care should be taken to see that the boards have sufficient support to prevent "bellying" when the concrete is being rammed in. When the lower portion of the wall has been built the vertical posts can be raised, bolted to the portion of the wall that is built, and the next section of wall proceeded with. This will avoid the necessity for providing sufficient timber to board up the wall the complete height. The boards could be held in position at intervals by light bolts, the bolts being threaded at one end and with nut and washer for tightening. Another method is to place a strip of galvanized iron across the top, or nail pieces of wood across. The bolts would be removed immediately the concrete had taken its initial set.

For internal walls the following concrete mixture:—

1 part cement,
3 parts sand (mixture of fine and coarse),
3 parts limestone gravel

is safe, but is not considered a good mixture on account of the large percentage of sand.

As to whether the outside of a cement concrete wall should be plastered or cement washed, this is purely a matter of choice, and depends on the type of building and the finish desired. Roughcast is a common finish for the outside of concrete walls, but would be more expensive, of course, than the cement wash.

Sooty Mould on Citrus Trees.

Replying to the Secretary of the Beetaloo Valley Branch of the Agricultural Bureau, who asked for the cause of and remedy of Sooty Mould, the Deputy Chief Horticultural Instructor (Mr. A G. Strickland) says Sooty Mould is directly connected with various scale insects, including the common black and brown scales. Various scale insects, aphides, &c., secrete a sugary honeydew, and it is on this honeydew that the well-known Sooty Mould grows.

Sooty Mould does not attack the tissues of fruit or leaf in any way, but merely grows on the surface. Nevertheless, when Sooty Mould is abundant, it is a sign of fairly heavy scale infestation, and quite apart from the question of scale, the presence of the mould interferes with the normal functioning of the tree. Furthermore, fruit is often so disfigured as to necessitate cleaning.

Control of Sooty Mould is entirely dependent upon control of the insects which make its growth possible. Elimination of the scale will get rid of honeydew secretions, and the Sooty Mould will disappear. Black or brown scales may be controlled by fumigation or white oil sprays applied in summer.

Value of Farmyard Manure.—Bonedust v. 45 per cent. Super.

The following questions: 1. "What is the value of farmyard manure?" and 2. "How do the manurial qualities of bonedust compare with 45 per cent. super?" received from the Jervois Branch of the Agricultural Bureau, were referred to Mr. R. C. Scott (Supervisor Experimental Work), who says:—

1. Farmyard manure will vary widely in its composition according to the class of animal, the nature of the bedding used, amount of decomposition, &c., but on the average, good material will contain 0.5 per cent. nitrogen, 0.26 per cent. phosphoric acid, and 0.63 per cent. potash. In other words, 1 ton of rotted mixed farmyard manure will contain 11lbs. of nitrogen, equivalent to 55lbs. sulphate of ammonia; 6lbs. phosphoric acid, equivalent to 28lbs. 45 per cent. superphosphate; 14lbs. potash, equivalent to 29lbs. sulphate of potash. However, these ingredients do not rapidly become available for use of plants, and particularly is this the case with the phosphates, with the result that even when heavy dressings are utilised it is necessary to apply the usual quantity of phosphatic fertiliser. In addition to the fertilising value of farmyard manure, this material also has appreciable influence as a soil amendment, warming cold soils, improving the water-holding capacity of light land, and encouraging the action of soil bacteria.

2. The usual analysis of bonedust shows 3½ per cent. nitrogen and 40 per cent. acid soluble phosphate, whilst 45 per cent. superphosphate contains 45 per cent. water soluble phosphate. The nitrogen is readily made available; in fact, is equal to that in sulphate of ammonia, whilst the phosphoric acid is slightly slower than that contained in a water soluble phosphate. Therefore, in comparing the two fertilisers, it may be said that superphosphate does not contain nitrogen, but on the other hand the phosphoric acid is more readily available for the use of plants.

POULTRY INQUIRIES.

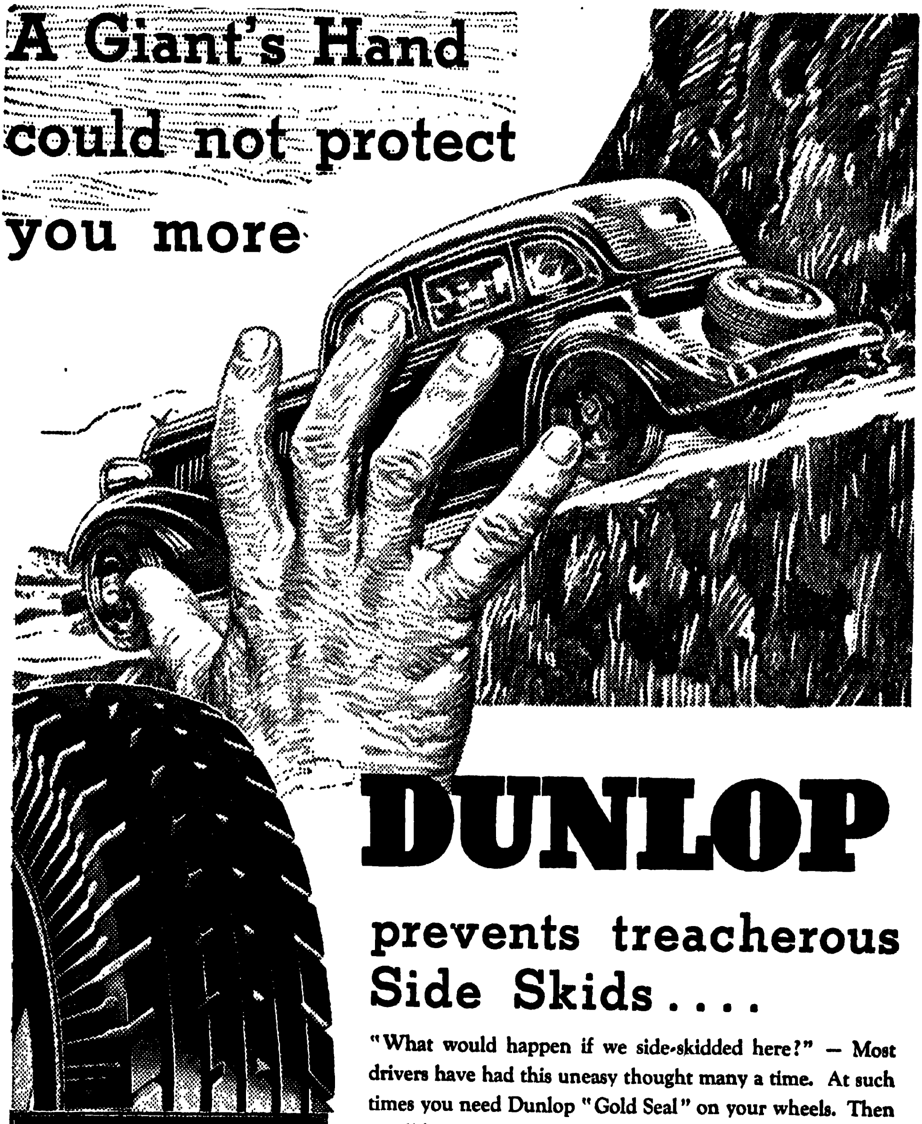
[Replies supplied by Mr. C. F. ANDERSON, Government Poultry Expert.]

Paralysis in Pullets.

Jervois Agricultural Bureau: What is the best treatment for pullets affected with paralysis?

Generally speaking, with pullets it is only occasionally that any number of them develop this trouble, but during the last two or three years there have been two cases where the trouble has been serious.

The experience of the Department is that this complaint may be due to two or three causes, the principal ones being the continued breeding from immature stock; that is, either from pullets which are only in their first laying season or from cockerels which have not fully developed before being used as breeders. It is strongly advised that



A Giant's Hand
could not protect
you more

no females be bred from until they have completed one full season's laying. The cockerels should be also fully developed before being used as breeders, and in the early part of the breeding season it is advisable to use second-year male birds.

The breeding stock should always have runs attached to the pens to provide sufficient exercise for the production of eggs suitable for breeding. The Department, however, has traced the principal cause to that of errors in the rearing of the birds. Quite a number of producers keep their chickens too much in confinement during the rearing season. It is essential that when the chickens leave the hot brooders—that is, from three to four weeks of age—they should be placed in portable cold brooders and have range during the growing period, frequently moving them on to fresh ground to provide the necessary exercise and not retard the growth of the chickens.

Another probable cause is that the young stock do not perch early enough. When chickens are from eight to ten weeks of age frames of wire netting 1in. in gauge, and kept from 12ins. to 15ins. above the ground, should be provided so that the pullets are kept off the damp ground during the night.

For the first two or three nights the pullets can be placed on these wire netting frames, after which they will readily take to them.

Feather-eating Poultry.

Taplan Women's Agricultural Bureau: Why do fowls pull feathers from others and eat them?

Reply—Some of the causes are over-crowding of the birds, too long a time between feeding, and frequently one bird may start the trouble, and unless it is taken out of the pen quickly, the trouble gradually spreads throughout the flock. Allow the birds to have a certain amount of range during the daytime, and feed the birds at least three times a day. They can have mash in the morning, wheat at mid-day, and wheat at night. If there are only a few affected, a little Stockholm tar applied where the feathers had been picked will frequently stop the trouble.

VETERINARY INQUIRIES.

[Replies supplied by Veterinary Officers of the Stock and Brands Department.]

Hon. Secretary Weavers Agricultural Bureau asks: "Does the frog of the horse's hoof come out periodically or no."

Reply—The "frog" or "hoof pad" grows from a vascular membrane which covers the so-called "sensitive frog." As it grows it is cast off when it grows to a certain thickness, while the part next to the ground is worn away by friction. In consequence owing to the frog's rubber-like nature, rags of horn along the edges are a common and natural process.

"Thrington" reports pony stiffness in hind quarters and over-heated fetlocks after getting at a bag of wheat.

Reply—The following treatment is suggested:—(1) Give following drench: Raw linseed oil, 1 pint; oil of turpentine, 4 tablespoons. Shake thoroughly and drench carefully. (2) Subsequently give 1 teaspoon of powdered nux vomica night and morning for 14 days. To give, mix the treacle and smear well back on the tongue. (3) Feed on good quality chaff (cut on green side so that not too much grain in it). Do not overfeed.

"Butler Tanks" has horse whose mane is thickly coated with scurf.

Reply—The trouble appears to be a form of mange. Treatment with sump oil and kerosene should be beneficial, though first of all the hair should be clipped from affected areas, and the scabby, scurfy patches well scrubbed with soap and warm water in which has been dissolved some washing soda, in order to remove the scabs, &c., so that the dressing used can be applied right on to the skin. (If it is only applied on top of a

collection of scurf, scab, &c., it is largely a waste of time.) See that every part of the body that is affected is treated and no patches missed, otherwise it is only a matter of time after treatment is discontinued before the condition of the animal becomes as bad as ever again. It should be necessary to dress the parts only once every two or three days and four or five applications should suffice. At the same time as giving local treatment to the skin, give the animal a tonic course of Fowler's solution of arsenic, giving 1 tablespoon in damped feed night and morning for a fortnight.

"Wisanger" reports 15-year-old mare in constant work, staggering gait, ravenous appetite, but would not drink. Died within three days.

Reply—The description of the case very strongly suggests the trouble to have been botulism, or so-called forage poisoning. Treatment is not very hopeful in these cases, but should be on the following lines:—(1) If animal still able to stand, put into "slings." (2) Give at outset a drench of 1 teaspoonful of potass. permanganate (Condy's crystals), dissolved in 1 quart of water, and follow shortly after with a drench of 1lb. Epsom salts, or raw linseed oil 1½ pints, turpentine 4 tablespoons. (3) Give 1 teaspoon doses of powdered nux vomica on back of tongue every 4 hours. (4) Feed on bran mashes and green feed.

Blackheath Agricultural Bureau reports colt rising two years with an over-shot bottom jaw.

Reply—The backward condition of the colt is due to his not being able to bite off the food properly when grazing owing to failure of the incisor teeth to meet. Provided that the animal is hand-fed, there is no reason why he should not become a profitable worker.

INCREASING THE STOCK CARRYING CAPACITY OF MALLEE FARMS.

[By R. L. Griffiths, D.D.A., Agricultural Instructor.]

(*Continued from page* 1218.)

THE IMPROVEMENT OF NATURAL PASTURES BY THE USE OF PHOSPHATIC FERTILISERS.

It will be noted that most of the species forming the natural grazing of the Mallee are far from ideal pasture plants, and that together they do not make a very good mixture. Consisting of grasses and various cultivation weeds, there is great likelihood of a protein deficiency. Also, in some of the newer country, particularly white sandy land, there is certainly a deficiency of phosphates.

The good pasture is almost invariably a mixture of grasses and leguminous plants, with some perennial species forming the basis of the mixture where possible. There are no perennial species in these natural pastures, nor are there any legumes. Even after adequate dressings of superphosphate, no perennial species appear naturally, and in the low rainfall areas—those below 12in. average annual rainfall—it has not been found possible so far to induce leguminous plants to grow. Here the effect of superphosphate is simply to encourage a more plentiful and probably also more nutritious growth of the existing herbage, thus increasing carrying capacity to some extent.

Within the areas of somewhat better rainfall—12in. to 15in. per annum—leguminous plants will grow, but do not thrive unless there is a very considerable reserve of phosphate in the soil. It is only after the continued application of super, either to cereal crops or as a top-dressing, that clovers begin to thrive.

With still higher rainfall—over 15in.—there is much less difficulty. It appears quite definitely that the higher the rainfall the less phosphate is required to encourage leguminous growth. It is certain, however, that without the building up of phosphatic reserves in the soil the naturalised clover species will not form any appreciable percentage of the plants for grazing.

In the low rainfall areas the addition of extra super to the last crop prior to a pasture period is justified, simply to improve the existing species, while in the better rainfall parts continued high dressings of 1cwt. per acre or more with each cereal crop—to encourage clover growth in the pastures—is essential if farms are to reach high stock-carrying capacity. In addition, when land is to remain pasture for any extended period, it should be top-dressed at least every second year with superphosphate, using 1cwt. per acre if possible.

There appears to be no necessity to sow seed of these leguminous plants. It is not known exactly where the seed comes from, but it is certain that on lands in the Murray Mallee with 12in. or more average annual rainfall, when sufficient phosphate is added to the soil, Hare's Foot Clover, Burr Medic, Hop Clover, Woolly Clover, and Clustered Clover all appear. Probably the pasture could be improved more quickly if small quantities of the seed of some of these, particularly of Burr Medic and Clustered Clover, the seed of which can be easily purchased, were sown with the last crop before a grazing period.

The importance of encouraging these leguminous species cannot be over-emphasised. They are very superior pasture plants to those in the existing pastures, having a better balance between proteins and carbohydrates. As they are mostly low creeping plants they thicken the pasture, filling gaps which would be left open by grasses and other herbage. They provide a residue, after maturity, that is not easily destroyed by wind or rain, and which is more useful and nutritious than that of the common grass and weed species. Although all of these clover species are annuals, when they begin to form a percentage of the pasture they will

continue to appear each year, and, should the plants become reduced in number, or appear weak and unhealthy, extra superphosphate will always improve the position.

In addition to actual grazing value, also, these leguminous plants serve a very useful purpose in the improvement of soil fertility and condition, because, alone of all orders of plants, the *Leguminosae* obtain their necessary nitrogen supplies not from the soil, but from the air. Colonies of bacteria form in nodules on the root system, and these have the power to fix nitrogen from the air for the use of the plant. Thus all residues of leguminous plants returned to the soil are a direct gain in nitrogen—which is one of the elements most likely to be lacking, particularly in sandy soils.

It will be found on Mallee farms that the clover species appear first, and develop best, on the heavier classes of soil, and those containing much lime, and that a greater reserve of phosphate is necessary to encourage them on sandhills. It is possible, however, with good management to cover even the sandy country with clover, and the ultimate value, both in the carrying of stock and the improvement of the land, more than justifies the trouble and expense incurred.

Burr Clover (*Medicago denticulata*).

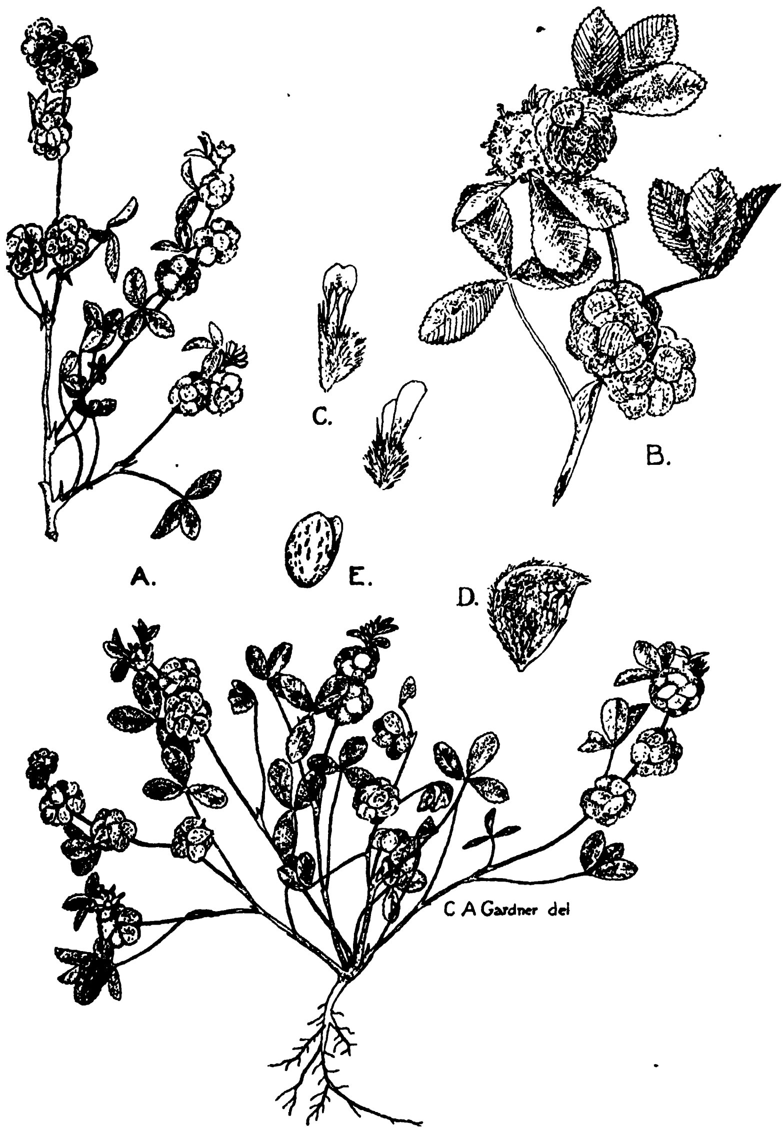
All of the leguminous plants which appear are not of equal value. The characteristics and relative value of those most common are as follows:—

Hare's Foot Clover (*Trifolium arvense*).

This is usually the first leguminous species to appear, and is an indication that the soil is reaching a condition suitable for clover plants. It is upright and slender in growth, not providing a great bulk of fodder. Although the analysis shows quite a high food value, this plant is not very palatable to stock, and is often neglected by them. It grows over a larger area of country and in lower rainfalls than most of the other species, but in general can be regarded as rather a poor specimen of leguminous plant, and chiefly useful as an indication that better clovers may be encouraged to grow by further attention and the use of more super.

Medics (*Medicago denticulata*).
(*Medicago tribuloides*).

The more common of these, *Medicago Denticulata,* is frequently called Trefoil, or Burr Clover. Both are extremely useful plants, and their appearance is generally recognised as an indication of land in good heart. Certainly their presence in pastures indicates increased stock-carrying capacity. They grow luxuriantly,



[From *Journal of Agriculture,* Western Australia.]

Woolly Clover (*Trifolium tomentosum,* Linn.).

provide a very large amount of grazing, and seed freely. Stock invariably do well in pastures containing a percentage of these Medics, which belong to the same plant family as Lucerne.

Although only annuals, their free-seeding habits ensure reproduction each year. The seed is useful in another respect also. There have been many instances where sheep, turned on apparently bare paddocks, have retained or even improved their condition on the seedpods alone of these plants. The seedpods are somewhat troublesome in the wool of sheep, being the chief cause of "burry fleeces," but manufacturers are now able to deal effectively with burry wool. Although it may be necessary to accept a somewhat lower price per pound for fleeces containing these burrs, it is generally recognised that the price per fleece is greater, as the improved pasture considerably increases the growth and weight of the fleece. On Mallee farms where these plants grow freely one of the chief problems of better stock-carrying capacity has been solved.

Hop Clover (*Trifolium procumbens*).

Woolly Clover (*Trifolium tomentosum*).
Hop Clover (*Trifolium procumbens*).
Clustered Clover (*Trifolium glomeratum*).

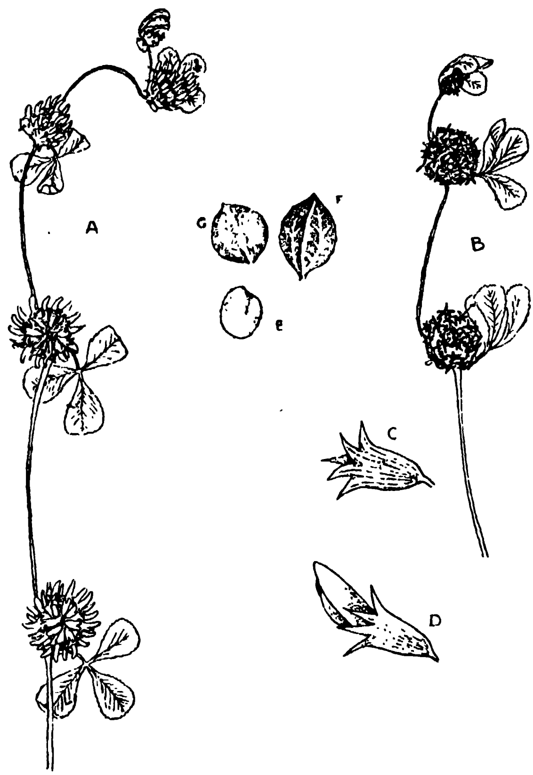
These *Trifolium* species, smaller in size of each plant than the Medics, and somewhat creeping in habit, also serve a very useful purpose in the pasture. They usually do not appear until Burr Clover is becoming established, and are all very nutritious and palatable to stock. Even after maturity they continue to provide good grazing. Because of their creeping habit they cover the ground, filling gaps that otherwise would not be utilised, and so increase the density of the pasture.

A pasture which contains good grass species, Burr Medic and these clovers is approaching the ideal in moderate to low rainfall areas. The seed of one of these, Clustered Clover, is usually quoted in seedsmen's catalogues at a very moderate price, and being very small in size, contains an enormous number of seeds to the pound, so that, if these smaller clover species are not apparent on the farm after adequate super dressings have been used, the sowing of 1lb. to 2lbs. of Clustered Clover seed per acre is an advantage.

The Mallee farmer who is situated in an area with over 12in. average annual rainfall, and who is interested in the keeping of livestock and the improvement of soil fertility and condition, can do more by using sufficient phosphatic fertiliser, thus encouraging growth of leguminous plants in his pastures than by any other means.

IMPROVEMENT BY THE SEEDING OF PASTURE SPECIES.

A great deal of experimental work has been done in the endeavour to find plants for these areas to sow a pasture after a cereal cropping programme, which will give good stock-carrying capacity without undue delay, and which will be sufficiently permanent to continue for a period of years. Unfortunately, although many species of plants have been tried, very few have proved successful, and of these there is only one true perennial plant, which is Lucerne.



[From *Journal of Agriculture*, Western Australia.]

Clustered Clover (*Trifolium glomeratum*).

A—Flowering branch. B—Seeding branch. C—Calyx (enlarged). D—Flower (enlarged). E—Clover seed. F—Sorrel seed. G—Sorrel seed with husk removed.

No perennial type of grass will live through the hot dry summer period which is so often experienced. It has happened on occasions that species like Perennial Rye Grass and *Phalaris Tuberosa* have lived for more than one season, usually when they have been fortunate enough to be established in a year with a summer of rainfall above the average, but normal summer conditions invariably kill them.

It appears, then, that sown pastures, with the exception of Lucerne, must be composed of annual plants, which can be depended on to seed sufficiently freely to re-establish the pasture each year.

Plant species which can be recommended for seeding under certain conditions are Lucerne, Wimmera Rye Grass, King Island Melilot, Evening Primrose, and Early Subterranean Clover, and the relative use of these is as follows.

Lucerne (*Medicago sativa*).

Lucerne is the most important and valuable plant which can be established as a pasture on Mallee farms, although it appears very difficult to persuade farmers that this is the case. Officers of the Agricultural Department have attempted for many years to persuade farmers in the semi-arid parts of the State to sow lucerne, but with very little success up to the present time. It is not intended in this article to discuss fully the problems of Lucerne growing, as in Bulletin No. 246 of the South Australian Department of Agriculture, "Lucerne Growing in South Australia," W. J. Spafford, Deputy Director of Agriculture, has already done so, but to deal only with those aspects which affect the mallee wheatgrower who is desirous of establishing better pastures.

Probably the chief reason why wheat farmers do not attempt the growing of Lucerne is that they have seen it grown under irrigation, where the stand is dense, the growth free, and several cuts are obtained each season. Obviously such Lucerne cannot be grown in areas where the only moisture received is the scanty rainfall.

Lucerne (*Medicago sativa*).

But in spite of the wide difference in conditions, Lucerne will grow in these areas. Lack of moisture will reduce the plants to one or two per square foot, or perhaps even less, but these plants will do what no other pasture variety can do—they will supply green growth through the greater part of the year, the only dormant period being in winter and early spring, when there is usually abundance of other pastures. Under normal circumstances the summer grazing will not be very much, but after each summer rain some growth will appear, often sufficient to give stock a much-needed change from dry fodders, a nutritious food high in protein content, which will improve health as well as condition; while in an abnormally wet summer the Lucerne growth can easily be greater than the farm stock can utilise.

Another reason why Lucerne has not become popular is that it has mostly been attempted only on small areas. These are unsuccessful, particularly if only part of a paddock is sown. If Lucerne is grazed too heavily, and the crown of the plant eaten out, it usually dies. Where only a part of a paddock is sown all livestock given access to the area will overgraze the Lucerne and so kill it. Also on small areas there is often a gathering of vermin—rabbits and hares—on the Lucerne patch, and these are more harmful than the farm livestock. If, therefore, the growing of Lucerne as a pasture is to be successful it must be sown on large areas and over complete paddocks. Where rabbits or hares are plentiful it will probably not be much use if only one farmer in a neighbourhood attempts to grow Lucerne, but when most of the community do so the damage done by vermin will not be appreciable.

When established, Lucerne will live through dry summers in the low rainfall areas, because of its deep rooting habit, but it must be grazed judiciously. It is not naturally a pasture plant, being more fitted for cutting, as fresh growth comes from the crown before the previous growth is mature, and if the new growth is grazed too soon the plant is weakened and its life shortened. Even under good grazing conditions, Lucerne usually does not live in these areas for more than four to six years, and only then if it receives annual top-dressing with superphosphate, but this life is much longer than that of any other pasture plant. The best management is to divide the area sown to Lucerne into comparatively small paddocks, and graze each in turn quickly with large numbers of stock. If it is possible to cut the first spring growth with a mower for silage or hay this is an advantage, as the cutting stimulates the plant, and the hard base of the cut stems prevents the stock damaging the crown for the rest of the season.

Cost of the seed was one of the reasons why farmers did not sow large areas of Lucerne. During recent years the cost of seed has decreased considerably, and the amount spent on 4 to 6lbs. seed per acre, all that is necessary in these areas for a pasture likely to last at least four years, is not very great.

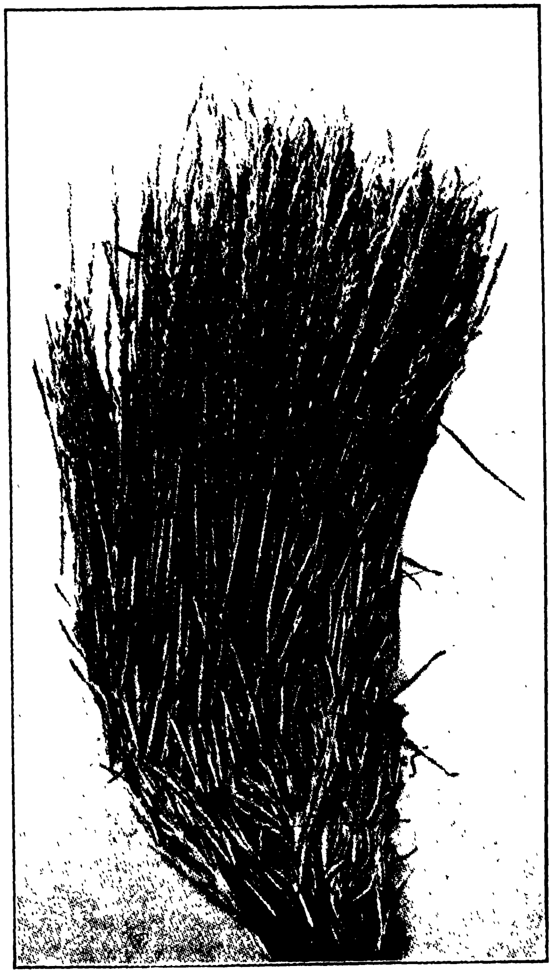
The majority of attempts by farmers to grow Lucerne to date have been by seeding it in a cereal crop. This often failed, as the cereal, in the later stages of its growth, reduced the soil moisture to such an extent that most of the young Lucerne plants died. For this reason it is now generally advocated that the Lucerne be sown with a disc drill, and a dressing of superphosphate through the stubble residue during the autumn months of the following season. This method is usually successful, though weed growth may kill out some of the young Lucerne plants. The most certain method is to sow on fallow land, with a light seeding also of an early maturing cereal, and to cut the growth very early in the spring for silage or hay. The advantage of cutting instead of grazing the first growth of Lucerne is considerable, enabling the plant to stool and establish a crown to better advantage, and where the cereal growth is removed early, sufficient soil moisture remains for the Lucerne.

When the first growth is grazed, it is essential to use large numbers of stock, to graze quickly and evenly, and to remove the stock before the plants are eaten too closely. If care is taken in developing the plants, and in subsequent grazing methods, there is no difficulty in establishing Lucerne pastures in wheat areas of moderate to low rainfall.

It is certain that when wheatgrowers become good keepers of livestock also, they cannot afford to be without Lucerne on part of their holdings, because it is the only possible permanent pasture plant, it gives a highly nutritious feed which balances the ration in conjunction with cereals, grasses, or the usual pasture weeds, and it gives green pasture during late spring and summer when the other plants which appear even in wet years, are likely to be species such as Buckbush and Paddymelon, of little fodder value.

Wimmera Rye Grass (*Lolium* sp.).

If Lucerne is the most useful of all sown fodder plants, Wimmera Rye Grass is certainly the next in importance. Although only an annual—probably a variation of Italian Rye Grass—it seeds freely, and continues in the pastures each year when once established. At present in the Murray Mallee area farmers are much more willing to sow this grass than to sow Lucerne. It is generally considered that Wimmera Rye Grass will grow wherever Barley Grass prevails. This is certainly so in this particular district, over the whole of which Barley Grass grows



[From Victorian *Journal of Agriculture*.]

A specimen of Wimmera Rye Grass.

freely. Good stands of Wimmera Rye Grass have been seen along the Murray River, and even north of it in the country with the lowest rainfall, averaging not more than 9in. to 10in. per annum, and throughout the area the higher the rainfall the better the growth of this grass. It should be on every farm because—

(1) It is the only grass species which has proved successful, and it can be established cheaply and easily.

(2) It provides a greater bulk than any of the natural grasses, matures rather later in the spring, thus giving a longer growing season, is palatable at all stages, provides good residue even after maturity, and has no objectionable features as a pasture.

(3) It will compete successfully with Barley Grass reasonably well in the low rainfall areas, and will almost entirely replace it in better rainfall parts. As Barley Grass leaves much to be desired as a pasture, and also acts freely as a host to Takeall, whereas Wimmera Rye Grass appears to be immune to this disease, or almost so, the advantage is obvious.

(4) It will grow on all classes of Mallee land, and, while preferring the heavier types, is not difficult to establish on sandy land, provided adequate super has been supplied.

Farmers often raise the objection that Wimmera Rye Grass develops into a bad cultivation weed, difficult to eliminate from fallowed areas, and usually appearing to some extent in the cereal crops. This is undoubtedly the case, but is more of an asset than a liability. A grass which was easily killed out on cultivation land could not be expected to persist in the pastures. It grows freely with the cereal crops, upright in habit, and not killing out any appreciable number of cereal plants, as some weeds do, while its presence ensures the re-establishment of the pasture the next year. Only with bad farming methods will Wimmera Rye Grass be a menace to cereal crops in low to moderate rainfall areas, and any slight reduction in yield from sown crops is more than balanced by increased stock-carrying capacity during the following years.

Wimmera Rye Grass likes cultivation. It usually does not continue to form the bulk of a pasture unless the area is cultivated and cropped periodically. If land is to remain as pasture for an indefinite period of years it will pay to cultivate the pasture occasionally. Cases have been seen where a strip of pasture land has been broken up with a cultivator, and the balance left untouched. On the cultivated strip Wimmera Rye Grass formed the bulk of the pasture, and on the remainder Barley Grass prevailed. Thus, on a permanent pasture paddock it would pay to use a combine once about every second year, with the points cultivating, and at the same time using the implement to apply a dressing of phosphate, as this grass responds very well to phosphatic fertiliser.

It is not a perfect pasture by itself, being, like most grasses, more fattening than flesh-forming, but Wimmera Rye Grass with Lucerne, or with the naturalised clover species which have been previously described is certainly the ideal pasture for the Mallee areas at present.

It can be established with little expense and with no extra labour. The usual method is to sow about 2lbs. seed per acre—which will cost approximately 1s.—distributing the seed in the fertiliser-box of the drill or combine each time the box is filled when sowing the last cereal crop before a pasture period. The cereal crop must of course be for grain purposes and not for hay. Wimmera Rye Grass is a free persistent seeder. Even when grazed heavily it forms seedheads close to the ground, while in a crop it produces a very large amount of seed. It is best established when a harvester or reaper-thresher is used to reap the crop, because then the light grass-seeds all blow from the back of the machine, and provide an even seeding for the next year. Where a stripper is used the majority of the Rye Grass seed will be gathered in the machine, and be eventually blown out from the winnower, while only the seed on some of the shorter stools is left in the paddock for the next season.

Wimmera Rye Grass has so many advantages over existing grass species that all farmers are strongly recommended to establish it on their holdings.

King Island Melilot (*Melilotus indica*).

This is an annual leguminous plant, which is sometimes called Californian Lucerne. It can be sown with Wimmera Rye Grass to provide the leguminous portion of the pasture where other species are not growing freely. Although it is nutritious, stock need to acquire a taste for this Melilot, and sometimes appear rather to neglect it. It is generally believed that King Island Melilot is more palatable when grown close to the sea than inland. It will grow, to some extent, in rainfalls of 12in. per annum, but is not luxuriant unless the rainfall is 15in. or over. It has proved useful on many farms, but Lucerne, with the Medicago and

[From *Journal of Agriculture*, Western Australia.]

King Island Melilot (*Melilotus indica*, All.).

Clover species, is preferable. It has a strong characteristic odour, very sweet when the plant is cut for hay, but rather objectionable in milk and dairy produce.

Wheat growers should be rather careful of establishing this plant, because wheat merchants and millers are loth to purchase wheat from farms where Melilotus grows freely, as the odour from the seed, when reaped with the wheat, tends to

taint the flour. It appears that this is not so to any appreciable extent if the Melilot seed is screened out before gristing of the grain, but is very definitely noticeable where any of the seed is ground with the wheat.

On farms where King Island Melilot forms a proportion of the pasture, clean fallow cultivation will prevent it becoming a danger in this respect. It can be recommended on farms where other leguminous species are not forming a sufficient proportion of the pasture plants.

Evening Primrose (*Oenothera odorata*).

Evening Primrose is a biennial plant which serves a very useful purpose. It is only of moderate feeding value, and usually does not form a dense pasture, but it grows nearly all the year where there is sufficient soil moisture, and often provides green feed for stock when no other species are available. The chief value of Evening Primrose is that it prefers sandy soils, and will grow freely on poor classes of white sand where it is not possible to establish other plants. Under favourable conditions the Primrose appears to live longer than the two years which constitute its normal life period.

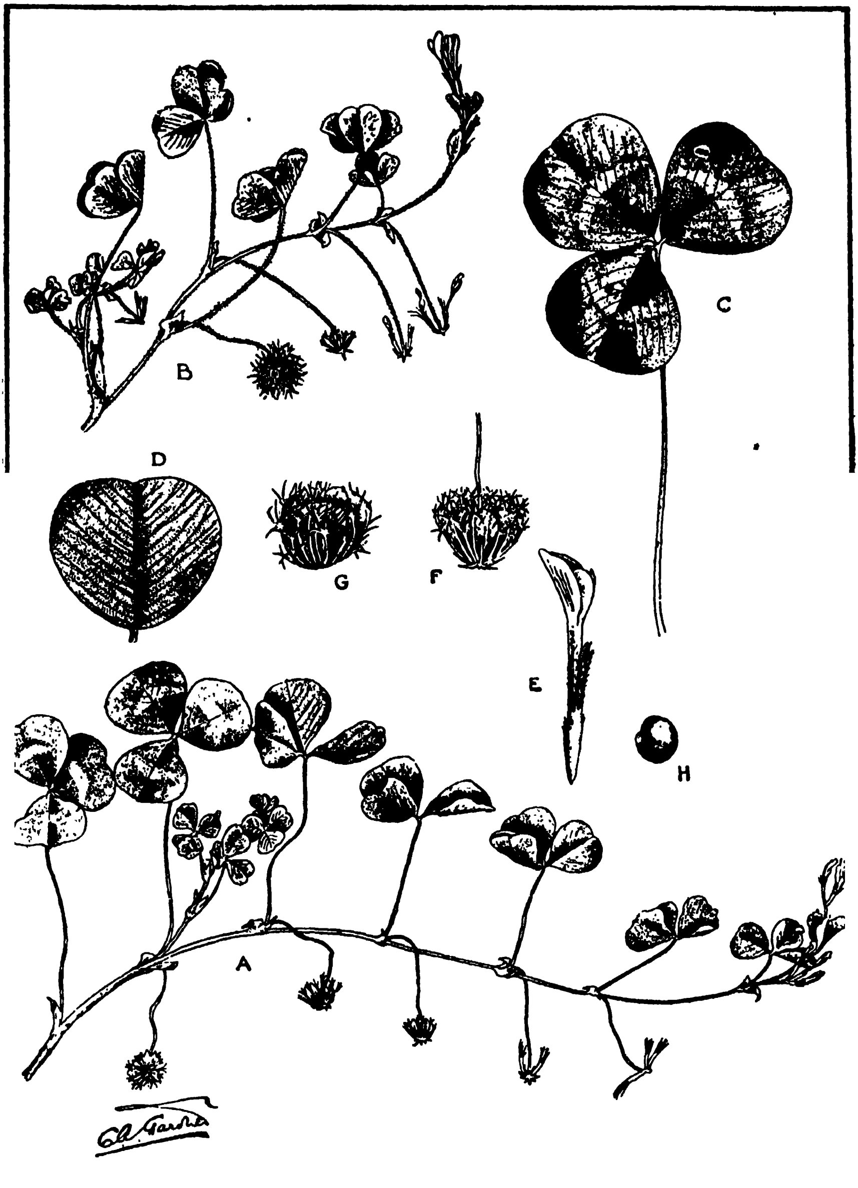
Evening Primrose (*Oenothera odorata*).

It will act as a sand-binder on drift sand areas, preventing the movement of surface soil, providing grazing for stock, and thus holding and improving the soil until eventually better pasture plants may be established. It is not likely to be successful in areas with under 14in. of rainfall, and is better in higher rainfall parts.

During the spring and summer months it develops a tall, hard, unpalatable stem, and seeds freely, so that the pasture remains permanent. To obtain maximum feeding value the stems should be cut with a mower after the seed has shed, so that the stock may easily reach the fresh growth which appears at the base of the plants.

Early Subterranean Clover (*Trifolium subterraneum*).

The original strain of Subterranean Clover has not proved successful in these areas. It is generally recognised that it needs a minimum rainfall of 20in. per



[From *Journal of Agriculture*, Western Australia.]

A and B—Portion of plant, showing habit and development. C—Leaf, showing whitish crescent-shaped markings. D—Leaflet with brown flecking (on veins near mid-rib). E—Flower. F—Maturing seed head. G—Ripe burr, with three pods. H—Seed.

annum. Subterranean Clover has been sown by some of the Mallee farmers. Should there be late spring rains the plant matures, develops seed, and appears again the next year. As soon as a normal dry spring occurs, however, the clover

plants die before maturing the seed, and, being only an annual species, do not appear again.

During recent years various research stations have selected earlier maturing strains, and by utilising the best of these, which at present is the Dwalganup strain, which comes from Western Australia, it is possible to establish Early Subterranean Clover in lower rainfall districts. Even now the limit of minimum annual rainfall is 16in. to 17in. The earlier maturity allows development of seed before hot dry weather kills the plants.

Although Subterranean Clover selections have yet only a very limited use in the better rainfall parts of the Mallee, it is likely that further selection work will evolve strains in the future which will be safe in still lower rainfalls. Subterranean Clover will grow on almost all classes of soil, and is established by sowing 2lbs. to 3lbs. seed per acre when top-dressing pastures, or in a mixture with other pasture species.

The subject of Subterranean Clover is fully dealt with in Bulletin No. 240 of the South Australian Department of Agriculture, written by W. J. Spafford, Deputy Director of Agriculture.

Blue Lupin (*Lupinus pilosis*).

The Blue Lupin is mentioned, not because it is a pasture plant, but because inquiries are often made concerning it, and it has received a certain amount of prominence during recent years. The Blue Lupin is not a pasture plant. Although a legume, and a soil renovator, it is not palatable to stock, which usually will not touch it.

It is worth growing as a sand-binder, and to hold badly drifted areas there is no better plant, where the annual rainfall averages 14in. or over. It will grow in somewhat lower rainfalls, but not very freely.

The only value of Blue Lupin to livestock is in the seed. Each plant produces a large amount of seed in pods, and each individual seed is somewhat larger than that of a garden pea. When ripe the pods burst, throwing out the seeds for a considerable distance. When the plants are mature and dead, the surrounding ground is covered with seed, and during the summer months sheep will enjoy the seeds, which are very nutritious. They invariable tramp sufficient of the seed into the sandy soils to grow a fresh crop of Lupin the next season, and so, although the plant is an annual, fresh plants grow each year.

GROWING OF CEREAL AND OTHER CROPS FOR GRAZING.

This article so far has dealt mostly with the improvement of pasture land which is not to be cultivated for a number of years. It frequently happens, however, that a paddock in a regular cropping rotation is used during one year for grazing. Stock are turned on to the stubble of the cereal crop, which provides bulk feed for two or three months. Autumn rains destroy most of the grazing value of the stubble itself, and the plants which appear afterwards often provide only low carrying capacity. There is usually a certain amount of self-sown crop, but not, except under unusual circumstances, enough to provide much grazing. In addition, various plants germinate and provide pasture. Where Wimmera Rye Grass and clovers are established on the farm, the pasture may be quite satisfactory, but in most cases the paddock will not carry many stock.

This can be greatly improved if cereals are sown. The amount of work involved need not be great, and so the cost of such seeding is kept to a minimum. The usual procedure is to use a disc drill, and, early in the autumn months, to sow seed and fertiliser without previous cultivation through the stubble residues. Farmers frequently sow these grazing crops without super, but this is not advisable, unless it is certain that the soil contains a considerable reserve of phosphate, which is unusual on Mallee farms. The addition of super will do much to improve the bulk

and quality of the grazing. It is wise also to seed heavily, not using only the quantity proved most useful for grain or hay crops. Livestock are certain to bushels per acre is proportion of the plants while grazing, and so a seed quantity of 1½ to 2

All of the cereals—wheat, oats, barley, ... grazing crops and each is useful in a particular way.

Wheat.

As a general rule wheat is not used to any great extent. Farmers have learned, because of the prevalence of diseases such as Takeall and Flag Smut, that it is wiser to assist in reducing these diseases by keeping the land as clear as possible of wheat plants during the rotation period between the grain crops. Where these diseases are not a serious menace wheat plants will provide good grazing, nourishing and palatable to stock, although not growing so quickly during the winter months as barley or rye will. If wheat is used for this purpose, comparatively early, vigorous, quick-growing varieties are best, such as Sultan, Sword, Ford, Gluyas, Waratah, Nabawa.

Oats.

Oats are most frequently used. They provide good pasture, but most of the varieties in common use are rather slow starting, and so do not give a bulk of feed when most required, early in the season. They are certainly the best of the cereals for providing grazing during the spring and early summer months, recovering, after grazing, better than wheat or barley does. Oats of the Algerian type are not very palatable to livestock, which will prefer any of the other cereals to them if given a choice.

None of the varieties in common use in the Murray Mallee District at present is quite satisfactory but a good deal of interest is now being shown in the use of oats as a grazing crop and it is probable that in the near future more useful types will be developed. The varieties now in general use are Algerian which is somewhat unpalatable and slow growing during the winter, but is useful for providing feed late in the season; Palestine, which grows quickly, but does not recover well after being grazed; Early Burt and Lachlan, which are fairly satisfactory; Mulga, which at present appears to be the most useful, being a vigorous, quick grower and evidently palatable to stock at all stages of growth.

Barley.

Barley serves a useful purpose as a grazing crop. Although susceptible to Takeall, it does not appear to be attacked by this disease to the same extent that wheat is, and, while it might be wiser to avoid both of these cereals for grazing where Takeall is a menace, barley would probably not be so dangerous in this respect as wheat. Barley has the advantage that it thrives on light soils, and will grow quickly during the winter months, thus providing early feed.

The disadvantages are that the plant is somewhat shallow and fibrous-rooted, more likely to be pulled out by stock than the other cereals, and, while good winter feed is provided, barley does not recover well after grazing later in the season. It is generally considered that the six-row types provide more bulk of pasture than the two-row malting kinds. Varieties not used to any extent in this district are the skinless barleys, such as White Skinless and Black Hulless. It is generally considered that these are the quickest growing of all, and so are worth a place for early winter grazing.

Rye.

Rye is the most hardy of all the cereals, and is rapidly gaining in popularity for use as a grazing crop. It thrives even better than barley on light soils, and is often successfully used as a sand binder on drifted areas. Rye is a quick, vigorous grower, will provide very early feed, recovers well after grazing, and is quite palatable to stock during the early stages of its growth.

It becomes tough and fibrous as the plant nears maturity, and stock will then neglect it. Thus a pasture of rye should be kept hard grazed, unless it is intended to use it for winter pasture, afterwards allowing the crop to grow for silage There hay, or grain, which, with a plant so vigorous as this, is easily been taken from the have been cases in this district where two cuts
one rye crop

Mixtures of Cereals.

It will be noted that none of the cereals is an ideal grazing crop. Some provide feed early and not late, the others *vice versa*. Thus there is a considerable advantage in using a mixture of the cereals, always including either barley or rye to provide the winter feed, and wheat or oats for the spring period. Where there is danger from Takeall, rye, and oats would be the safest mixture. All of the four may be mixed together if thought desirable, and as a mixture of cereals always grows more vigorously than any separate one of them—provided plenty of seed is used, with sufficient super, to stimulate the growth—quite high stock-carrying capacity can be obtained in this way.

It is not wise to use more than one mixture in any paddock, nor more than one variety of any cereal sown separately, as if this is done it frequently happens that one variety or mixture proves more palatable than the others, and so a part of the paddock is grazed too hard by the stock, and the remainder neglected.

Mixture of Cereals and Legumes.

A pasture consisting only of cereal plants is likely to be rather more fattening than flesh forming, and would be improved by the addition of some leguminous plants. On some farms these will appear naturally, in the form of the Medics and Clovers, and so the ration will be balanced. Where Clovers are not present it would be an advantage to sow a leguminous plant with the cereals, but the choice is very limited. Seed of Burr Medic and Clustered Clover could be sown with the cereal grazing crop, in the areas where these plants are likely to establish themselves.

Field Peas, of the Dun and White Brunswick varieties, grow quite well during winter and spring months in this district, but these do not recover after grazing, and so are of no use for this purpose. They can be sown alone in the better rainfall areas, particularly the earlier White Brunswick variety, and allowed to grow until almost mature, then used for fattening sheep or lambs for market, for which purpose this crop is well suited.

The only other plant worth considering is the Common Vetch (*Vicia sativa*). Vetches, or Tares as they are often called, are leguminous plants, hardy, free-growing, and frequently used elsewhere in forage mixtures. They will grow quite well in the moderate rainfall areas, and will recover after grazing. The addition of 8lb. to 10lb. Vetch seed per acre to that of the cereals would definitely increase the carrying capacity and make the forage more nutritious.

Some care must be taken with Vetches on wheat farms. They should only be used in a mixture which is to be hard grazed and not allowed to reach maturity or which is eventually to be used for silage, so that the seed does not mature. The Vetch can easily become a weed on a wheat farm, and is then very troublesome, as the seed is one of the very few which it is almost impossible to remove from wheat grain by any type of seed grader.

Summer Fodder Crops.

Very few attempts have been made to grow summer fodders in these areas. Because of the low rainfall and the usual dry hot summer, it is not possible to depend on the successful growing of summer crops. There have been some instances, however, when heavy rains happened to fall during the late spring or early summer months, of good growth being obtained from Sudan Grass.

This is likely to be the only summer fodder worth considering, as it is the most drought-resistant of all the crops whose growing period is during the hot months. It is probable that a good deal could be done with Sudan Grass in some years, particularly when preparation had been previously made by fallowing a paddock as early as possible during the autumn, and subsequently keeping it clear of plant growth by cultivation until the spring. Sudan Grass sown on such prepared land during September or October, at the rate of 6lbs. to 8lbs. seed per acre with super would have a reasonable chance of success.

The cost of the operation would not be great; if the crop should fail the land will remain as fallow for the next season, and the risk is worth taking by the man interested in his livestock, as even a small ration of green forage, when usually all the pasture is dry, would be very beneficial.

Certain precautions must be taken in the feeding of Sudan Grass to stock. It is a member of the Sorghum family, and all plants of this family, under certain circumstances, are likely to be poisonous. It was thought that Sudan Grass was safe, and that any cases of poisoning came from mixtures or hybrid plants growing with it, but recent experiences of stockowners in South Australia show that Sudan Grass itself can be dangerous.

The stock poisoning is due to the development of prussic acid in the plants during the early stages of growth, especially if that growth has been checked in any way. When the plants reach the flowering stage all danger is past. Stock therefore should not be allowed to graze Sudan Grass until it reaches the flowering stage. If cut and wilted for some hours before feeding it is safe at any stage of growth. With the limited amount of rainfall available, it is not likely, in the Mallee, that there would be more than one growth of Sudan Grass during the growing period, although with sufficient moisture several can often be obtained between spring and autumn, so that to use it economically it might be best to cut the crop, and feed it as a partial ration to supplement the usual grazing.

THE USE OF CONSERVED FODDERS.

In districts of low to moderate rainfall the usual green pastures for stock grow only from six to eight months of the year, and the natural grazing for the balance of the year—quite often from December to May or June—is poor. It has been mentioned previously that the residues left after maturity of many pasture plants are not very nutritious, and the same may be said of cereal stubbles. Stockowners meet this shortage in one of two ways, either by reducing the number of livestock kept during this period, or by hand-feeding of conserved fodders to supplement the grazing.

Where farmers are growing lambs for local or export trade requirements they endeavour to dispose of them before summer weather dries out the pastures. This cannot be done unless lambing is early, and early lambing is not safe in these parts, where the opening of the season is often late, unless provision is made to hand-feed the ewes.

Many farmers keep a small permanent flock, and buy more sheep when they have a surplus of feed, selling again when a shortage occurs. This is often not profitable, and it is certain that if the farm flocks are to be reduced in number periodically to avoid overstocking during the lean period, the keeping of sheep will never reach its greatest profit. If farmers wish to keep the maximum number of livestock in these districts they must consider hand-feeding as a part of the regular farm routine during three or four months of most years.

Cereal Grain for Hand Feeding.

After a normal season considerable residues remain on pastures and stubbles. These are low in feeding value, and it is not to be expected that a breeding ewe can satisfactorily grow a fleece, develop a lamb, and maintain the lamb after birth on such bulk feeds alone without the addition of some concentrates. Farm-grown concentrates are likely to be the most economical, and, on Mallee farms, these will be provided by cereal grains, which can be stored in bulk on the farm without much expenditure, using tanks or barns for the purpose. Storage in bulk is the only satisfactory method. All of the cereal grains are useful for this purpose—rye, wheat, oats, and barley. An amount of 1lb. to 1½lbs. per sheep per day of these grains, with roughage, will provide a full ration.

Rye is not grown to any extent at present for grain purposes, and so is not likely to be used. *Wheat* is chiefly grown for marketing, and is not greatly used for stock feeding, although when the price is low it might be more profitable to do so. Recent tests made through the Department of Agriculture have proved that pinched or shrivelled wheat has a high stock-feeding value, being greater in protein content than full grain so that rather than accept a reduced price for wheat of this kind, it can be better utilised for the feeding of stock.

Barley and *Oats* are the grains usually available, as the growing of at least one of these crops forms a part of most crop rotations on wheat farms.

Oat grain is most commonly used at present, and is a very satisfactory concentrated food. It, as well as the other grains, can be fed best through some type of self-feeder, as then all members of the flock have a reasonable opportunity to obtain a fair ration. These grains can also be fed quite well by spreading out on an area of bare hard land, provided they are spread sufficiently for all of the stock to obtain their share. *Barley* grain is very useful. The digestible protein content is usually less than that of oats, and so the grain is not quite so suitable for breeding ewes, but as a maintenance ration it is quite satisfactory. Barley gives very good results if sprouted before feeding. This can be done in the following manner. Use about 1½bush. of grain in a 3bush. bag, tying at the top. Soak the bags in shallow troughs partly in and partly out of water for 24 hours, turning two or three times. Allow to stand for a further 24 hours, when the grain will be found to be definitely sprouting, except in very cold weather, when a longer period may be necessary. There have been cases where ewes with lambs at foot have kept their condition, and have grown the lambs very quickly on a ration as low as ¾lb. sprouted grain per head per day. The effect of this treatment appears to be that the grain becomes more digestible.

It must be remembered, when hand-feeding grain to stock, that the full ration must not be commenced suddenly. This applies to all changes of feed, but more particularly to grain. Severe digestive and other troubles, including a break in the wool, may occur from the sudden change. A small amount must be given at first, gradually increasing each day until the full quantity is reached.

Use of Hay and Chaff for Hand Feeding.

During dry years, when there is a definite shortage of pasture, more bulk must be supplied, as ruminant animals need some bulk of food to ensure good digestion. Hay or chaff can be made to serve this purpose very well, but not hay as it is so often made by farmers. A large proportion of hay on farms is cut when the plant is so mature that the hay consists of grain and straw. Horses appear to do quite well on this, but other livestock do not. If hay of this class is fed to sheep the heads will be eaten, and most of the straw wasted. Even when cut into chaff and fed from troughs or self-feeders the position is not much better, as the stock will use the grain and leave the balance if possible.

Hay need not be cut at so late a stage. Cereal plants contain their full nutriment at the flowering stage, though not their full weight of dry matter. Until the grain reaches the milky stage the nutriment is evenly distributed throughout the plant, but after this period most of the food constituents move upward, until, at maturity they are nearly all in the grain. Hay for the feeding of farm livestock, therefore, should be cut during the period between the flowering of the plant and the milky stage of the grain.

Some farmers state that the hay is more troublesome to cut and cure at this stage, but the difficulties are not great. Sheaves should be made small in size, to avoid any danger of moulds forming in the centre of the sheaf, and long open stooks should be made, so that the moisture evaporates quickly. A decided advantage to farmers in cutting hay at this stage is that the hay season is earlier, and more easily completed before the reaping of ripe grain commences.

All of the cereals make better hay at this stage. Barley awns are not hard, and not likely to be troublesome to the mouths of livestock, as they are when near maturity. Rye has not become tough and fibrous, and wheaten and oaten hays are more nutritious. It is generally believed that if Algerian oats are cut green for hay, the product is bitter and unpalatable. This may be so, although it is not at all certain, but in any case there are many other oat varieties which could be used for this purpose. New green cut hay has some tendency to cause scouring in livestock, but this tendency disappears after the hay has been stacked for a few months.

When sowing hay crops for the feeding of livestock it should be remembered that a mixture of varieties will produce a greater quantity per acre than any single cereal; thus wheat and oat, or oat and barley mixtures, are commonly used for this purpose.

Cereal hay is high in digestible carbohydrates, and somewhat low in digestible protein, and therefore is decidedly better for maintenance or fattening purposes than for production of milk in ewes, or the growth of the lamb. It is better if some legume can be included. On some farms clover grows to such an extent that the butts of hay sheaves include clover plants. This is a satisfactory state of affairs, but unfortunately is more the exception than the rule on Mallee farms at present.

It is possible to include a legume in the hay crop, and the product would be better for stock feeding than any hay now produced. A very fair growth of Field Peas can be obtained in areas of 14in. or more average annual rainfall. Because of quick growth and earlier maturity the White Brunswick variety is better for this purpose than the Dun pea. A mixture sown for hay with seed consisting of ½bush. of peas, with ½bush. to ¾bush. per acre of a tall-growing, early-maturing variety of oats or wheat should be very satisfactory, and the success would be more assured if this were sown on fallowed land. The pea plants will grow with the cereal, climbing the wheat or oat plants as they grow taller, so that a mixture of this kind can be cut for hay with the binder in the ordinary way. In a dense heavy crop some tangling occurs, and adjustment to the outside divider of the binder may be necessary. This consists of the attachment of a revolving coulter to the front of the divider, adjusted to run on the ground, and a scythe blade set edge up on the top of the divider, to cut any overhanging growth. Naturally a crop of this kind could only be handled in well-cleared paddocks. Curing and stacking is no different from that of all cereal hay.

This would supply a balanced ration, and the feeding of 3lbs. to 4lbs. per head per day to sheep with lambs should be approaching the perfection of hand-feeding.

Silage for Livestock.

Mallee farmers have been growing crops for grain and hay ever since the country was first cleared, and are more or less familiar with the use of these products for livestock feeding; but only very few of them have made or used silage. Because this product itself, and the method of its manufacture, are so different from anything in their past experience it is very hard to convince them of its value.

Silage is the only food product which will retain the natural juices of the plant in addition to its nutriment, and which can be said completely to take the place of green forage. It will stimulate milk secretion in dairy stock better than any other foodstuff, and the same applies to breeding ewes. Silage will enable breeders to develop lambs well, and early in the season, when market prospects are at their best, and to be successful in this way every year, irrespective of seasonal conditions —in fact, so important is this food product that no breeder of stock should be without it if there is any intention of attaining maximum stock-carrying capacity.

Much has been written recently in South Australia concerning the making and utilising of silage, so it is intended here to mention only some facts which may be useful to Mallee farmers. A number of these farmers have attempted to make silage in stacks, and their efforts have frequently been unsuccessful, or only partially successful. The product obtained has usually been dark in colour, with considerable waste material. On an ordinary wheat farm, with limited labour, it is difficult to make satisfactory silage in stacks, particularly where cereal crops are used and cut into sheaves with the binder. The crossing of the sheaves in the stack allows air spaces, and these, together with the air in the hollow stems of the plant, are the causes of unsatisfactory results.

Also the work involved in building the stack, and in weighting it down afterwards, without any labour-saving machinery, is very great. If stacks are to be made, the method now adopted at Roseworthy Agricultural College, of a stack held within a framework of upright poles, so that all the sheaves may be placed in the one direction, is the best.

A better method of silage making in these areas is undoubtedly in trench silos, as in most of these soils the trenches can be easily scooped out by horse labour, and the rainfall is not sufficiently high to cause much danger of flooding the trenches at any time. These trenches are made long, comparatively narrow, and usually from 6ft. to 9ft. deep. The labour of filling them is much less than that of a stack, as team and loaded wagons are driven through the trench over the material already collected, thus assisting in pressing out the air; the sheaves are thrown down from the wagon, and spread all in one direction, lengthwise in the trench; and when the filling is complete, horses and scoop can again be used to supply ample weight of earth over the top.

Some very good samples of trench silage have been made by farmers in the Mallee. There is very little risk of failure, and farmers who once utilise silage for feeding sheep or cattle always wish to continue its use. Trenches of this kind can be made permanent by building stone walls along the sides, as smooth as possible on the inside surface. Where limestone is available, which is the case in many parts of these areas, this can be done economically with stone and lime cement, and it prevents all danger of the side walls falling in, which sometimes happens, particularly in the more sandy soils.

Cereal crops make good silage, but even better can be made from grass and clover mixtures when there is a surplus of pasture, or from the pea and cereal mixture previously mentioned.

Full information concerning silage, general conservation of fodders, and their use for livestock, can be obtained from the following publications of the South Australian Department of Agriculture:—

Bulletin No. 102—"Equivalence of Livestock Foodstuffs and Feeding Rations," by Arthur J. Perkins, Director of Agriculture.

Bulletin No. 274—"The Manufacture and Utilisation of Silage," by W. J. Spafford, Deputy Director of Agriculture.

Journal of Agriculture, Vol. 38, No. 7—"The Conservation of Fodders under South Australian Conditions," by Dr. A. R. Callaghan, Principal Roseworthy Agricultural College.

FARM SUBDIVISION AND WATER RETICULATION.

To attain maximum stock-carrying capacity it is necessary not only to provide the right quantity and kind of pasture, but to subdivide the farm area in such a way that the stock may obtain a change of paddock at reasonable intervals. Mallee farms are more faulty in this respect than those of most districts, partly because they have not been cleared for so long a period, but also because very often in these areas fencing-posts are not obtainable locally, and so are more costly.

A well-planned subdivision system is essential for livestock farms, while cereals can be grown in paddocks of any area. One of the best systems is a double fence enclosing a lane through the middle of the farm from end to end in one direction, with all subdivision fences at right angles to the lane. This is particularly useful if the farm buildings are in the centre of the area, as they should be. All paddocks then have direct access to the lane and to the farm headquarters. Unfortunately, many Mallee farms are irregular in outline, making a plan of subdivision more difficult.

Subdivision alone will greatly increase stock-carrying capacity. The grazing of a few head of stock on a large paddock is always wasteful, as parts of the paddock are favoured and others neglected; while also the better pasture species will be picked out, sometimes to such an extent that they are destroyed, while the remainder will not be grazed at all. It is a common sight on a Mallee wheat farm to see a small sheep flock in a paddock several hundred acres in extent. The opposite can be seen on properties of intense culture, such as Wood's Point, on the reclaimed Murray Swamps, where thousands of sheep graze paddocks only a few acres in area, being changed every few days to a fresh paddock, and coming back to each periodically for another grazing period. Rotational grazing such as this has given astonishing increases in carrying capacity. It is utterly impracticable, of course, in districts dependent only on scanty rainfall for their pasture, except as a demonstration of the value of closer subdivision.

Livestock remain more healthy, also gain growth and condition better, if they are given fresh grazing areas at frequent intervals. In small paddocks the grazing can be close and even, and the stock removed at the right time for the pasture to recover. Also on a well-subdivided farm growing and fattening stock can be given the best of the grazing, with store stock following on each paddock to clean up the residue.

Farm subdivision has hardly commenced on many properties, and, as it is costly, improvement may be slow. It is certain, however, that with livestock development smaller paddocks are essential, until eventually the average area per paddock will be something between 50 and 100 acres.

Equally essential is the provision of water for the stock. On most Murray Mallee properties sub-artesian water is available in unlimited quantities. All farms are provided with one or more bores, windmills, and storage tanks, but on most of them there is little or no reticulation. Livestock cannot be expected to do really well if they are forced to travel long distances daily for their supply of water, and so, as soon as possible, it is necessary that water be carried in pipes and supplied by troughs to each paddock.

The development of stock-carrying capacity in these areas will be a gradual process, but it is essential that all farmers should do their best in this respect, as only by so doing can the farms improve in productivity and income, while, if the keeping of livestock is neglected, within a short period of years there is a definite danger of many farms becoming useless either for crops or pasture, because of impoverished soil and increasing sand drift.

SUMMARY.

(1) Country of light soils and moderate rainfall will not stand continued cereal cropping. Humus content and fertility decrease, while sand drift becomes a menace.

(2) The only practical way to restore depleted fertility and humus content is by the keeping of livestock. Sheep are the most useful livestock, and should develop into an important industry, and not only a sideline.

(3) To enable farmers to keep large permanent flocks of sheep, carrying capacity must be increased. This is possible by—

- (*a*) The improvement of existing pasture species, and the encouragement of better species by adequate dressings of phosphatic fertiliser.
- (*b*) The introduction, by seeding, of better species.
- (*c*) The growing of cereal or other crops for grazing.
- (*d*) The use of conserved fodders for hand-feeding.
- (*e*) Smaller paddocks and better provision of water.

(4) Chemical analyses of pasture species show that many of the natural pasture plants are deficient in food constituents, chiefly protein, and that others which can be encouraged by the use of phosphate, or by seeding, are better in this respect.

(5) Pastures which develop naturally consist chiefly of Spear Grass, Barley Grass, Silver Grass, Brome Grasses, Wild Mustard, Wild Oats, Geranium, Cape Dandelion, and Mediterranean Grass. Of these the grasses are annuals, with a short growing period, and leave little residue of value after maturity. Mediterranean Grass appears to be the best of them, and the recent replacement of Barley Grass by it is an advantage. Geranium appears on pasture land, but is of only moderate feeding value, while the remainder are cultivation weeds which are never likely to give high carrying capacity unless supplemented by other species. In addition, the seeds of Spear Grass, Barley Grass, Rigid Brome Grass, and Geranium are harmful to stock.

(6) The bulk and quality of pastures can be improved by the use of superphosphate, while, in areas of over 12in. rainfall, leguminous plants can be encouraged to grow also by the same means. The higher the rainfall, the better the leguminous plants develop, the most useful of which are Burr Medic, Clustered Clover, Hop Clover, and Woolly Clover. These legumes, with the natural pasture species, considerably improve the carrying capacity.

(7) Many sown species have been tried experimentally, but only few have been successful. Those which can be recommended for seeding under special conditions are Lucerne, Wimmera Rye Grass, King Island Melilot, Evening Primrose, and Early Subterranean Clover.

(8) Lucerne is the best of the sown fodder plants because it is perennial, and will provide growth of high protein content through most of the year. It should be established over large areas and on complete paddocks, and should be grazed judiciously, not eating out the crown of the plant. It may be estabilished by seeding 4lbs. to 6lbs. per acre with super in stubbles, or by seeding with an early cereal crop to be cut for silage or hay.

(9) Wimmera Rye Grass is easily the best grass for Mallee farms. It will grow wherever Barley Grass prevails, provides greater bulk than any other grass, has a longer growing season, is palatable at all stages, provides good residue after maturity, has no objectionable features, and can be established cheaply and easily. It is usually established by sowing about 2lbs. seed per acre with a cereal crop, provided the cereal crop is sown for grain, and reaped with harvester or reaper-thresher.

(10) King Island Melilot will give leguminous pasture in the absence of other species. It is not very palatable, and needs about 15in. rainfall per annum to grow luxuriantly. Wheat-growers should not allow this Melilot to develop in their wheat crops, as merchants and millers claim that the odour from the seed affects the wheat flour.

(11) Evening Primrose will grow on light sands; it acts as a sand-binder, is a biennial, and supplies some growth during most of the year, but is only of moderate feeding value. It is useful in light country until better species can be established.

(12) Early Subterranean Clover has only a limited use on Mallee farms, as even the Dwalganup strain needs a minimum annual rainfall of 16in. to 17in., while later maturing strains are killed by the hot dry summer conditions before maturing seed.

(13) On areas to be used as pasture for only one year more stock may be carried if cereals are sown for grazing. All of the cereals are useful; wheat and oats provide good spring grazing, while the quicker growing barley and rye provide more early feed. Mixtures of barley or rye with wheat or oats are better than single cereals, while all four may be utilised together if thought desirable. Because of differences in palatability only one mixture should be used in each paddock. Heavy seeding, with the addition of superphosphate, is advisable.

(14) The sown cereal pasture is improved if a leguminous plant is added. Seed of Burr Medic or Clustered Clover can be used, while the Common Vetch will also make a good mixture with the cereals. Care should be taken on wheat farms not to allow Vetch plants to mature their seed, as it cannot be removed from wheat grain.

(15) Summer fodder crops are difficult to grow because of the low rainfall. Sudan Grass may be successful in some years if sown on prepared land, and would provide useful green forage during summer. Sudan Grass should only be grazed after reaching the flowering stage, because of the danger of poison.

(16) In areas of moderate rainfall pastures only remain alive for 6 to 8 months of the year, and if permanent flocks are kept, must be supplemented by the feeding of conserved fodders during the lean period.

(17) Where bulk foods are available—pasture residues or stubbles—grain at the rate of 1lb. to 1½lbs. per sheep per day will adequately provide for the necessary concentrates. Shrivelled wheat is useful for this purpose, while oats and barley are also satisfactory. More benefit seems to be obtained from barley if it is sprouted before being fed to the stock.

(18) Where no pasture is available, bulk foods are necessary, and hay can be utilised. Hay for this purpose should be cut between the flowering stage and the milky stage of the grain—not later. At this stage all of the cereals may be used—wheat, oats, barley, or rye—while a mixture of field peas with wheat or oats makes an ideal hay for feeding livestock.

(19) Silage is the only food product which retains the succulence of the plant in addition to its nutriment. It stimulates milk secretion, and is therefore of great value to breeding ewes. It ensures marketing of lambs at the right time, and so is almost essential to stock-breeders. The best and most economical method of silage making on Mallee farms is in scooped trenches, as the labour involved is less than that of building stacks, and satisfactory results are more certain.

(20) Maximum carrying capacity cannot be attained unless the farm is well subdivided, so that grazing livestock may have frequent changes of feed, and each paddock grazed evenly in reasonable time; or without reticulation of water supply, in order that the stock may obtain water requirements without walking long distances each day.

PARAFIELD EGG-LAYING COMPETITION, 1934-35.

[A general review of the Competition by C. F. Anderson, Government Poultry Expert.]

The Competition which concluded at Parafield Poultry Station on 31st March, 1935, was probably one of the most instructive of the series conducted at this Station.

As in all other Competitions under the supervision of the South Australian Government, the test covered the full period of the year, commencing on 1st April, 1934.

In order to provide for the increasing demands of the poultry industry, the Government increased the number of pens from 243 to 501.

Highest Score in Competition—274 first-grade eggs. White Leghorn pullet owned by Mr. S. Hill, Bridgewater.

The Competition was all single testing. The weighing of each individual egg throughout the currency of the test was continued, and it is emphasised more each succeeding year that this is the only system of egg weighing that gives an accurate record of the performance of each bird.

For many years it was considered that the bulk weighing of eggs during the month of July was a fair indication of the average weight of egg to be produced by respective birds for the remainder of the first laying season. Again, it was considered doubtful if the average pullet, which commenced laying some time in April and did not produce eggs weighing 2ozs. during the month of July, would reach the 2oz. minimum during her first laying season.

The continued and very accurate weighings conducted at Parafield Egg Laying Competition have proved that a number of ideas concerning the weight of eggs have been without foundation.

I would emphasise the importance of accurate weighing in Competition work; this is, in fact, the crux of the whole Competition. The principle adopted at Parafield is to weigh to the nearest fraction of an ounce.

After closely studying the weighing of the eggs, it has been found at Parafield that there is a considerable variation in the weight of eggs according to the number of eggs laid by some birds.

Some birds will lay a sequence of five eggs, miss a day or two, and then lay another sequence of five or six eggs. It has been found in most cases that the size of egg laid by a number of birds would probably weigh the full 2ozs. at the commencement of the sequence, but by the time the fourth and fifth egg have been laid the weight has dropped to 1⅝ozs. or 1¾ozs. After the bird has stopped laying for two or three days, and started again, it has been found that the first egg laid is 2ozs., but with regular production the size gradually falls away again. For Competition work it is apparent that the deciding factor is between heavy laying stock producing eggs of standard weight, and stock producing only a small per-

Home Project Utility Section. Winning bird owned by Master Eric Pratt, of Abattoirs. Winning score, 247 first-grade eggs.

centage of full-size eggs, and a large number of under-sized eggs. A study of the percentage of first grade eggs laid during the periods of the various weighings is very interesting, and shows just where the weakness in the majority of competing birds is, as regards the weight of eggs.

For the initial weighing period, that is from 1st April to 31st May, a weight of 1¾ozs. was the standard for first grade eggs, and 89 per cent. of all eggs laid were first grade, while for the second weighing period, that is, from 1st to 30th June, 1⅞ozs. was the minimum for first grade eggs and 89 per cent. of all eggs produced were first grade.

From 1st July to 31st March the standard for first grade eggs was a minimum of 2ozs., and the percentage of first grade eggs decreased to 77 per cent. This fact emphasises the importance of breeders striving to increase the percentage of 2oz. eggs during the most prolific laying period of the year, also during the period

when the bulk of the eggs are exported overseas. It has been conclusively proved over a period of many years that the 2oz. egg is the most profitable one from an export viewpoint.

The following is the number of birds entered for the Competition:—

Section 1.—*Wet Mash.*		
Class 1.	White Leghorns	333
Class 2.	Any other light breed	15
Class 3.	Black Orpingtons	63
Class 4.	Any other heavy breed	30
Section 2.—*Dry Mash.*		
Class 5.	White Leghorns	12
Class 6.	Any other light breed	(no entries received)
Class 7.	Black Orpingtons	9
Home Project Utility Section.—*Wet Mash.*		
	White Leghorns	19
	Black Orpingtons	3
	Rhode Island Reds	1
	Total birds competing	485

The Home Project Utility Section, in which 23 entries were received, is for scholars who are taking poultry as a Home Project in the State schools. This Section is an incentive to the scholars to breed only the best of stock and is one deserving of every support. It is very pleasing to see that a number of scholars, who have graduated through the Home Project System of poultry keeping, are now making very definite advance with the industry as a means of livelihood.

It will be seen, therefore, that with 485 birds competing, all under single testing, it was a reliable judge as to the suitability of the conditions adopted.

Egg Weighing.

Regulations regarding the weighing of eggs were as follows:—

First grade eggs shall weigh:—

From 1st April to 31st May—a minimum weight of 1¾ozs.
From 1st June to 30th June—a minimum weight of 1⅞ozs.
From 1st July to 31st March—a minimum weight of 2ozs.

For the purpose of deciding the leading positions in all sections, only first grade eggs were considered.

The eggs were collected twice daily—at 11 a.m. and 4 p.m., and were weighed immediately following collection.

With the number of birds competing, one man was occupied for full time in the care of the birds, and additional assistance was provided for the collection, weighing, and recording of eggs laid.

The Winter Test.

It is the practice in this particular Competition to conduct a winter test—that period is from 1st April to 31st July, or 122 days. From a stud point of view, the winter test is looked upon as most important, for it is recognised that, for the best returns to be obtained from poultry from an egg-laying point of view, it is essential that a reasonable number of eggs should be produced during the winter period. This is also the highest priced period for eggs in this State. Again, it is almost impossible for a bird that does not lay a reasonable number of eggs up to 31st July to have much chance of recording a good score during her pullet year.

From a stud-breeding aspect it is very questionable whether it is advisable under any condition to consider a hen suitable for the breeding-pen that has not laid well during the winter period.

The following table shows the leading birds in each Section during the winter test:—

HOME PROJECT UTILITY SECTION.

Name. School. Breed.		•
Milton Smith, Salisbury (White Leghorn) ..	79	452
Robert Swift, Murray Bridge (Black Orpington)	73	456
Max Couche, Thebarton (Rhode Island Red)	69	455
Mervyn Steer, Sturt (White Leghorn)	65	443
Eric Pratt, Abattoirs (White Leghorn)	63	441

The results for the winter test were satisfactory, the leading bird being a Black Orpington pullet owned by Mr. F. F. Welford with a score of 94 first grade eggs.

FEEDING.

There were two methods of feeding—one for wet mash and the other for dry mash, with wheat at midday and night. The wet mash was fed at approximately 7.30 a.m. The dry mash was fed daily, followed by chaffed greenfeed with wheat at mid-day and again at night.

It is rather interesting to note that in all Sections the wet mash birds have done better than the dry mash birds. These results confirm experimental work in feeding tests which have been conducted from time to time at Parafield. The reason is difficult to explain and the only suggestion that can be offered is that the climatic conditions are not conducive at Parafield to the best results from dry-mash feeding.

The mashes were composed of equal parts, by weight, of bran, pollard, and wholemeal, with 1lb. meatmeal, and ½lb. linseed meal per 100 birds. The linseed meal was fed from April 1 to September 30. Chaffed greenfeed varying in percentage according to the period of the year was also added to the mash.

The following table shows the average monthly price of the various foodstuffs fed to the birds, delivered at Parafield Poultry Station:—

TABLE II.

Average Monthly Price of Foodstuffs.

Month.	Wheat, per bush	Bran, per ton.	Pollard, per ton.	Whole-meal, per 60lbs.	Meat, meal, per ton.	Onions, per cwt.	Linseed, Meal, per ton (2,000lbs.)
1934.	*s. d.*	£ *s. d.*	£ *s. d.*	*s. d.*	£ *s. d.*	*s. d.*	£ *s. d.*
April	2 5	4 12 6	4 15 0	2 10½	12 0 0	5 0	9 10 0
May	2 6	5 5 0	5 0 0	2 11	12 0 0	4 6	9 10 0
June	3 0	5 5 0	5 0 0	3 0	13 0 0	4 6	9 10 0
July	3 6	5 5 0	5 0 0	3 9	13 0 0	6 6	9 10 0
August	3 6	5 5 0	5 0 0	3 6	13 0 0	3 6	9 10 0
September	3 6	5 5 0	5 5 0	3 5	13 0 0	3 6	9 10 0
October	2 9	5 5 0	5 5 0	3 5	13 0 0	6 0	9 10 0
November	2 8½	5 0 0	5 2 6	3 2	13 0 0	6 0	9 10 0
December	2 9	5 0 0	5 2 6	3 1	13 0 0	6 0	9 10 0
1935.							
January	2 9	5 0 0	5 2 6	3 1	13 0 0	6 0	10 5 0
February	2 11	5 0 0	5 2 6	3 3	13 0 0	8 0	10 5 0
March	3 0	5 0 0	5 2 6	3 3	13 0 0	5 0	10 5 0
	Average price 35·29d.	Average price 5 1 10½ =12·22d. per bush.	Average price 5 1 5½ =12·17d. per bush.	Average price 38·70d. or 12·9d. per bush. of 20lbs.	Average price 12 16 8 per ton (2,240lbs.)	Average price 5 4½	Average price £9 13 9 per ton (2,000lbs.)

The average cost of feeding per bird was 4s. 8d., which is slightly higher than the 1933-34 test.

PRICES RECEIVED FOR EGGS.

The eggs were disposed of through similar channels as in previous years, the same prices being obtained as is the case with the average commercial egg farmer. The eggs were collected twice daily and marketed practically throughout the year twice a week.

In studying the prices received for eggs, it will be seen that prices were the lowest for the months of December, January, and February, reaching the lowest level in January of 7¼d. per dozen. It is evident that, if the position of the poultry-keeper, who is farming solely for egg production, is to be made secure, attention will have to be given to obtaining better prices during that period, for it is obvious that, with the falling production during these months, coupled with the increased cost of feeding due to the rearing of the young stock, the position of the poultry-keeper during the months of December, January, and February is most difficult.

One pleasing feature of the egg prices is that, during the months of July, August, September, October, and November, when production is at the peak, satisfactory prices have been received for the eggs.

The following table shows the average monetary price received:—

TABLE III.

Average Monthly Prices for Eggs.

Month.	1⅞oz. and over.	1¾oz.
1934.	per doz. s. d.	per doz. s. d.
April	1 3	0 10
May	1 3¼	1 1
June	1 0	0 9
July	0 11¾	0 10
August	0 11¾	0 9¼
September	0 11¾	0 9¼
October	0 11¾	0 10
November	0 10¾	0 9
December	0 8¾	0 7¾
1935.		
January	0 7¼	0 6¾
February	0 8¼	0 7½
March	0 10½	0 8

The average price for the year for eggs of 1⅞ozs. in weight and over was 11.22d. per dozen, as compared with 11.802d. for year 1933-34, while the average price for 1¾oz. eggs was 9.12d. per dozen.

PROFIT OVER COST OF FEEDING.

The profit over cost of feeding can be considered quite satisfactory. The average return per bird was 14s. 4d., and the cost of feeding 4s. 8d., leaving a profit over cost of feeding of 9s. 8d. per bird.

The average number of eggs laid per bird is quite satisfactory. In all, 442 birds completed the test, and the average number of all eggs laid was 191.5, composed of 153.5 first grade eggs and 38 second grade eggs, which is approximately 80 per cent. first grade and 20 per cent. second grade.

In comparing the difference between the wet mash and dry mash average production, it will be seen that the White Leghorns fed on wet mash averaged 194.22 eggs, as against 188.81 eggs fed on dry mash, while the Black Orpingtons fed on wet mash averaged 203 eggs, against 155.77 eggs for birds fed on dry mash.

The highest average production for all breeds was recorded by the Black Orpingtons with the fine average of 203 eggs per bird.

The second highest average was produced by three Barnevelders with the average of 195.66 eggs. The most outstanding feature of the Barnevelder entry was that of 578 eggs laid during the test only nine eggs were under the first grade weights, consequently this trio averaged 192.66 first grade eggs a bird, as compared with the next highest average of 171 first grade eggs.

The average production of the birds entered by the Home Project Workers was also very pleasing, the average being 188.73 eggs a bird; this was an excellent beginning for the Project workers.

The following table shows the number of first grade, second grade, and total average number of eggs laid of all breeds.

TABLE IV.

Breed.	No. Birds that Completed Test.	No. First Grade Eggs Laid.	Average No. First Grade Eggs Laid.	No. Second Grade Eggs Laid.	Average No. of Second Grade Eggs Laid.	Average No. of all Eggs Laid.
Wet Mash Classes.

Black Orpingtons	9	1,311	145·66	91	10·11	155·77

DEATH RATE.

During the currency of the test 43 birds died, which was equivalent to just under 9 per cent. With a Competition of 485 birds, this death rate can be considered as just satisfactory, and it is to be hoped that this percentage will not show any further increase. This factor is causing concern in Competitions throughout the world, and every effort should be made by careful selection of the stud stock to breed poultry that can stand up to reasonable production during the first season.

The following are the winning scores in each section:—

FIRST GRADE EGGS ONLY.

SECTION 1.—WET MASH.

STANDARD CERTIFICATES.

For the first time the Department of Agriculture has instituted a system of standard certificates. It is realised that birds that have completed the twelve months' test and laid a reasonable number of first grade eggs are entitled to some recognition. The standard has been fixed as follows:—

For light breeds at 200 first grade eggs.

For heavy breeds at 180 first grade eggs.

Of the 442 birds that completed the test, 119 obtained the standard certificate. This is equivalent to 27 per cent. of all birds that competed.

It is to be hoped that the system of standard certificates will eventually lead to the establishment of a stud breeders' register, the object of which would be the gradual improvement of the poultry flocks of the State.

The following were the winning birds in each Section:—

The highest score in the Competition was recorded by a White Leghorn owned by Mr. S. Hill, of Bridgewater, with the good score of 274 first grade eggs.

In the Black Orpingtons Mr. H. J. Mills again won with the score of 269 first grade eggs.

The Home Project Section was won by Master Eric Pratt, with the very creditable score of 247 first grade eggs; the bird was a White Leghorn. Master Max Couche was second in this Section with a score of 224 first grade eggs recorded by a Rhode Island Red.

A GENERAL SUMMARY OF THE RESULTS.

Number of birds that completed test		442
Average number of all eggs laid		191.5
Averages various breeds competing:—		
Birds fed on wet mash—	**Birds.**	**Eggs.**
Black Orpingtons	61	203.08
Barnevelders	3	195.66
White Leghorns	299	194.22
White Leghorns, Home Project Utility Section	19	188.73
Langshans	3	182.66
Rhode Island Reds	24	176.83
Cuckoo Leghorns	3	162
Minorcas	10	126.5
Birds fed on dry mash—		
White Leghorns	11	188.8
Black Orpingtons	9	155.77

Average cost of food per bird, 4s. 8d.

Average return per bird, 14s. 4d.

Average gross return over cost of feeding, 9s. 8d.

TROPHIES.

The Red Comb Egg Association Incorporated has been instrumental in securing a valuable set of trophies for winners of the various sections from the South Australian Farmers' Co-operative Union, Limited, Messrs. Betteridge & Hall, B. J. Walters Limited, D. Lanyon & Sons, F. H. Faulding & Co. Limited, W. H. Burford & Sons, Lever Bros., W. D. & H. O. Wills, Wm. Jackett & Son, Meggitts Limited, L. E. Saunders, A. K. Andrewartha, C. H. Glatz, J. E. Neldner, Adelaide Chemical & Fertilizer Co. Limited, Wingfield Casing Co. Pty. Limited, Australian Veterinary Laboratories, and Bridgewater Milling Co., whose donations have been greatly appreciated.

OFFICIAL SINGLE TEST EGG-LAYING COMPETITION, 1935-36.

CONDUCTED AT PARAFIELD POULTRY STATION.

ONLY FIRST GRADE EGGS RECORDED.

FEEDING TESTS AT PARAFIELD POULTRY STATION

[New Series of Tests by C. F. ANDERSON, Government Poultry Expert.]

In continuing the experimental feeding tests at Parafield Poultry Station, a new series of tests commenced on 1st April, 1935. Five tests each of 50 white Leghorn pullets were selected. The pullets were chosen as nearly even in age, type, and maturity as was possible.

In order to gain further information on the various methods of feeding, some of the tests are similar to the series which concluded on 31st March, 1935.

The following are the methods to be adopted, together with the results from 1st April to 30th April.

Feeding Tests commenced on 1st April, 1935.

1. Wet mash, composed of crushed barley and crushed wheat, with greenfeed and meatmeal; 2ozs. wheat per day.
2. Standard bran and pollard mash, with greenfeed and meatmeal; 1½ozs. wheat per day.
3. Bran and crushed wheat mash, with greenfeed and meatmeal; 2ozs. wheat per day.
4. Mash of crushed oats and crushed wheat with greenfeed and meatmeal; wheat, 2ozs. per day.
5. Commencing with a crushed barley and crushed wheat mash, greenfeed, meatmeal and then the feeding to be changed according to the season of the year.

	No. Eggs Laid 1st April, 1935, to 30th April, 1935.	No. Eggs Laid Month of May, 1935.	Total Eggs Laid 1st April, 1935, to 31st May, 1935.

EGGS.—10/- per Setting of 15 Eggs. Incubator Lots, £2 per 100.

DAY OLD CHICKENS.—17/6 per dozen; £4 per 100.

BLACK MINORCAS.

EGGS.—7s. 6d. per Setting of 15 Eggs. Incubator Lots, 30/- per 100.

DAY OLD CHICKENS.—15s. per dozen; £3/10/- in lots of 100.

Free on Rail, Salisbury.

DELIVERY.—CHICKS—July to September.
EGGS—July to September.

Intending breeders should realise the importance of establishing their flocks with only the very best of stock, also pay particular care to the size of the egg. The future of the poultry industry in South Australia is almost entirely dependent on the export trade; the size of the egg for export is of the greatest importance. The breeding stock at Parafield is carefully selected and every egg set or sold is of a minimum weight of 2ozs., and a large percentage considerably over.

All Eggs and Chickens sold from Parafield Poultry Station are guaranteed to be produced at Parafield.

EARLY BOOKING IS ADVISABLE.

Further particulars can be obtained from the Manager, Parafield Poultry Station, Salisbury, or Poultry Expert, Department of Agriculture, Flinders Street, Adelaide.

THE STATE EXPERIMENT ORCHARD, COROMANDEL VALLEY, NEAR BLACKWOOD, SOUTH AUSTRALIA.

[By GEO. QUINN, Chief Horticultural Instructor.]

(*Continued from page* 1262.)

ROOTSTOCKS—FOR PEAR TREES.

Under the widely differing conditions of soils and climate occurring in the various orchard districts of South Australia, the pear may be fairly claimed to have proved itself the least fastidious of all of our orchard trees. Providing the necessary moisture be available to the roots, and what is accepted as ordinarily good tillage be given to the soil, this tree thrives well in the open hot country possessing a limited depth of loam above the clay or marly subsoil. In the deep rich valley soils of the wetter and colder districts it proves equally at home. Its power to resist excessive moisture in the soil during fairly long periods has led to it being utilised to plant the lower lands in the orchards where perhaps the quince tree only could endure a longer period of waterlogging.

It has been largely due to the great vigour of vegetation displayed by most varieties of the pear, when grown under such conditions, that our orchardists, when planting certain pears freely a couple of decades ago, frequently desired that their trees should be worked on rootstocks less inclined to stimulate and maintain rank growth than that found in the seedling pear. That was the only reason underlying the demand which arose in this State at that time for pear trees grafted on quince rootstocks.

In older countries of Europe and to a lesser degree in America, the use of the quince rootstock as a means of reducing the vigour of growth, and incidentally inducing an earlier arrival at the stage of fruitfulness in the variety of pear worked upon it, has been accepted as a standard practice amongst horticulturists for probably centuries past. In Europe the subject has been studied with meticulous care, and pomological literature in describing the characteristics of varieties of pears rarely omit to mention their respective adaptabilities to the dual stocks. It has been discovered by trial and failure which of the favoured varieties are directly compatible with the quince, and which require to have an intermediate stem piece of a more compatible variety grafted between them and the quince rootstocks.

When these trials with the two generally accepted rootstocks for pears, *viz.*, pear seedling and quince, were initiated in 1909, the four varieties selected and propagated for testing thereon were listed amongst those suited for the overseas export trade in this fruit which was then beginning to attract the attention of our orchardists. Amongst these varieties only the Glou Morceau was generally recognised as having displayed sufficient affinity for the quince rootstock to warrant it being propagated directly upon that stock.

As there was at that time a great surplus of quince trees grown in this State, and growers showed a disposition to try to work some of them over to export and canning varieties of pears, the writer deemed it desirable to test the degree of compatibility with the quince stock displayed by sorts other than the Glou Morceau variety. This variety at that time was considered our most desirable pear for overseas export and local cold storage purposes. Incidentally, it may be mentioned also that owing to the great improvements made during recent years in the handling, packing, and cold storing methods applied to fruit in transit overseas, all of these four

varieties of pears have now been superseded in the overseas and local markets, either by new varieties or old varieties formerly found incapable of standing up to the less effective conditions of transport in vogue a quarter of a century ago.

The rootstocks used in these trials were procured from the then leading local fruit tree nurseryman in South Australia. The pear seedlings had been raised by him from imported French seeds, and the quince rootlings had been propagated by him from plants of the Angers variety of quince, originally imported from European sources.

The seedling pear stocks which were carefully selected for evenness of vigour and good healthy condition generally, were budded in 1909 in the nursery of the Blackwood orchard. The quince rootlings were similarly worked during the same summer. The nurseryman in question utilised this stock to meet the demand for Glou Morceau trees worked upon the quince.

[*E. W. Pritchard, photo.*]

Beurre Easter on Pear Seedling Stock.

This so-called Angers variety of quince is stated to be barren, vigorous-growing and possessed of a free rooting capacity, when planted as cuttings or propagated by "stools." In this latter characteristic it differs from the ordinary fruiting varieties of quinces which do not readily strike roots from cuttings planted in the open nursery beds in South Australia.

The scion varieties budded upon these two stocks consisted of Glou Morceau, Beurre Diel, Beurre Easter, and Vicar of Winkfield. The latter was at that period sometimes erroneously called Napoleon, and the first-named "Winter Duchess" in our local markets. The budwood used in propagating the trees planted in these trials was obtained from selected healthy productive types of trees growing in neighbouring orchards. With the exception of Beurre Easter, these sorts were stated in most English horticultural literature available at the time to thrive when worked on the

quince rootstock. In the case of this variety, however, Dr. Hogg's "Fruit Manual," Fifth Edition, page 572, states it is "a good bearer and succeeds well either on the pear or quince stock." If by this it is meant when worked directly on to the quince rootstock, our experience in these 24-year-old trials does not confirm this statement. Further, doubts are also thrown on the likelihood of at least two others, *viz.*, Beurre Diel and Vicar of Winkfield, proving a permanent success when grown directly on the quince rootstock in this warmer and drier climate, and in soils such as are found in the Blackwood State Orchard.

The land devoted to this trial is located in Block D at the western end of the orchard and lies immediately above and parallel to the cherry rootstock trial plot, but across the main central roadway which runs east and west along the southern slope of the orchard property.

[*E. W. Pritchard, photo.*]

Vicar of Winkfield on Pear Seedling Stock.

It is a parallelogram measuring 254ft. long and 34½ft. wide. On the upper long side the ground falls to the west about 24in., and on the lower margin 23in. per chain. Along the eastern end the fall to the north is approximately 21in., and at the western 18in. per chain. It will be noted, therefore, that the surface of the slope is fairly even with a slightly greater fall towards the western aspect.

Soil profiles were examined in four places along the alignment of the trees at a distance midway between the two rows of rootstocks. Each of these inspections was made of the land lying between trees of the same variety of pear worked on the two different rootstocks.

At the eastern end where the Glou Morceau variety was planted, only 7in. to 8in. of brown clay loam seemingly deficient in organic matter overlaid the moist plastic clay which at 10in. became fairly consolidated. A layer of this dark-red clay 14in. thick, but still moist, was resting on a shaly crumbling marl which was 12in. thick. At 50in. below the surface the soil was very solid, but not rocky. Opposite the Beurre Diel trees the surface loam and clay immediately below it coincided with the preceding description. It was readily bored to a depth of 27in. with the soil auger. At 34in. down a crowbar had to be used to loosen the tightly compacted bluish-slate coloured clay. At 42in. down the land became extremely hard but not rocky. Further westward opposite the trees of Beurre Easter, the surface soil had evidently been shallowed by repeated slight erosions. The stiff moist yellowish crumbling clay was met at 8½in.

[*E. W. Pritchard, photo.*]

Beurre Diel on Angers Quince Stock.

below the surface, and persisted for a further 10½in. deep, where it changed into a light slaty-blue clay mixed with broken stones too large to permit boring operations with the 5in. auger. At 41in. deep the land became extremely firm, but no rocky stratum was reached at that depth. At the western end of the slope the ground occupied by the Vicar of Winkfield trees carried a layer of dark clay loam only 6in. deep when plastic red clay was met. There were evidences of erosion here also. This clay rested on a 10in. layer of yellowish marly clay readily bored through. At 21in. deep the clay changed to a blue slaty colour and became quite gritty with particles of broken slate stone offering great resistance to the auger. At 36in. deep the solidity increased but no rocky stratum was reached. The

general opinion formed by the writer respecting this land was that the surface loam is very shallow and poor, both in texture and richness, increasingly so towards the lower western portion occupied by these pear trees.

For the first 2ft to 3ft. in depth, however, the clay and marly sublayers should not offer too great a resistance to the penetration of the pear seedling roots, but would be calculated to repel the more naturally shallow penetrating quince roots. Incidentally it may be mentioned that a plot composed of similar soil occupied by well developed healthy 20-year-old Japanese and European varieties of plum trees worked on seedling Myrobalana plum stocks, runs along the western end of these Pear Rootstock Trials.

[*E. W. Pritchard, photo.*]

Vicar of Winkfield on Angers Quince Stock.

The rootstocks in these trials are planted in two parallel rows running east and west. The trees on the pear seedlings are placed on the upper or southern side adjoining a plot occupied by Peach Rootstock Trials, the quince stocks occupying the lower or northern side next to the central roadway running through this half of the orchard land. If any advantage attached to the headland position, these latter stocks should have received it right throughout the length of the row.

There were three trees of each of four different varieties worked on each of the two kinds of rootstocks, totalling 24 trees in all. They were planted on the equilateral triangular system, 20ft. apart from each other. The three Glou Morceau on pear seedlings at the eastern end of the upper row stand facing in "staggered" order, the three trees of the same variety located in the lower row but worked on the quince rootstocks. The trees

of Beurre Diel, Beurre Easter, and Vicar of Winkfield followed in respective order down the two rows in a westerly direction.

By adopting this method it was thought to localise more strictly any variations in the soils and aspects in the positions occupied by the respective varieties worked on the two stocks. The trees were all planted during August, 1910.

Since that time they have all been subjected to the usual annual cultural treatments deemed necessary to the well-being of orchard trees growing under similar conditions. These consisted of pruning, firstly for shaping, and afterwards for general maintenance, in keeping with the individual evidences of growth and cropping displayed from year to year. They have been sprayed systematically with fungicides and insecticides for the repression of Black Spot (*Venturia pirina*) and Codlin Moth (*Cydia pomonella*), the two pests which are most commonly in evidence in pear trees in this State. The soil tillage has consisted of one early spring or late winter ploughing about 5in. deep, followed by several scarifyings throughout the summer season to maintain a loose pulverized surface layer, approximately 3in. to 4in. in depth.

[*E. W. Pritchard, photo.*]

Beurre Diel on Pear Seedling Stock.

Although no progressive measurements of growth were recorded from these trees from time to time, they were, owing to their location, constantly under observation. It was noted that with the exceptions of the trees of Beurre Easter and one of Vicar of Winkfield, all on quince rootstocks—two of which had to be replaced within the first few years—they all made healthy growth and progress.

At the end of 1916—six years after planting—the other three varieties worked on quince stocks began to slacken somewhat in the extension of their terminal growths or leaders, to form fruitspurs abundantly and display the usual evidences of settling down generally into crop production.

Those on pear seedling stocks, without exception, continued to grow vigorously and although their yields were lighter, they began to bear a sprinkling of pears very soon after a commencement had been made by their respective contemporaries growing on the quince rootstocks. With the above exception of the Easter Beurre on quince roots, the trees all continued to maintain a healthy condition generally until 1922, when one of the Vicar of Winkfield trees on quince stock, which had cropped well for several years, died, and the other trees of this variety on the same stock began to show signs of dying back from the terminal points of the leading limbs.

About 1928 the trees of Beurre Diel on quince rootstocks began—but to a lesser extent—to give evidences of decline in a similar manner. Those of the Glou Morceau, however, on the same kind of stock, continued to retain a healthy condition though practically stationary in stature. None of the trees of Beurre Easter on quince rootstocks at any time made more than a very stunted growth, and in 1924 another tree died. Since then the two survivors have maintained a miserable existence, as the accompanying photographs of the better developed one of them clearly indicates. As these and other trials conducted in the State Orchard at Blackwood have been instituted for demonstration purposes as much as for obtaining data therefrom, these useless trees of Beurre Easter pear grafted directly on to quince rootstocks have been retained in the plot purely as striking examples of what should be avoided when propagating this variety.

In November of this year (1934) trunk measurements were taken of the girth of each tree's rootstock immediately below its line of union with the scion—which was usually found to be several inches above ground level. The girth around the indicated line of fusion of stock and scion variety, and the circumference of the tree stem approximately 6in. above the line of union, were also taken. At the same time, the dimensions attained by the top of each tree were recorded by gauging the height of the leading framework limbs, and of the widest spread of the branches generally. These latter were obtained by measuring horizontally from several points through the branches at right angles and taking the mean or average from these results.

These horizontal gaugings were made at heights above ground ranging between 8ft. and 9ft. on trees worked on Pear Seedlings, and between 3½ft. to 7ft. on those on quince rootstocks. In gauging these heights and widths, one isolated slender branch extending much beyond its fellows in the tree's framework was not accepted as indicating the fair average height or spread of a tree. Although these trees had all been trained to the vase or open-centred goblet form, in a few instances the conical form and central leader natural to most varieties of pears had tried to assert itself.

The small table A shows the averages calculated from these measurements of each tree of each of the four varieties grown on the two rootstocks.

In the cases of the Glou Morceau and the Beurre Diel the quota of three trees of each variety on the two rootstocks were available for measurement purposes, but of the Easter Beurre and Vicar of Winkfield varieties, whilst the full quotas on the pear seedling were present, only two trees of each of these sorts were remaining on the quince rootstocks.

TABLE A.—*Showing Average Measurements of the Growths of Stems and Branches of Four Varieties of Pear Trees worked on Pear Seedling and Angers Quince Rootstocks.*

Rootstock.	Average Girth of Stocks below Union (inches).	Average Girth around points of Union (inches).	Average Girth of Tree Stems 6″ above Union (inches).	Average Heights of Trees (feet).	Average Spread of Branches (feet).	Height of Guaging Branch Spread (feet).
			Variety.—Glou Morceau.			
Pear Seedling, 3 trees.......	$37\frac{3}{4}$	$34\frac{1}{6}$	$29\frac{1}{4}$	15	$17\frac{2}{3}$	9
Quince (Angers), 3 trees.....	32	$31\frac{2}{3}$	$22\frac{1}{3}$	12	$12\frac{1}{2}$	7
			Variety.—Beurre Diel.			
Pear Seedling, 3 trees.......	$26\frac{1}{6}$	25	$23\frac{1}{6}$	$13\frac{2}{3}$	$14\frac{2}{3}$	8
Quince (Angers), 3 trees.....	$19^5/_6$	21	$16^7/_{12}$	$9\frac{2}{3}$	$9^5/_6$	7
			Variety.—Beurre Easter.			
Pear Seedling, 3 trees.......	$27^5/_{12}$	$25\frac{1}{3}$	$23\frac{1}{4}$	$12\frac{1}{6}$	$13\frac{1}{3}$	8
Quince (Angers), 2 trees.....	$11\frac{1}{2}$	$13\frac{1}{2}$	$7\frac{3}{4}$	$4\frac{3}{4}$	$3\frac{3}{4}$	$3\frac{1}{2}$
			Variety.—Vicar of Winkfield.			
Pear Seedling, 3 trees.......	$30\frac{2}{3}$	$27\frac{2}{3}$	$24\frac{1}{3}$	$14\frac{1}{3}$	$14\frac{1}{3}$	8
Quince (Angers), 2 trees.....	$18\frac{1}{3}$	21	18	$7\frac{1}{2}$	$7\frac{3}{4}$	$3\frac{1}{2}$

As previously indicated, these trees have all been moderately pruned and in several instances during later years, large limbs have necessarily been removed where they had been broken off or bent into such a position as to render them obstructive to tillage operations, owing to the great weight of fruits borne by them during certain seasons.

These remarks particularly apply to the trees growing on seedling pear rootstocks, and more especially to two trees of the Vicar of Winkfield variety. Owing to the studied discouragement of further ascension applied when pruning the leaders of the trees growing on seedling pears during recent years, a number of them now show a mean spread about equal to their respective heights.

The trunk measurements set out in Table A when perused in conjunction with accompanying photographs of the butts of the trees, emphasise the smooth, even tapering sturdy character presented by the stems of those worked on pear seedling stocks. The line of fusion of the stock and scion is very clearly definable from the different structural lines of crackling displayed by their respective outer layers of dry bark. No abrupt lateral distention of the stem is present at this point to bear silent witness to the existence of internal disruption between the fusing tissues of stock and scion.

The measurements and photographs of the trunks of the trees grafted on the quince rootstocks on the other hand show that, with the exception of the Glou Morceau variety, they failed to reach the full girth of the trunks of any of the other three varieties worked on them. In fact it may be claimed that the ability of the stock to keep an even pace with the expansion of the tree stem of the variety worked upon it, would be a true measure of the degree of its success in the establishment of a permanent and efficient union.

Influence of the Rootstock on the Quality, Early Cropping, and Gross Production of Fruit.

The accompanying figures set out in Tables B, C, D, and E, present in consecutive order the total annual yields of the trees of the four varieties of pears grown on the respective stocks. The fruits were harvested and graded into first and second qualities. The first grade pears consisted of sound, clean-skinned, well formed fruits above 2½in. in diameter. The second grade embodied all of the remainder of the crop. The first grade would pass as "Standard" export quality, and the bulk of the second grade would meet the usual requirements of local and interstate markets.

/* Two trees only, one tree on quince rootstock died in 1922.

It is claimed by many European horticultural writers that the quality attained by most varieties of pears is superior both in colour and flavour when the sorts are compatible with, and grown on, the quince rootstocks. Whilst this claim may be granted for a limited period after the fruiting stage has commenced, it has not, at any rate under the conditions of soil and climate prevailing at Blackwood, been found to persist very long excepting in one instance.

In analysing the data contained in Tables B to E in this report, it will be seen in the case of the *Glou Morceau* variety that at the end of the first cropping period of eight years, *viz.*, in 1924, the three trees on the quince stocks had yielded 523lbs. more in weight of pears than the three comparative trees on the pear seedling rootstocks, and of this increase 387lbs. consisted of first grade fruit. This represents an advantage of 52.88 per cent. more first grade pears than was borne on the trees on the pear seedling stock. In the results obtained during the next 10-year period (1934), however, the positions had been reversed. The trees growing on pear seedling showed a gross increase in yield of 2,630lbs. over that produced on those worked on the quince rootstocks, and 2,950lbs. or equal to 244.66 per cent. represented the increase in first quality fruit over that carried by the trees on quince roots. Viewed from another angle, the percentage of first quality fruit in the gross yield from the trees on pear seedling stock receded from 69.23 per cent. in 1924 to 64.54 per cent. in 1934, whilst the percentage of first grade in the gross yields of those on the quince stocks fell from 70.88 per cent. to 31.66 per cent. during the same period. Covering the full 18-year period of fruiting recorded from 1917 to 1934 inclusive, the three trees on pear seedling stocks yielded 65.20 per cent. of first grade pears, and those grown on the quince stocks produced 43.14 per cent. of first quality fruits.

At the end of the 1924 period the three trees of *Beurre Diel* worked on quince rootlings had yielded nine crops, and those on the pear seedling had fruited eight times. As this first crop on the former weighed only 2lbs. 10ozs. it is practically negligible. In the 1916 to 1924 period the trees of Beurre Diel on the quince stocks had produced a gross weight of 411lbs. of pears greater than those grown on the trees on pear seedling. This contained 116lbs. or equivalent to 7.75 per cent. more first grade fruits than were borne on the trees on pear seedling.

Taking the percentages of their aggregate yields, the trees on the pear seedling stocks graded out 88.34 per cent. of first quality, whilst those from the trees on quince roots showed 76.61 per cent. During the subsequent 10-year period ending 1934, the gross crops from the trees on the pear seedling stocks had outweighed those from the trees on the quince roots by 2,102lbs., including an advantage of 1,924lbs., or an equivalent to 168.18 per cent. more of first grade fruit than that produced by the trees on the quince stocks. During this second period the percentages of the gross total yields from the trees on pear seedling and quince stocks which were graded first grade, were 70.73 per cent. and 51.18 per cent. respectively.

Taking the yields of the full cropping periods, *viz.*, 18 and 19 years respectively, for the trees on pear seedling and quince rootlings, the three trees of Beurre Diel on the former rootstocks bore 1,690lbs. more fruit than the same number of trees on the latter. Of the gross yield of 6,035lbs. on the pear stocks 75.68 per cent. has been first grade, whilst of the aggregate of 4,344lbs. harvested from the trees of quince stocks, 63.52 per cent. has been of that quality.

These figures show that whilst the gross increase in yield was 38.89 per cent., the increase in first grade fruit has been 65.49 per cent. in favour of the trees grown on pear seedling stocks.

The production of fruit from the trees of *Beurre Easter* grown directly on to the quince rootstocks has been so indifferent that no further comment is offered at this stage other than to state that the few fruits borne on these trees could not be identifiable as arising from scions taken from the same tree as were those which are growing on the pear seedling stocks immediately adjacent in the next row.

Instead of developing into a fleshy pear somewhat above medium size which ripens into a luscious, juicy, well-flavoured fruit, these pears scarcely grew to the size of a golf ball and remained a hard mass of lignified cells entirely lacking in juiciness or flavour. This change of character in the fruit could not be attributed to over-croppng, as a tree of similar size and leaf spread growing on an appropriate stock would have developed these few fruits to a normal, or what is more likely, an abnormal state of development in so far as size is concerned.

[*E. W. Pritchard, photo.*]
Glou Morceau on Pear Seedling Stock.

The trees of *Vicar of Winkfield* on the quince rootstock began to crop in 1916, and those on the seedling pear in 1919—three seasons later. At the end of the 1924 period the former had borne nine crops and the latter six only. Notwithstanding this discrepancy, the three trees of this variety growing on the pear seedling stocks had produced 97lbs. more pears than those on the quince roots. This is perhaps partly attributable to the fact that one of the trees on the latter stock died in 1922. At any rate, the percentages of first grade pears in the gross yields were 72.63 from the trees on pear as against 67.97 on the quince rootstocks.

During the next 10-year period to 1934 the gross yield from three trees of this variety growing on pear stocks exceeded that borne on two trees on quince stocks by 2,621lbs. (If calculated on an equal unit basis of trees the excess would still reach 1,936lbs. in favour of those grown on the pear stocks.)

The percentages of first grade pears from the total yields of the trees on pear seedling and quince rootling stocks were 46.15 and 40.21 respectively, during this period.

A summary of the total yields from the 16 consecutive yearly crops of the three trees of Vicar of Winkfield on pear seedling stocks, and seven yearly crops from three trees and 12 crops from two trees of the same variety grown on the quince stocks shows that the former returned 5,646lbs. of pears, of which 3,020lbs., or 53.48 per cent. were first grade. The trees on the quince stocks produced 2,897lbs. gross, of which 1,572lbs., or equal to 54.26 per cent., were classed as first grade.

The total croppings of the four varieties of pears worked on the respective rootstocks, as recorded from 1916 to 1934, inclusive, indicate that from 12 trees grown on pear seedlings a gross yield of 25,711lbs. was harvested. Of this total 17,368lbs., or 67.55 per cent. consisted of first grade fruit. The trees grown on the quince rootstocks returned 12,684lbs. gross, from which 6,657lbs., or 52.48 per cent., were first grade pears.

Any evidence regarding the influence of the rootstock in promoting the earlier arrival of the cropping stage, and thereafter increasing the production of fruit in the aggregate, as indicated in the records of these trials, may be summarised as follows:—

From the trees of *Glou Morceau* variety grafted on seedling pear and Angers quince rootlings, and planted out in the trial plot at Blackwood in 1910, the first fruits were recorded from trees on both stocks in 1917. Those growing on the quince rootstocks, however, rapidly secured, and for 11 years held priority of place in aggregate production, *viz.*, until 1928.

The *Beurre Diel* trees on the quince rootstocks produced the first fruits in 1916; those on pear seedlings began to crop sparingly in the following season (1917). The trees of this variety worked on the quince maintained the leading position in gross production for 16 years, *i.e.*, until 1931.

Those of *Beurre Easter* worked on pear seedlings began to crop in 1917, and the trees of this variety grafted on the quince produced their first few straggling pears in 1920. As the trees of this variety grafted on quince rootstocks bore only a few fruits intermittently throughout the period of the tests, the quantities in the aggregate are not worth consideration or comparison with the fine yields produced on the trees on pear seedling stock in the adjacent row.

The *Vicar of Winkfield* trees grafted on the quince stocks began to crop in 1916, and those of the same sort on pear seedlings three seasons later, *viz.*, in 1919. Nothwithstanding this lead at the start those on the pear seedling stocks had in 1924 overtaken the aggregate yield of those on the quince rootstocks. It is true that one tree of this variety on the latter stock had died in 1922, but subsequent crops harvested from the other two show that, after allowing for an average increment equivalent to the loss of crop therefrom in 1923 and 1924 seasons, this primary position must have been reached in 1925 harvest by the trees on the pear seedling stocks.

It will be seen, therefore, that any appreciable advantage accruing from the earlier cropping by pear trees worked and grown on quince roots could be realised only wherever very special circumstances made this procedure worth while.

As previously mentioned, the trees in this trial plot were planted 20ft. apart on the equilateral triangular system which permits space for setting out 125 trees per acre area. Using the very complete cropping data given in Tables B to E as a basis for calculation, it should be possible, under conditions of soil and climate similar to those prevailing in the State

Orchard at Blackwood, for the results set out in Table F to be obtained from an acre of pear trees of the varieties named in this report, or of other equally productive kinds when worked on pear seedling; or if compatible, on the Angers quince rootstocks. The yields are quoted in pounds avoirdupois, but to translate these weights into bushels they may be divided by 47, which is the approximate weight of a bushel of average varieties of pears grown in this State.

TABLE F.—*Total Crop Yields Calculated as Obtainable within 24 Years after Planting an Acre of Orchard Land with 125 Pear Trees worked on Seedling Pear and Angers Quince Rootstocks respectively.*

Rootstock.—Seedling Pear.		Quince (Angers).	
Variety.—Glou Morceau.

Second grade	109,417	Second grade	76,645
Total	235,250	Total	157,728

The Present Condition of the Pear Trees.

As the pear is amongst the longest lived of all the kinds of orchard trees we cultivate, the condition of those under review in respect to their general healthfulness and anticipated future production must of necessity receive due consideration at the end of a 24-years' trial.

The writer has attempted to show from growth measurements and crop yields recorded during that period that, as far as these trials go, the pear tree when grafted on rootstocks of its own species would ultimately be calculated to prove more profitable than when propagated on the Angers quince rootlings.

At the present time the three trees of *Glou Morceau* variety growing on the pear seedling stocks are healthy, well-developed trees, making extensions freely, but not to excess, ranging from 6in. to 18in. in length on laterals and leaders throughout the trees. They convey the impression of possessing a capacity to continue to give heavy yields similar to those recorded from them during recent years.

The three trees of the same variety growing on quince stocks in the adjacent row are also healthy and making a moderate number of annual shoots varying from three inches to a foot in length, but the higher points of the leading limbs are more or less at a standstill.

[*E. W. Pritchard, photo.*]

Beurre Easter on Angers Quince Stock.

In respect to the quince rootstocks themselves, their girths now extend beyond the circumference of that of the stem measured around the line of union with the scion variety of pear. Admitting that the prospects for future cropping in respect to these trees are equally promising as those from trees on the pear seedling stocks, still, based on past performances an increase of 59 per cent. in the number of similar trees per acre of orchard would be required to bring their aggregate yields up to that promised by the trees on pear seedling stocks.

The three trees of *Beurre Diel* on pear seedling stocks are equally healthy and thriving, though a little smaller in stature than those of Glou Morceau. Their gross productiveness promises to continue to be very high.

The three trees of this variety on the quince stocks are now dwarfed and stunted, though healthy in general appearance. The evidences of active growth are scattered and limited to a few shoots from 6in. to 12in. long.

The rootstocks are reasonably even in circumference, but are uniformly smaller than the diameter through the stem at the line of union with the pear scion. One wonders how such small trees as these could have produced the weights of pears borne by them in the past, but the yields have fallen during recent seasons, and all outward evidences indicate that a further and considerable decrease will take place in the future.

The three trees of *Beurre Easter* on pear seedling stocks are healthy and thriving, showing to a very desirable degree annual extensions on laterals and leaders. The rootstocks and scions have merged into the formation of even tapering stems. Though excelled in the aggregate yields by the two preceding varieties, these trees have been consistently productive since their third year of cropping, and promise to continue to bear well in future.

[*E. W. Pritchard, photo.*]

Glou Morceau on Angers Quince Stock.

The two surviving trees of this variety on the quince stocks grow very slightly and crop even less—the fruits being quite valueless. The rootstocks have swollen beyond the girth of the scion variety, and they appear to have been irregularly supplied with main roots. This latter feature may be accidental but the trees are consistently lopsided in this respect.

The surface soil at this position on the plot becomes undoubtedly less tractable for root action than further eastward where the two former varieties are growing on this rootstock.

Two of the three trees of *Vicar of Winkfield* variety growing on the pear seedling are declining somewhat, and fairly large limbs have from time to time been cut away from them in consequence of this. Their foliage seems healthy, but scanty compared with that on the third specimen. The rootstocks have made perfect unions with the stems forming even tapering

trunks on two of the trees. The third and most westerly tree is a fine healthy-looking specimen, substantiating in a practical manner the suspected improvement in the quality of the soil on this extreme end of the plot. Excepting this one, these trees of Vicar of Winkfield on the pear seedling are not showing much promise of continuance of the good yields recorded during the past few seasons from them. They are located where the surface soil has become shallow owing to water movements slowly and persistently removing the lighter and richer top soil.

The two remaining trees of this variety on the quince rootstocks are dwindling in stature and are generally in an indifferent condition of vitality. The rootstock in each instance is smaller than the tree trunk, and the promise for development is not encouraging. The yields from these trees are diminishing and will probably decline at a greater rate during the next few seasons. The soil hereabouts is poor in texture owing to surface erosions and lack of organic matter.

Whatever may be achieved from the use of the quince as a rootstock for these varieties of pears when grown in deep rich moisture-holding flat lands, the writer is convinced that when planting pear trees on the shallower and more quickly drying clay loams of the hill slopes—such as are found in most of our coastal fruitgrowing centres in this State—it is not advisable to use this stock. In these trials no manures or fertilisers were applied, and consequently, whatever elements of fertility were removed by the repeated slight surface erosions from a portion of the western end of the plot must, to some degree at any rate, account for the great discrepancies in tree development and cropping displayed by certain trees of some of the varieties growing on both kinds of rootstocks in that particular portion of the area.

Although not hitherto referred to as calculated to have a bearing on the future choice of rootstocks for pear trees, the advent of the pear root Woolly aphis (*Eriosoma pirina*) into the pear orchard of this State since these trials have been in progress, has opened up a new and unsuspected aspect of this important question. This pest has been observed to show a distinct partiality for the roots of the French seedling pear stocks, and more particularly when planted in loamy hillside soils in the Mount Lofty Ranges. At it does not attack any portion of the tree above ground, artificial methods of prevention appear to be inapplicable or uneconomic, and no help would appear to be derivable from the introduction of the *Aphelinus* or allied genera of insects parasitic on aphides. It is therefore evident that notwithstanding its proved suitability as a rootstock for orchard pear trees, some type or variety of *Pyrus communis* which is highly resistant to the attacks of this root aphis must be discovered and propagated vegetatively for use as a substitute rootstock. The Horicultural Branch of this Department has, in co-operation with one of the leading fruit tree nurserymen, already moved in this direction, and selected a number of apparently resistant seedlings from beds of badly infested seedling pears. These have been propagated by root grafting and kept under observation. After about five years propagating and culling, the most resistant to the root aphides have mostly proved to be difficult of propagation, so that the discovery of a pear stock which will do for the pear growers what the Northern Spy has done for the Australian apple growers in circumventing the attacks of a serious root-inhabiting pest, would appear to be a time-consuming, but, nevertheless, a very essential quest.

(To be continued.)

THE WEED *CITRULLUS COLOCYNTHIS* (COLOCYNTH), A PERENNIAL WILD MELON.

[By H. C. TRUMBLE, M.Agr.Sc. (Agronomist) and C. M. EARDLEY, B.Sc. (Curator of Herbarium), Waite Agricultural Research Institute.]

INTRODUCTION.

Two species of annual wild melon have been known in South Australia for a considerable number of years. These are the Bitter Melon (*Citrullus vulgaris*, Schrad.), and the Paddy Melon (*Cucumis myriocarpus*, Naud.), both of which have been introduced from South Africa (1).

Recently attention was drawn by Mr. D. Sargent of Naidia to the presence, between Swan Reach and Maggea of a third type of melon, similar in many respects to the annual bitter melon, but perennial in character, and possessing certain features tending to render it a serious weed under cultivation. This perennial type has been received at the Waite Institute and identified both at Adelaide and at the National Herbarium, Melbourne, as the Mediterranean Colocynth (*Citrullus Colocynthis* (L.), Schrad.). This appears to be the first record of the plant in Southern Australia. It was recorded at Townsville, Queensland in 1926 (8).

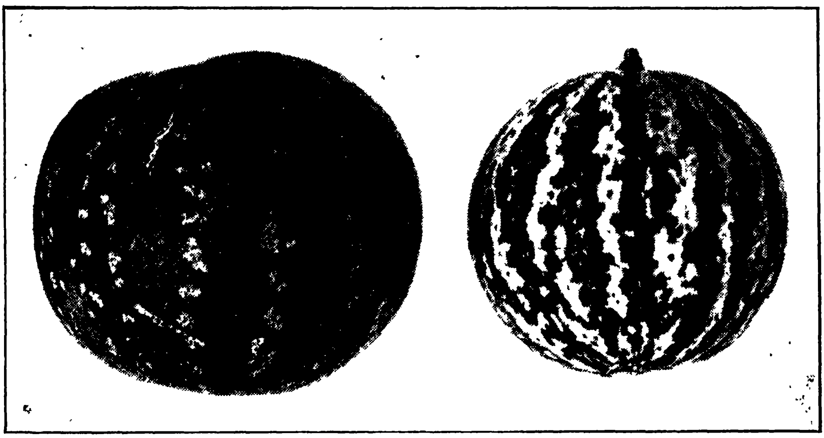

Figure 1.—Fruit of the Bitter Melon (*C. vulgaris*) left, and the Colocynth (*C. Colocynthis*) right.

According to Mr. Sargent, the weed appeared at Swan Reach approximately ten years ago but little notice was taken of it as it was considered to be the ordinary annual Bitter Melon. The local council is said to have considered it as a new weed, but was informed that it was the ordinary melon (*C. vulgaris*).

Two years ago a flock of 200 sheep was taken from Swan Reach to Naidia after remaining in the stock yards at Swan Reach in a hungry condition. Whilst the sheep were at Swan Reach they apparently ingested a quantity of the fruits and seeds of the Colocynth. On arrival at Naidia, the sheep were turned into a paddock of from 100 to 150 acres, and according to report numerous plants of Colocynth appeared in the paddock the following season. These have been removed by hand pulling or grubbing but seedlings still continue to appear. Mature plants of the Colocynth are evident along the roadside from Swan Reach to Naidia, and its present distribution appears to be from Swan Reach to Maggea, a distance of 28 to 30 miles. It has also been recorded at Waikerie however, and it possibly occurs at other points along the river as well.

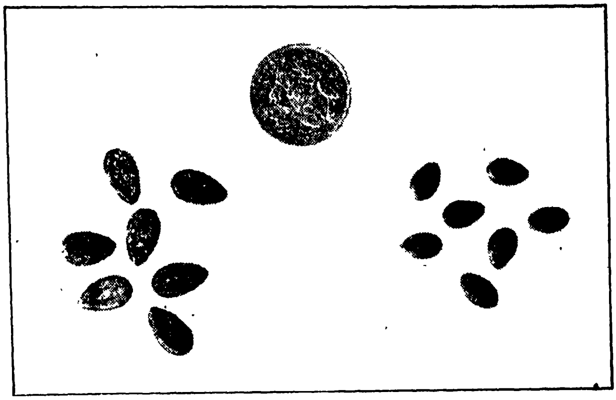

Figure 2.—Mature seeds of the Bitter Melon (*C. vulgaris*) left, and the Colocynth (*C. Colocynthis*) right.

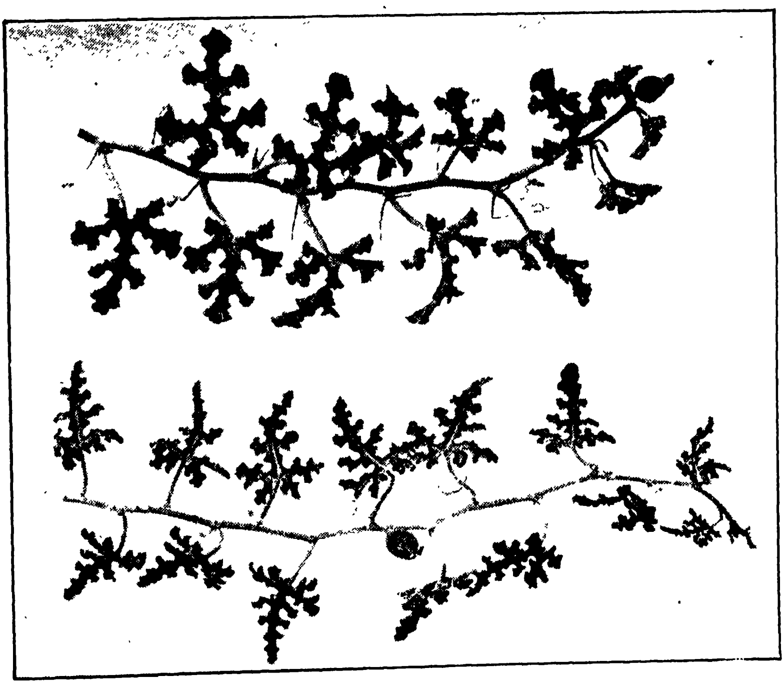

Figure 3.—Leaves of the Bitter Melon (*C. vulgaris*) above, and the Colocynth (*C. Colocynthis*) below.

ANNUAL TYPES OF WILD MELON.

The ordinary Bitter Melon, also called "Wild," "Bastard" or "Cow Melon," is a fairly common weed and quite well known to farmers in the southern parts of the State. Though J. M. Black in his "Flora of South Australia" records it as far north as Oodnadatta, it is chiefly found on sandy land, particularly in the settled districts of the Murray Mallee and close to the sea.

A distinction should be drawn between this species and the Paddy Melon which often grows in association with the Bitter Melon. The two species are alike in possessing long creeping stems with tendrils, small yellow flowers and leaves of a similar nature, but the fruit of the Paddy Melon is only one inch or less in diameter, that is, no bigger than a golf ball, but often smaller, and conspicuously

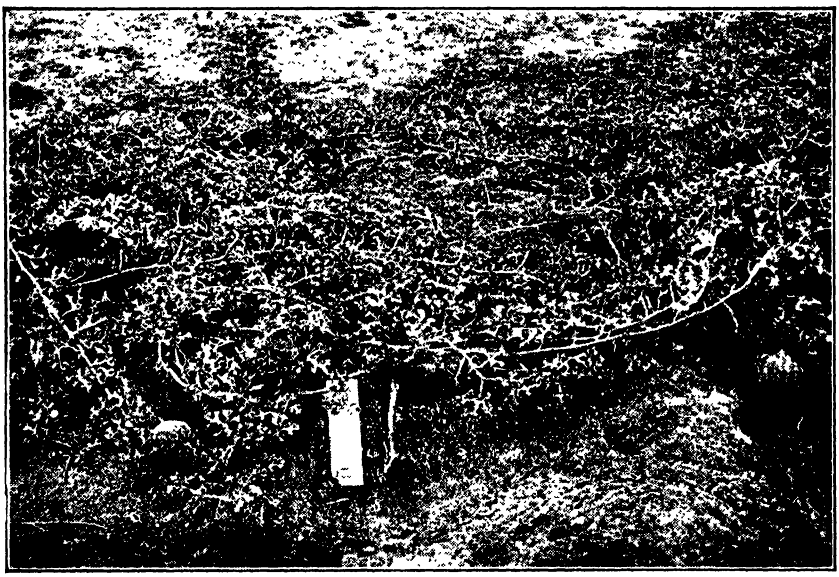

Figure 4.—Plant of the Bitter Melon (*C. vulgaris*), showing habit of growth, root system and fruits.

covered with soft, harmless prickles, like some varieties of gherkins. The fruit of the Bitter Melon, on the contrary, has quite a *smooth rind,* although it is hairy when small and it is similar to the garden Water Melon externally. It is round, large, varying in diameter from 2½ins. to 6ins., and it resembles the Water Melon on being cut open, except that the flesh is whitish instead of pink. The taste is bitter, and the seeds are mottled instead of black; the Water Melon and Bitter Melon are, in fact, the cultivated and wild forms respectively of the same species (Black).

The Colocynth is somewhat similar in appearance to the ordinary Bitter Melon (Black, Fl. S.A.) and specimens of the former have apparently been previously regarded as the annual Bitter Melon.

The following account describes the more important field differences between these plants and will enable ready identification to be made.

THE COLOCYNTH (*C. COLOCYNTHIS*).

1. The tap-root is *perennial,* hard, woody and conspicuous (Figs. 5 and 6), 2ins. to 6ins. in diameter, *bulky at the crown* and more than 3ft. in length.

2. *Both* sides of the leaf are covered with short stiff hairs and feel rough to the touch.

3. The plants are *greyish-green,* rather straggling in appearance, with the leaves regular and on long stalks, *showing much of the stem.*

4. The ripe fruits are rarely more than three or at the most four inches in diameter, lightish in colour, with longitudinal bands of yellow alternating with *speckled* bands of green.

5. The ripe seeds are characteristically oval and flattened, dull yellow in colour, *without markings* and ¼in. or very little more in length.

THE BITTER MELON (*C. VULGARIS*).

1. The tap-root is *annual, slender* and relatively soft (Fig. 4).

2. The leaves are rough below but *smooth above.*

3. The plants are a fresher or more *succulent green,* less straggling in appearance, with less conspicuous leaf stalks, less regular and larger leaf lobes and *showing less of the stem* (Fig. 3).

Figure 5.—Plant of the Colocynth (*C. Colocynthis*), showing stems, root system and fruits.

4. The ripe fruits are very hairy when young and small, up to 6ins. in diameter when mature, darker and greener in colour than the Colocynth and with *narrower* and *less distinct longitudinal bands* of yellow, which are broken, forming discontinuous patches (Fig. 1).

5. The ripe seeds are similar in shape to those of the Colocynth but noticeably larger—almost ⅜in. compared with ¼in.—white at first, but when mature pale brown in colour with *fine black markings* (Fig. 2).

METHOD OF CONTROL.

The eradication of both the Paddy Melon and the Bitter Melon is comparatively simple in practice both plants being annuals.

In the case of the Colocynth however, the perennial root system must be destroyed in order to eliminate the weed. Ordinary methods of cultivation appear to be ineffective as cut portions of the crown are capable of renewed vegetative growth. Mr. D. Sargent finds that it is necessary to hand-grub and burn both the root portion and the fruits, before the latter have become dry, when the seeds are set free.

Sheep are reported to eat the fruits of both the Bitter Melon and the Colocynth on certain occasions, probably when hungry, with other green material scarce. An instance of the manner in which sheep can spread the seeds has already been given and it is probable that the seeds are capable of remaining in the soil for several years before germinating. In this connection it is interesting to find (6) that the fruits of *C. Colocynthis* are used by the people of the Nile for smearing their water bags to prevent camels from damaging them.

The Colocynth is said to be poisonous in large quantities; the dried pulp of the fruit has a drastic purgative action and is used in pharmacy (7).

In handling plants of Colocynth growing near Swan Reach, a highly objectionable odour was observed after pulling or bruising the vegetative portions.

Figure 6.—Old plant of Colocynth (*C. Colocynthis*), showing well developed root system and accumulation of old fruits.

SUMMARY.

Specimens of a perennial wild melon which has appeared at Waikerie and Swan Reach have been received, and identified as *Citrullus Colocynthis* (Colocynth), a Mediterranean plant not previously recorded in South Australia.

The plant resembles the well known Bitter Melon, *Citrullus vulgaris,* but is more difficult to eradicate on account of its woody, perennial root system. A description is given, enabling the Colocynth to be readily identified.

ACKNOWLEDGMENTS.

Thanks are due to the National Herbarium, Melbourne, for the confirmatory identification of the Colocynth, to Mr. A. D. Cocks, who carried out the photography, and to Mr. D. Sargent, who brought the weed to our notice.

Mr. Alcock's remarks on the winning entry were as follows :—

An excellent one, showing that care had been experienced in making and curing the hay. Mr. Wookey makes a practice of waiting until the pasture is ready, then he cuts it and leaves it until ready for cartage. This year, on account of hot weather, it was only cut two days before he stacked it.

Suitability of Plants.—These consisted mainly of Kentucky Blue, Strawberry Clover, King Island Melilot, Rib Grass, Black Medic, and Perennial Rye Grass. Thus, a good mixture of grasses and legumes was obtained.

Curing was done carefully before the hay dried out and bleached. The plants retained their green colour, and were in excellent condition and handled exceptionally well.

Stage of Cutting.—The pasture was cut on 24th November, before the grasses had matured, and also before the Melilotus was too stalky and coarse. This most important item needs attention when making grass hay.

Apparent Nutritive Value.—A very attractive sample of grass hay. It was very palatable, of good appearance, and an even proportion of grasses and clover mixed together. Strawberry Clover was introduced into the mixture, which, although rather hard to cure, always improves palatability.

Storing.—The stack was well built, and had been carefully thatched with cutting grass.

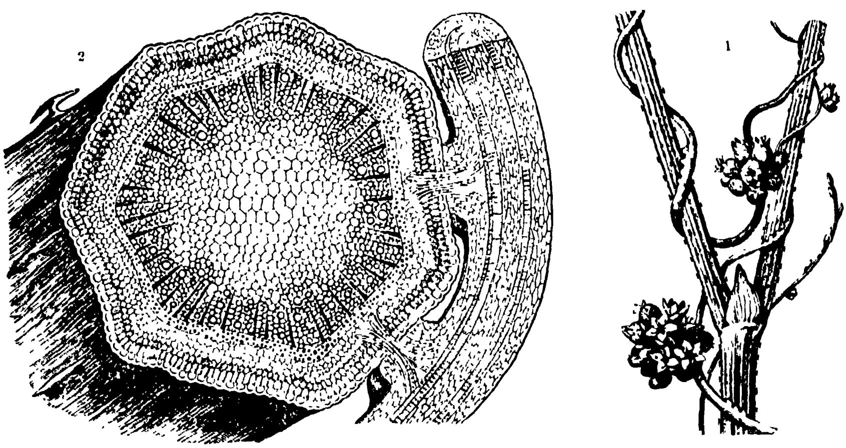
IMPORTANT WEEDS OF SOUTH AUSTRALIA.

[By G. H. CLARKE, B.Sc., Botanist at the Roseworthy Agricultural College.]

No. 14.—DODDER.

Cuscuta Epithymum, L., *et spp.*

The Dodders, or *Cuscutas*, are leafless twining parasites which nourish themselves at the expense of various other plants, attaching themselves by means of special suckers termed *haustoria*, which penetrate the tissues of the host stems and establish connections with their conducting systems. They are devoid of chlorophyll—the green pigment typical of most plants—the slender stems being red or yellowish in colour instead of green; consequently they are dependent upon the hosts they infest for elaborated foods as well as for supplies of water and mineral salts. In all, there are about 100 species of Dodder, the genus *Cuscuta* being represented in most temperate and tropical countries of the world. Apart from those introduced, there are three species in Australia, and these are to be found growing parasitically upon various native shrubs and herbs, mostly of small



(*After Kerner and Oliver.*)

Figure 1.—*Cuscuta europaea* **parasitic on a hop-stem.**

size. With the exception of a few American species which occur on trees, the great majority of true Dodders attack only small herbaceous or shrubby plants. But the Dodders are very closely simulated, as regards their general habit, by species of *Cassytha*, another genus of leafless twiners, several species of which are found abundantly throughout Australia as parasites upon many different native plants including many tall shrubs and trees. Though quite unrelated, botanically, to *Cuscuta*, the *Cassythas*, or false Dodders, are so similar in their manner of growth that they are often called Dodders, especially by foresters. Thus the "Dodder" of Australian foresters is not the true Dodder, but one of the larger species of *Cassytha*, e.g., *C. melantha* or *C. pubescens*, etc., and is easily distinguishable from species of *Cuscuta*, quite apart from differences in structure and arrangement of the flowers and fruits, by its green colour due to the presence of chlorophyll, and by the greater tensile strength and, in some species, much greater coarseness of the twining stems. Owing to their chlorophyll the false Dodders are only partially parasitic upon the plants they attack; like Mistletoe and its allies, species of *Cassytha* are able to synthesise their own foods, and absorb only

water and mineral substances from the branchlets of the hosts on which they grow. On the other hand, species of *Cuscuta,* or true Dodder, are unable to effect such a synthesis, and so are entirely parasitic upon the host plants attacked. It has been stated that the true Dodder does form a small amount of chlorophyll under certain conditions, but this is, however, exceptional.

Certain European species of *Cuscuta* are of considerable importance inasmuch as they are known to attack cultivated plants, often with disastrous results. The most important of these is the Lesser Dodder, *Cuscuta Epithymum,* L., which lives upon various small plants such as Lucerne, Clover, Heath, and Thyme. A variety of this, sometimes regarded as a separate species (*Cuscuta trifolii*), is the Clover Dodder, a serious enemy of Clover and other leguminous crop plants. Another species, *Cuscuta Epilinum,* Weihe., is parasitic upon Flax and Hemp. A third species, the Greater Dodder (*C. europaea,* L.), infests a great variety of plants, including Hops, Vetches, Nettles, Sugar-beet, Potatoes, etc. Several other species also attack crop plants. The Lesser Dodder (*C. Epithymum,* L.) is the common introduced form in South Australia, and is the basis of our description, but this description will apply almost equally well to other species, at least in so far as it deals with the habit of growth and life history of the parasite.

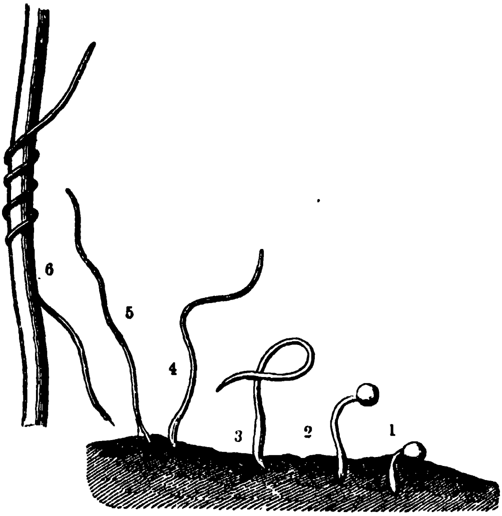
Botanical Name.—The name *Cuscuta* is generally regarded as having been derived from *kechout,* one of the Arabic names for the plant; an alternative derivation is from a Hebrew word meaning "to bend," in allusion to the twining habits of Dodder *Epithymum*, literally "on Thyme," is self-explanatory.

The Family.—The true Dodder belongs to the *Convolvulaceae*, or Morning Glory family, of which it represents a very distinct and specialised subfamily, the *Cuscutoideae,* characterised by holo-parasitism and by structural features connected with this type of habit. The parasitic mode of life is, however, exceptional for the family as a whole, the great majority of *Convolvulaceae* being free-living, though many are climbers and may use other plants for support. The family comprises about 50 genera and 1,000 species, of which 9 genera and 15 species occur in this State in addition to a few introduced forms. Of those growing locally, *Convolvulus, Calystegia,* and some species of Ipomoea, are climbers, the first two being known as "Bindweeds." Of these the "Lesser Bindweed" (*Convolvulus arvensis,* L.) is one of the most troublesome introduced weeds in Australia. In view of the very specialised nature of the Dodders, a consideration of the characters of the family *Convolvulaceae* may conveniently be postponed until we have occasion to deal with a more typical representative such as the Lesser Bindweed. Most members of the family have rather large, tubular, and radially symmetrical flowers, but *Cuscuta* has small flowers crowded in spherical clusters or in spikes. Despite their small size, however, the flowers possess a typically Convolvuloid structure.

The Genus.—The characters of the genus are, of course, those of the subfamily of which it is the sole representative. The plants are quite leafless, even the embryo being devoid of cotyledons or seed leaves, and they consist of slender stems, red or yellowish in colour, and attached by suckers or haustoria to the host plants about which they twine in a spiral manner. The flowers are small, pink or whitish in colour, and borne in lateral clusters. Each consist of a 5-lobed (rarely 4-lobed) calyx and corolla, the latter being tubular and more or less bell-shaped, especially after flowering. The 5 (rarely 4) stamens are attached to the corolla tube which also bears, below the origin of the stamens, a small crown of fringed or toothed scales. The ovary has two styles, and later becomes a more or less globular fruit containing 2-4 seeds. The separation of the genus into

species depends upon such characters as the presence or absence of stalks to the flowers, the diameters and branching of the stems, the size and arrangement of the flowers, and the structure of the floral organs.

Description of C. Epithymum, L.—A reddish-coloured annual with slender branching stems; flowers reddish-white, fragrant, sessile, in globular clusters of 5-10 mm. diameter. Calyx spreading, deeply lobed, the lobes acute, as long as the tube of the corolla; corolla with 5 nerveless pointed lobes as long as the tube; scales fringed and almost closing the tube; stamens exserted but shorter than the corolla; styles distinct; stigmas linear. Period of flowering—Spring-Summer.



(*After Kerner and Oliver.*)

Figure 2.—Greater Dodder (*Cuscuta europaea*). **Stages in germination of seeds.**

Life History.—Dodder infestations are usually traceable to contaminated seed of Lucerne, Clover, etc., and when such seed is sown the resulting crop is soon attacked by the seedling parasites. The seeds of *Cuscuta* are very small, those of the Clover Dodder being usually less than a millimetre in diameter. They are more or less rounded in shape and are of the colour of light dirt. By the use of appropriate sieves they may be separated easily from seed of Lucerne. They germinate readily in damp earth, but usually much later than the seeds of susceptible plants sown at the same time. Thus the host seedlings are usually well advanced by the time the parasite is ready to attack them, as also are the new aerial shoots of herbaceous perennials.

The seed contains a slender spirally coiled embryo imbedded in an endosperm tissue filled with reserve food. When germination begins, the embryo lengthens and twists itself in such a way that one end emerges from the seed as a fine whitish thread which soon turns downwards and enters the soil, becoming somewhat dilated, and attaching itself to soil particles or other objects. The other, much narrower, end turns upwards, elevating the remainder of the seed into the air. At the same time the reserve materials of the endosperm are gradually absorbed by the embryo, which soon discards the seed coat and stores the surplus food in its lower dilated end. The middle region lengthens rapidly so that the embryo becomes a slender thread of which the tip moves slowly round in a circle, so that it may come in contact with a suitable support. Should it do so, the stem makes two or three turns round the support, and the growing point repeats its revolving movement, showing a preference for the living parts of the supporting stem. Wherever it comes into contact with such parts, the stimulus of

contact causes it to make a few close coils, so that the one stem may attach itself by such coils to several branches of the one host, or even to several distinct plants. If, after germination, the seedling parasite fails to make contact with a suitable support, it ceases to grow after it has reached a length of from 1-2 centimetres; but it remains viable in this condition for a long time and may subsequently attach itself to seedlings formed by subsequent germination. In all cases, the primary root soon dies and connection with the ground is lost, the parasite being incapable of nourishing itself once the reserves of the original seed have become exhausted.

The twining habit is of interest because, in Dodder, this character is combined with the same sensitiveness to contact as is possessed by tendrils such as those of a vine. The parasite forms both loose coils and close coils; it twines loosely round a support in the manner of twiners in general, but in places it forms a few close coils, wrapping itself tightly round the host in the same way as a tendril encircles a supporting object. As regards its direction the twining is similar to the thread of a right-handed screw, though an Indian species, parasitic on a fern, has been described in which the direction of twining is the reverse of this.

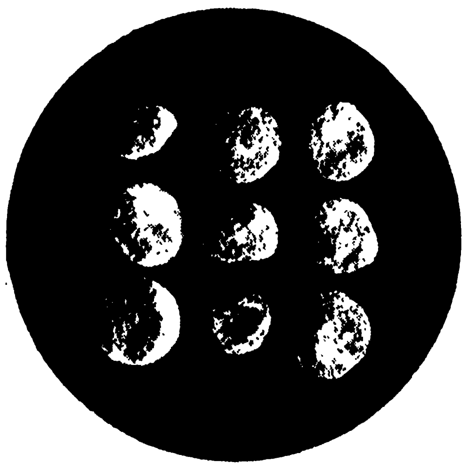
The loose turns are due, as in the case of other twining plants, to the stimulus of gravity acting upon a growing point which normally revolves or *nutates*. The apex of an erect shoot does not grow upwards in a direct line. Invariably it follows a spiral path, moving round in a circle of varying width. In twining plants, not only is this circle much wider than in others, but there is an increased sensitiveness on the part of the growing point to gravitational influence, the actual twining being the result of this stimulus acting upon the sensitive and nutating apex. If the effect of gravity is annulled by rotating such a plant about a horizontal axis, the normally twining stem can be induced to grow in a straight line, and this has been shown by experiment to be true of Dodder as well as of other twiners.

Close coiling round the support is brought about in an entirely different way. The young stem, near its growing point, is sensitive to contact with external objects, and, like a tendril, it bends sharply towards the support when so stimulated. It would seem, however, to be more sensitive in some respects than a tendril, since it is said to reject a dead support, and to be able to discriminate between such and living stems or leaves which are, of course, essential for its nutrition. Contact stimulation causes the parasite to make two or three sharp turns round the stem at this point, and suckers or haustoria are formed where it is in contact with the host stem, the stem of the parasite usually becoming thicker in these situations. The Dodder will not twine on stems greater than a certain diameter, the maximum thickness for most species being about 1 cm., though in the case of Clover Dodder, the supporting stems are usually less than half this thickness.

The haustoria appear as wart-like outgrowths on the side in contact with the host stem. They are situated close together in rows, and, as they grow, become firmly pressed and flattened against the host surface. At first smooth, they subsequently become granular due to a papillose development of their superficial cells. These cells secrete a fluid by means of which the sucker becomes firmly cemented to the surface of the host. When this has been effected, a process, which is the haustorium proper, pushes itself out from the centre of the Dodder stem, traverses the tissues of the sucker, and penetrates the tissues of the host, the penetration being assisted by the solvent action of the fluid secreted by the papillose cells of the sucker. The haustorium pushes its way through the cortical tissues of the host stem and comes to rest in the outer region of the conducting

system. The cells occupying the centre of the haustorium become differentiated to form channels by means of which the conducting systems of both host and parasites are placed in direct communication. It is worthy of note that both food-conducting and water-conducting elements are present in the haustorium of the true Dodder (*Cuscuta*), whereas in the false Dodrer (*Cassytha*) only the latter are found. By this means the Dodder is enabled to share both the water supply and the food supply of the host plant; and since connection with the ground is lost at an early stage, the growth of the parasite takes place wholly at the expense of the food substances so absorbed. The haustoria correspond both in position and mode of development to adventitious roots; thus the parasite consists, apart from its floral organs, simply of the branched twining stem with its haustoria representing modified roots.

The drain upon the host plant is not very heavy during the early stages of growth of the parasite, but it becomes very much more severe towards flowering time when large amounts of nutritive material are withdrawn for the development of flowers and seeds. The flower-heads are very numerous and appear as



(*From N.S.W. Farmers' Handbook.*)
Figure 3.—Seed of Clover Dodder (X 10).

almost perfectly spherical balls, ⅛in.-¼in. in diameter, of a pinkish-white colour. Each ball is a cluster of tiny bell-shaped flowers, each of which may form four seeds. Thus a very large amount of seed may be produced from a single plant of Dodder in flower.

Host Relationships.—Though dependent for all its food materials, Dodder does not confine its attacks to any one particular species, genus, or family of host plants. The lesser Dodder (*C. Epithymum*) is known to parasitise, in addition to Lucerne, many species of Clover, Thyme, Heath, and Furze, and the writer has observed it growing vigorously upon such local plants as Barrel Medic (*Medicago tribuloides*), Wallaby Grass (*Danthonia semiannularis*), Spear Grass (*Stipa variabilis*), Small White Everlasting (*Helipterum corymbiflorum*), Bean Caper (*Zygophyllum glaucescens*), and Ruby Salt Bush (*Enchylaena tomentosa*). Doubtless it grows equally well on many others. The absence of a specifis relationship between host and parasite in this case is in marked contrast with what obtains in the case of many bacterial and fungal parasites, which often show specificity as regards the host plants attacked. The absence of such specificity on the part of Dodder is doubtless to be explained by the fact that it feeds, not upon the

actual living substance of its hosts, but upon the reserve foods in process of being translocated from one part of the plant to another. Just as a standard type of brick may be used in the construction of houses of a great variety of different designs, so the simpler products of food synthesis, such as simple sugars

their cells, may be accompanied by a comparative uniformity as regards the simpler substances from which the more complex ones are built up, and into which the latter are broken down for purposes of translocation from place to place. Such an uniformity would explain the wide range of host species possible for a parasite which, like Dodder, nourishes itself by sharing the translocation stream of its host. But with intracellular parasites, on the other hand, there may be an actual mingling of the living substance of both organisms, and the intimate relationship so established may involve interchanges of substances of so high an order of chemical complexity, that slight differences in the protein constitution of plants belonging to different families, genera, or even species, may assume the importance of limiting factors for the growth of the parasite concerned. In such cases the parasite becomes greatly restricted as regards the range of host organisms vulnerable to its attack. In the case of hemi-parasites which, like Mistletoe and false Dodder, posses chlorophyll and utilise other plants merely as sources of water and mineral salts, the range of susceptible hosts may be even wider than it is with Dodder.

Control and Eradication.—Dodder-infested plants should never be fed to animals or utilised for the making of hay. There are two reasons for this; in the first place, since the seeds of Dodder pass unharmed through the digestive tract, the droppings of animals afford a medium for the spread of the parasite. A second reason is that, according to Pammell, certain species of *Cuscuta* are poisonous, and, though definite evidence on this point is wanting in the case of *C. Epithymum* and other species attacking Clover and Lucerne, there are on record two cases where serious digestive troubles followed the ingestion, by horses, of hay, which was badly contaminated with Dodder.

The use of clean agricultural seed is always important, but in no case is it more so than in that of Lucerne. Though Dodder is easily detected when present in quantity as an impurity in seed, the presence of only a few seeds to the ounce is to be regarded as a serious contamination, and this small amount may easily escape recognition. Such low percentage impurity is by no means uncommon, since the parasite usually occurs in patches, and when the infested patches are harvested along with the rest of the crop, the percentage of Dodder seed on thorough mixing may be small enough to escape detection, and yet large enough to constitute a serious impurity. It is a matter of great importance, then, to use only such seed of Clover or Lucerne as is certified as being free from Dodder. Dodder seed may be separated easily by using sieves with holes 1¼ mm.-1½ mm. diameter, but there is always a possibility of a few seeds being left behind if the sifting process has not been very thorough indeed. A special method of removing Dodder from other seeds makes use of the fact that the seed coat of the former is relatively rough as compared with that of Lucerne and Clover. The sample is mixed with a fine powder which is sensitive to the attraction of a magnet. This powder clings to the surface of the Dodder seeds, which are also small and light, thus enabling them to be removed by subjecting the sample thus treated to the influence of a series of electromagnets.

Devitalisation by heat is another method of seed treatment which has for its object the lowering of the germination capacity of Dodder without harming the seed of Lucerne. The seed is heated at 65° C. for two hours. This method is analagous to the somewhat similar treatment of Wheat grains for the prevention of Loose Smut, but is of doubtful value.

It is important that Dodder be recognised early when present in a crop. On no account should it be allowed to form seed, and steps should be taken to get rid of it as soon as its presence is discovered. When Dodder patches are found in a Lucerne crop the method of procedure usually recommended is to cut down the affected plants with a scythe as close to the ground as possible, taking care to

cut the crop well beyond the apparent limits of the Dodder, and to remove carefully and burn all affected material. But as there is some danger of dropping this material during removal, where circumstances permit it is probably better, as suggested by Long, to heap the whole together in the centre of the cleared patch, cover with straw or light rubbish, and burn on the spot. When the central heap has been reduced to ashes the whole of the cleared area should be covered with chaff to a depth of several inches and burnt over.

Other methods suggested are the spraying of the infested patches with a 15 per cent. solution of sulphate of iron, or with a solution of sodium arsenite ½lb. in 5galls. of water. The object of these methods is to destroy the Dodder without killing the Lucerne or Clover, and the spray should be applied so as to wet both the plants and the surface of the soil. Where arsenical solutions have been used animals should not be allowed access to the sprayed patches until all traces of poison have been removed by rain or watering.

Dodder seeds remain viable in the soil for five or six years, and so, where a crop has been extensively attacked by the parasite and the latter has been allowed to form seed, such a paddock should not be sown to another susceptible crop for seven or eight years.

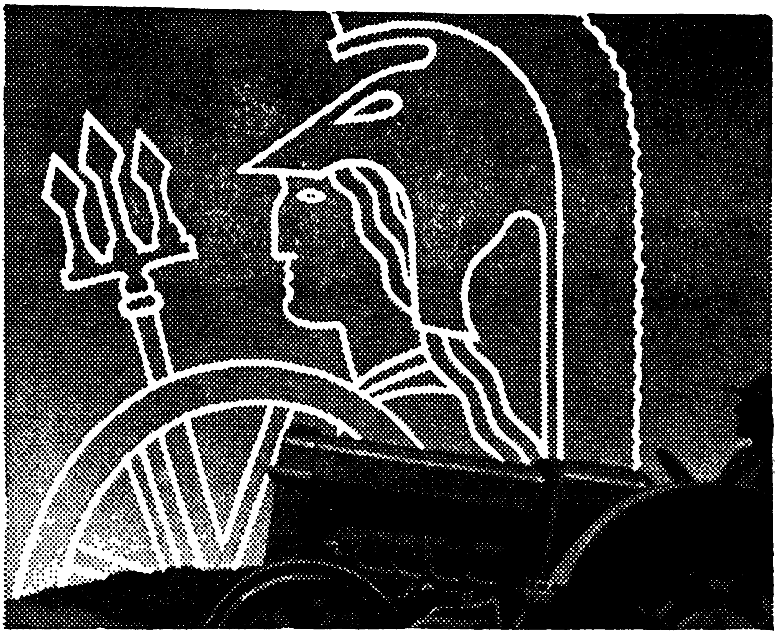
SHEEP BLOWFLY.

In a report to the Governing Council of Roseworthy Agricultural College the Principal (Dr. A. R. Callaghan) recently stated that towards the end of January all of the farm flocks were jetted to prevent blowfly strike. The material used was a well known brand of sheep dip at the rate of 1 packet to 40galls. of water. Use was made of the orchard spray pump and the orchard spray gun in place of a jetting gun, at a pressure of 140-150lbs. The jetting did not prevent the fly from striking, but it prevented serious damage from the strike and it saved the work of cleaning up "struck" sheep and the application of a dressing, because the maggots died. Quite a number of sheep lost a little patch of wool about the size of a man's fist, indicating that they had been struck, but in no case were live maggots found and the skin of the sheep was dry and clean, without showing any raw flesh, as is seen when maggots are at work. Further, the sheep did not appear to lose condition as is the case with "struck" sheep. The work could be improved on by the use of a jetting gun instead of a spray gun, because, on examination, the solution had not reached the skin of some of the sheep. A proper jetting gun would be more convenient for the work and would greatly facilitate the operation.

Mr. C. A. Goddard, R.D.A. (Assistant Wool Instructor at the School of Mines), in reply to several requests from country districts for treatment to prevent blowfly strike in sheep, recommends the following preparation and treatment:—Take ½lb. each of white arsenic and washing soda. Boil in 1gall. of water for 20 minutes. This will give a 5 per cent. solution of arsenic. Dilute with 9 parts of water to reduce to .5 per cent. of arsenic. Swab thoroughly to wet skin and wool. Use this as a preventive treatment, and not on badly affected sheep.



CITRUS INDUSTRY.

EXPORT OF ORANGES TO THE UNITED KINGDOM—1935 SEASON.

The attention of shippers of oranges to the United Kingdom is drawn to the undermentioned Federal Regulations in regard to the conditions to be observed in order to participate in the Government Bounty.

1. *Fruit to which Bounty is Applicable.*

The bounty, which is to be paid at the rate of 2s. per export case, shall apply only to the following fruit:—

(*a*) Oranges exported from Australia to the United Kingdom during 1935, with the exception of navel oranges shipped later than 15th July.

(*b*) Oranges of "Special" and "Standard" grades as defined herein.

2. *Picking of Fruit.*

The fruit must be clipped from the trees by means of a blunt-nosed clipper. No protruding stems must be left on the fruit, and where necessary a second cutting, in order to remove superfluous wood, must be made. The fruit must be placed gently, *not dropped,* in the picking box.

3. *Handling of Fruit.*

Throughout the whole of the operations, from the picking of the fruit to the wrapping and packing, *gloves* must be used. *Mis-shapen* or excessively corrugated fruit shall not be shipped.

4. *Pre-cooling.*

Wherever possible all fruit shipped is not to exceed a temperature of 53 degrees at the time of loading, and every effort is to be made to comply with this requirement.

5. *Grading.*

Oranges shall comply with the following provisions:—

(*a*) The outer layers or shown surfaces of the oranges shall be a true indication of the contents of each case.

(*b*) Each case shall contain one variety of oranges only, and the oranges shall be wrapped in paper of a quality approved by the Secretary, Department of Commerce.

(*c*) The oranges in any case shall not vary in size by more than one-quarter of an inch, and no orange shall measure less than two and one-quarter inches in diameter. For the purposes of this paragraph—

"Two and one-quarter inches" shall include fruit of a size two and one-quarter inches or greater diameter, but less than two and a half inches.

"Two and a half inches" shall include fruit of a size two and a half inches or greater diameter, but less than two and three-quarter inches.

"Two and three-quarter inches" shall include fruit of a size two and three-quarter inches or greater diameter, but less than three inches.

"Large" shall include fruit of a size three inches or over in diameter.

(*d*) The oranges shall not be dry. They shall be mature, of normal shape and appearance common to the variety, sound and of reasonably even colour, and shall be packed in either of two grades, namely, "Special" or "Standard."

"Dry," in relation to oranges, means that the proportion of juice extractable is less than 35 per cent. by weight of the whole orange.

"Mature," in relation to oranges packed for export to the United Kingdom, means that the fruit shall be in such condition that the quantity of N/10 soda solution required to neutralize the acidity content of 10 cubic centimetres of juice drawn from the mixed juices of not less than five oranges taken at random from any case or cases bearing a similar mark shall not be more than 30 cubic centimetres.

(*e*) Oranges described as *Special* shall consist of oranges complying with the requirements of paragraph (*d*) above, and in addition shall be substantially free from disfigurements, such as are caused by scars, scratches of the skin, excessive navel segments, cavities, punctures and blemishes caused by any insect or fungus pest. Such disfigurements shall not exceed 2½ per centum of the total surface area of any individual orange.

(*f*) Oranges described as *Standard* shall consist of oranges complying with the requirement of paragraph (*d*) above, but disfigurements such as caused by scars, scratches of the skin, excessive navel segments, cavities, punctures and blemishes due to any fungus or insect pest may be allowed to the extent of 10 per cent. of the total surface area.

(*g*) In order to ascertain the proportion of juice extractable from an orange, the halves of a freshly divided orange shall be rotated upon a conical glass lemon-squeezer under hand pressure only. The resultant juice shall be strained through a strainer of not less than thirty meshes to the lineal inch.

(*h*) Oranges shall not be exported unless they have been sweated prior to packing for a period of at least seven days.

6. *Borax Treatment.*

Fruit intended for shipment to the United Kingdom must not be treated by the borax treatment, as fruit so treated is prohibited importation into the United Kingdom.

7. *Packing.*

Oranges for export into the United Kingdom shall be packed only by Packing Houses—private, proprietary, or co-operative—licensed or approved by the State Departments of Agriculture. The fruit shall be packed in clean, new cases or trays manufactured from seasoned softwood or hardwood containing not more than twenty percentum of moisture, smoothly sawn or dressed in a manner approved by the Secretary, and, in the opinion of the Secretary, sufficiently strong to withstand such handling as is ordinarily incidental to transport to destinations beyond the Commonwealth. Cases manufactured from karri and jarrah timber shall have the boards comprising the ends, tops, and bottoms dressed on one side at least, and the boards comprising the sides shall be smoothly sawn or dressed. The dimensions of the cases shall be as under.

Orange Cases.

Inside measurements (clear of divisions)—

Length	24in.
Depth	11½in.
Width	11½in.

The timber used in the construction of the cases shall be not less than the following dimensions:—

"Orange" Case—

Two ends, one centre, 11/16in. thick, 11½in. wide, 11½in. deep.
Sides and bottoms (six pieces), ¼in. thick, 5¼in. wide, 26 1/16in. long.
Unitised lid (four pieces), 5/32in. thick, 2½in. wide, 26 5/16in. long.
Cleats (two pieces), ¼in. thick, 1¼in. wide, 11½in. long.

The cases shall be wired or strapped at both ends and strapped in the centre.

8. *Loading and Stowage.*

Crates or other approved loading gear must be used for the loading of the fruit at the ship's side.

9. *Marking of Cases.*

The following particulars are to appear in prominent and legible characters on the end or ends of the cases:—

(1) A true description of the fruit (*e.g.*, "Washington Navel Oranges," or "Valencia Oranges," as the case may be).
(2) The word "Australia."
(3) The name or registered brand of the grower or the exporter.
(4) The number of oranges contained in the case.
(5) The grade of the fruit (*e.g.*, "Special" or "Standard," as the case may be).

10. *Payment of Bounty.*

Payment of the bounty may be made either to the grower, packing house, or shipper of the fruit. Where a claim for bounty is made by either the grower or packing house, particulars of each shipment must be furnished together with the name of the firm or company through whom the fruit was shipped. The claim must also be supported by a statutory declaration by either the grower or packer that the conditions prescribed for the picking, handling, grading, and packing of the fruit have been complied with.

STATE OF SOUTH AUSTRALIA.

FINAL RESULTS OF CEREAL AND HAY HARVEST, 1934-35.

[A. W. BOWDEN, Acting Government Statist.]

WHEAT.—1934-35—27,455,600bush. Average per acre, 8.61bush.
WHEAT.—1933-34—35,373,466bush. Average per acre, 9.26bush.

There are still a few minor wheat districts where the completion of the collection has been delayed and a number of odd returns from farmers in other districts outstanding but, rather than further delay the final results, a safe estimate has been made for all these and hence the totals now submitted may be accepted as final.

SURVEY OF CONDITIONS.

It will be remembered that the official estimate of the wheat crop published in December, 1934, was 29,000,000bush. This forecast was based on reports received during the first week in December and the indications were that the crop would prove to be more favourable than had been previously anticipated. Subsequent harvesting weather in some of the more important districts proved to be particularly unfavourable, and a large proportion of the decrease from the December forecast of 29,000,000bush. to the final result now published (27,455,600) must be attributed to this factor.

When the Chamber of Commerce fixed the f.a.q. standard for South Australian wheat at 60½lbs. the Chairman (Mr. H. E. Annells) said that before the new year, the samples at that time proved to be of a higher natural weight than the samples submitted when the f.a.q. standard was fixed on 31st January. This was due to the weather during the last week in the year when rain fell continuously while the grain was ripe but had not been harvested. The result was that the grain became bleached and there was a loss in natural weight. This feature is definitely borne out by the reports of the various Agricultural Inspectors with reference to harvesting conditions in late December and early in the new year.

Considering the above factor and also the severe grasshopper plague, the yield must be considered satisfactory. Compared with the December estimate, the Barley yield was 5,603,014 (5,500,000bush.); Oats, 2,412,117 (2,750,000bush.); Hay, 550,020 (538,500) tons.

GROWERS AND ACREAGE SOWN.

Wheat Growers.—There were 14,392 (14,943) growers of wheat for all purposes for the season 1934-35, and of this number 13,145 (13,919) reaped areas for grain. Approximately 1,828 (1,712) reaped areas of under 50 acres. Share farmers counted once only.

Acreage.—The grand total acreage sown to wheat, barley and oats for all purposes was 4,497,481 (4,949,349) acres, a decrease on the previous year of 451,868 acres.

Wheat.—3,459,380 (4,074,417) acres; grain, 3,188,225 (3,821,795) acres; hay, 264,373 (246,999); fed off, &c., 6,782 (5,623).

Barley.—334,462 (320,527) acres;grain, 316,807 (307,423); hay, 3,128 (2,729); and fed off, 14,527 (10,375).

Oats.—703,639 (554,405); grain, 367,192 (265,074); hay, 280,710 (247,879); fed off, etc., 55,737 (41,452).

PRODUCTION AND AVERAGES PER ACRE.

Wheat.—27,455,600 (35,373,466) bushels, decrease, 7,917,866 bushels—averaging 8.61 (9.26) bushels per acre.

Barley.—5,603,014 (5,254,280) bushels, increase 348,734 bushels averaging 17.69 (17.09) bushels per acre. This yield has only been exceeded by the crop of 6,070,161 bushels in 1932-33.

Oats.—2,412,117 (2,087,772) bushels, increase 324,345 bushels, averaging 6.57 (7.88) bushels per acre. This was a record crop.

Hay (wheaten, oaten and barley).—550,020 (524,191) tons, increase 25,829 tons, averaging 1.00 (1.05) tons per acre. Distributed as follows—Wheaten, 298,896 (290,009); Oaten, 247,603 (231,607); Barley, 3,521 (2,575) tons.

BENEFITS FROM FALLOWING.

The following return illustrates the benefit from cropping wheat on fallowed land:—

Grown on	Wheat Yield per Acre.				
	1934-35.	1933-34.	1932-33.	1931-32.	1930-31.
	Bush.	Bush.	Bush.	Bush.	Bush.
Fallow	11·02	11·60	12·86	14·81	11·05
Not fallowed	2·98	4·78	6·86	7·57	5·48
Total	8·61	9·26	10·43	11·81	8·34
	Inches.	Inches.	Inches.	Inches.	Inches.
Rainfall.—April-Nov.	12·15	12·15	14·70	13·27	11·31

Of last season's wheat crop, 2,233,258 (2,508,581) acres sown on fallow yielded 24,608,163 (29,092,873) bushels, averaging 11.02 (11.60) bushels per acre and 954,967 (1,313,214) acres sown on unfallowed land yielded 2,847,437 (6,280,593) bushels averaging only 2.98 (4.78) bushels per acre thus making the State average 8.61 (9.26) bushels per acre.

RAINFALL.

The mean monthly rainfall over the agricultural areas of the State is specially computed and recorded in comparison with the averages for the past 30 years. The following are particulars in inches of the rainfall from April to November for the chief Divisions of the State.

Year.	Whole State.	Central.	Lower North.	Upper North.	South-East.	Western	Murray Mallee.
	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.

1934	8·61	13·17	14·49	7·44	19·61	4·25	4·92
1933	9·26	13·85	14·79	6·61	16·14	6·21	5·42
Average, five years	9·74	13·98	14·73	8·13	13·90	6·28	7·05

THE MARKETING OF THE CROP.

The carry forward was 8,150,000 bushels, and with the 1934-35 crop a total of 35,605,600 bushels was available. 3,250,000 bushels are required for seed and probably 4,250,000 bushels for home consumption, including feed for stock and a three mouths' supply carry forward before the next crop is matured; less this 7½ million, the balance available for export was 28,100,000. To date of this Bulletin, it is estimated that 20,300,000 has been exported leaving a balance available for shipping of 7,800,000.

FIVE MONTHS OVERSEA EXPORTS.

(December 1934, to April 1935.) The principal countries to which cereals have been exported this season compared with last season is as follows:—*Wheat* (bushels).—United Kingdom, 8,397,403 (5,802,580); China, 3,594,793 (—); Japan, 3,459,142 (1,138,863). *Flour* (tons).—United Kingdom, 7,857 (12,427); Japan, 8,060 (3,244); Egypt, 6,697 (5,023). *Barley* (bushels).—United Kingdom, 362,586 (1,145,470); Belgium, 1,107,562 (118,868); New Zealand, 264,028 (144,180); Japan, 44,636 (253,422).

AREA INTENDED TO BE CROPPED, 1935-36.

Particulars have been received from farmers in all hundreds of the State as to the areas intended to be sown for the 1935-36 season. These indicate that the wheat areas for all purposes will be decreased by approximately five per cent. and the barley and oaten areas increased. Further information will be obtained after seeding.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

WOMEN'S BRANCHES.

A REVIEW OF THEIR PROGRESS.

[By FRED RICHARDS, Assistant General Secretary Agricultural Bureau.]

As the outcome of a recommendation made by a Sub-Committee of the Advisory Board of Agriculture in 1917, the Government approved of the formation of Women's Branches of the Agricultural Bureau, and the time appears to be opportune to review the progress of their work in view of the fact that the membership now exceeds 1,000 members.

The following table shows a list of Branches, together with the date of formation, number of members, and the name and address of the Secretary:—

Branch.	Date of Formation.	Number of Members.	Name and Address of Secretary.
Riverton	14/11/1917	27	Mrs. E. A. Gray, Riverton
Williamstown	8/2/1921	7	Mrs. A. Cundy, Williamstown
Saddleworth	21/7/1921	12	Miss G. Frost, Saddleworth
Kalangadoo	11/7/1923	18	Mrs. H. Brooks, Kalangadoo
Pinnaroo	7/11/1923	43	Mrs. P. Dowd (President)
Wilkawatt	17/7/1924	16	Mrs. W. Pritchard, Wilkawatt
Kangarilla	12/5/1926	8	Mrs. M. Steer, Kangarilla
Wasleys	31/10/1928	25	Miss J. Braun, Wasleys
Belalie	27/2/1929	47	Mrs. E. Orchard, Jamestown
Gladstone	29/5/1929	28	Mrs. L. Sargent, Gladstone
Eurelia	28/8/1929	18	Miss M. Stott, Eurelia
Auburn	28/8/1929	26	Miss L. Dennison, Auburn
Goode	28/8/1929	7	Mrs. P. Lange, Goode, *via* Ceduna.
Wirrilla	27/11/1929	20	Mrs. W. R. Jones, Auburn
Parilla Well	21/9/1930	25	Mrs. J. Johnson, Pinnaroo
Nelshaby	30/4/1930	17	Miss T. Franks, Nelshaby
Millicent	28/5/1930	16	Mrs. H. Hutchesson, Millicent
Parilla	30/7/1930	30	Mrs. A. Welden, Parilla
Warcowie	27/9/1930	9	Miss L. Martin, Hawker
Parrakie	29/10/1930	10	Miss J. Halliday, Parrakie
Penola	24/6/1931	59	Mrs. F. Kidman, Penola
Tantanoola	28/10/1931	16	Mrs. E. Telfer, Tantanoola
Clare	25/11/1931	38	Mrs. A. Pollock, Clare
Yurgo	27/1/1932	11	Mrs. Sanders, Yurgo
McLaren Flat	30/3/1932	29	Mrs. B. Powell, McLaren Flat
Warramboo	27/4/1932	16	Mrs. A. Steer, Warramboo
Balumbah	27/7/1932	16	Miss H. Jericho, Balumbah
Pygery	31/8/1932	14	Mrs. J. Heylen, Pygery
Mangalo	31/8/1932	13	Mrs. F. Coles, Mangalo
Rendelsham	30/11/1932	15	Mrs. Z. Bignell, Rendelsham
Coonawarra	30/11/1932	32	Mrs. F. Skinner, Coonawarra
Mundalla	25/1/1933	22	Miss M. Fisher, Mundalla
Kybybolite	22/2/1933	36	Mrs. W. Kekwick, Kybybolite
Morchard	31/5/1933	17	Mrs. C. Schulz, Morchard
Laura Bay	28/6/1933	21	Mrs. R. Burke, Ceduna
Taplan	28/6/1933	29	Mrs. W. Flynn, Taplan
O'Loughlin	25/8/1933	14	Mrs. A. Pfeiffer, Ceduna

A total of 50 Branches with a membership of 1,108.

An examination of this table will show that during the period covering the years 1917 to 1926, inclusive (10 years) only eight Branches were formed; in the next 8½ years (1927 to June, 1935), an additional 42 Branches had been approved by the Board.

It is particularly gratifying that, in every instance but one, regular meetings with good attendances are reported. It is also worthy of note that at several centres the formation of a Women's Branch has been the means of reviving Men's Branches that were in danger of being closed.

Perhaps the outstanding feature is the success that has accompanied the Branches that have been formed in the larger country towns, such as Pinnaroo, Jamestown, Gladstone, Millicent, Penola, and Clare. In more than one quarter the opinion was frankly expressed that with the large number of social activities and other women's organisations already in existence, the Bureau would be looked upon more or less in the light of a new toy, that would perhaps be regarded for a few months as a novelty and then gradually cease to function. That the reverse has been the case is borne out by the Annual Reports of the Secretaries, and it is not unusual for them to record a year's work, during which 12 meetings and sometimes more have been held, with an average attendance of between 40 and 50 members and visitors.

There is not the slightest doubt that an active Women's Agricultural Bureau is an acquisition to any rural district and the General Secretary, c/o the Department of Agriculture, will welcome inquiries concerning the formation of a Branch in any district of the State.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

DAIRY CONFERENCE.

Despite a rather disappointing attendance at the Annual Dairy Conference held at Mount Barker on May 9th, the general opinion of those who attended was that the Conference was of a very instructive nature, particularly so far as the discussions which followed the reading of the papers was concerned. Mr. E. A. Hunt, Chairman of the Mount Barker Branch, presided, delegates being present from Auburn, Saddleworth, Lyndoch, Adelaide, Jervois, Longwood, Ironbank, Hartley, Mount Compass, Milang, and Mount Barker. Messrs. P. J. Baily and F. Coleman (Members Advisory Board of Agriculture), H. B. Barlow, H.D.A. (Chief Dairy Instructor), R. C. Scott, R.D.A. (Supervisor of Experimental Work), R. Hill, R.D.A., P. H. Suter, D.D.A., H. J. Apps (District Instructors), H. C. Pritchard (General Secretary Agricultural Bureau), and F. C. Richards (Assistant Secretary), attended on behalf of the Department of Agriculture. Mr. P. J. Baily delivered the opening address. The following papers were read and discussed:—"Some Dairy Home Truths," J. Hudd (Adelaide); "The Powers of the Federal and State Government with regard to Interstate Trade," J. Yelland (Milang); "The Development of the Dairy Industry in Denmark," L. M. Hansen (Mount Barker). The following resolutions were carried:—"That the 1936 Conference be held at Strathalbyn"; "That the Government be asked to establish a fund from a levy taken on the sale of all pigs to compensate for all pigs condemned"; "That a fund be organised for compensation for tuberculosis and pleuro-pneumonia for dairy cattle up to two-thirds of market value"; "That we view with grave concern the serious effect margarine and all butter substitutes are having on the dairying industry, and that we urge both Federal and State Government to take immediate action to enforce at least 6d. per lb. levy on all butter substitutes manufactured in competition with dairy butter." Mr. P. Wise, of Mount Barker, capably carried out the secretarial duties of the Conference.

The Conference concluded with a social, at which delegates and visitors were entertained by the Mount Barker Branch.

PAPERS READ AT CONFERENCES.

THE FALL IN WHEAT.

[L. R. ROBINS, Saddleworth.]

Probably very few farmers in the State to-day need to be told that there has been a fall in wheat prices! Need they be told also that the wheat has fallen from grace on account of a falling-off in quality? The causes of the fall in price are many, including the carrying over of supplies until the accumulation is more than burdensome; the policy of encouraging home-grown wheats where the country is usually a big importer; fiscal problems and financial difficulties; and one fact not to be overlooked in South Australia is that with the lower quality wheats the demand has further fallen off, and the price is undoubtedly lower.

At a time when business is low we should cultivate every demand for our goods. We must create further demands for our wheat. Quite recently a deputation of British millers requested Canada to send *more* hard wheats. We all wish that they would ask Australia for more! Why do they not? The fact is that our wheats at one time held a name for colour and "blending quality." The demand for colour is not so insistent now, because it can be overcome more or less by artificial means, and it is met by the flood of weaker, softer wheats grown nearer home—which wheats have also come into competition with ours in blending, so that whereas a few years ago our wheats demanded a premium, now they are not wanted to the same extent, and the price has sagged considerably. This is a vitally important fact which is realised by those who in any way control the breeding, the production, and the marketing of Australian wheat, and it is one which vitally affects every farmer.

Owing to past methods of breeding and marketing our wheats, the struggle has been for quantity, and quality has been neglected, and this position has been accentuated by the present economic depression. But the time has come when every farmer should take a longer view, or we will be faced with the extreme difficulty of regaining lost markets. With concerted action in the direction of improving quality, not only should the price rise, but the demand for our wheats should increase and there should be a readier sale.

How is it that our wheats have deteriorated, and what does that mean? Except for a very small percentage of wheat which goes for feed for birds and animals, the great bulk of wheat is put on the market with the ultimate objective of making bread—and yet authorities are now openly saying that some wheats yield flours which are admirably suited for making high quality bread, whilst others are quite unsuitable for this purpose.

In the course of a brief discourse it is not possible to give details of how wheat is turned into flour, and how that is turned into bread, but the following short outline will show where the present-day wheats are largely failing. In the first place, wheat is a berry. It contains a starchy centre enclosed in a skin. That skin represents the bran and pollard. The centre of the berry consists of starch, sugar, and protein material. This centre becomes the flour in milling. Of this flour, about 90 per cent. is starch which forms the bulk of the loaf; the sugar assists the fermentation which causes the release of gas and makes the dough rise, with the consequent bulk of the loaf; and last, but most important of all, the protein material gives rise to *gluten* in the dough which holds the loaf together and gives it the texure and crumb.

This is the overshadowing property in baking at the present time. Gallipoli has been milled with as low as 4 per cent. gluten content, whereas many other wheats show 10 per cent. Besides this, the quality of the gluten is very poor in that variety. The complaints against the serious lack of quality gluten in present wheats are not confined to the home consumption of flour and wheat, but very strong representations have been made from overseas for stronger consistent flours. Just at the present time the demand from the Orient is the salvation of local wheat prices, and there is quite a good export trade in flour being built up. But the ever-increasing demand is for

stronger flours, which must of necessity compete with the United States of America and Canada, who have flours with high gluten content. We are placed next door to these potential markets, and if we can meet the requirements we hope to get the orders; but quality must count, and the organisation of other countries is carried to far greater limits than we can hope to attain. Besides this, modern transport has made it easier to carry goods quickly and easily to greater distances—it has brought markets nearer to those further away, if only they have the goods to supply, and if we cannot meet the demand while it is there, others would do so. Argentino has already standardised their wheats and thrown out the very weak ones. Even Egypt, who years ago had to be satisfied very often with very poor quality flour, has now legislated for a 12 per cent. gluten. This has since been lifted, but it shows the unmistakable trend.

Some of our wheats almost consistently give low test figures. Soil and climate may alter the quantity of gluten in many cases, but generally speaking, the hereditary constitution of any variety chiefly governs the quality, so that by growing an approved variety this should tend to check the drift in quality.

It should be pointed out that a weak wheat is not only unsuitable for milling for bread by itself, but when it is blended with a hard wheat to build up the strength the astounding position is that the weak wheat pulls down the strength of the blend much more than would be expected. For instance, I quote a test made by the Roseworthy College, where a 50-50 blend was made with Carrabin (test figure 121) and Waratah (test figure 30). The average of these figures would be about 76, but in actual practice the blend gives a test figure of 49. This means that through using Waratah a miller would have to use a similar quantity of Carrabin, if he had these two wheats, in order to build up his flour to a strength which would be marketable. From tests made it appears that this position is not so bad where the weaker wheat has a reasonable strength and is not of such a low figure—that is, a soft wheat which has a moderate test figure does not lower the figure of a hard wheat, when blended, in such an astounding proportion as in the case given above. This should show the magnified danger of growing a very weak wheat.

How to Improve the Quality.

We have a somewhat reassuring possibility of being able to improve strains in many varieties which are already grown, resulting in a better wheat with practically the same yield. Unfortunately it takes eight years to fix a new variety, so that except for new wheats which are already being fixed, we cannot look for a very quick alteration from that direction. However, Roseworthy College has some very promising strains tested over three years, while New South Wales came earlier into the field, and besides releasing Dundee with a splendid reputation for yielding and milling, they expect to have some more lines to put out in the next few years. We all hope that the efforts of wheat breeders will be the means of getting us out of the wood, and we can look forward in the immediate future to raising the standard by increased sowings of such wheats as Dundee and Carrabin.

In the meantime, we cannot too strongly recommend all farmers to grow a percentage of "hard" wheats, and to drop the very weak ones and replace with others which, if only of moderate quality, give a reasonable yield and do not reduce the standard below its present low level. We do not want an indiscriminate sowing of any one particular variety, because the farmer must try and find out a suitable wheat for his district, and if he has no experience of growing hard wheats in his district he should grow a percentage first. But for goodness sake grow *some* good wheat, because you must all realise that it is ultimately going into bread, and the demand for quality is still growing, while the competition in marketing wheat is likely to be even more keen.

There has been quite a number of artices published in agricultural journals and other papers on this subject, and it should not be necessary to stress the position any further. We are fortunate in having men in the Agricultural Colleges who have foresight and ability, and a desire to improve the standard to which our wheats have fallen. They

[*Papers Read at Conferences.*]

are working arduously to select strains within varieties, to maintain or increase the yield, and to bring out new wheats which will meet with success from both the farmers' and millers' points of view. Roseworthy College has already tested over 5,000 crossbred strains, and they have some 10,000 more tests to do yet. The magnitude of the work shows that they are fully seized with the importance of the results, and I urge every farmer not only to make an endeavour himself to follow this lead, but to impress the position on all farmers in his district. The work of our Colleges can only meet with full benefit if the farmer in his turn takes a hand in the matter.

A deficiency of sugar in wheat can be remedied, but millers cannot put gluten into flour if it is not in the wheat.

MANAGEMENT AND CARE OF THE FARM TEAM.

[R. H. EIME, Blyth.]

The mainstay of almost every farm is its team of horses, and with a little care and good management in the way they are fed, in the stable, in the team, in the manner they are trained or broken in, and the attendance to their general health, they can be a team of good appearance and temperament, and be admired by many a passer-by.

STABLING AND GROOMING.

The stabling of the team is to be considered. It must provide good shelter and at the same time be well ventilated. A stable with an open front facing the south is preferable. The situation should be such as to allow of good drainage from the stable and also the yard, a badly drained stable and a boggy yard being a menace to the health of its occupants. The managing of the horses in the stable is made easy if every horse has its particular place, and is tied up—especially for the morning and midday feeds. The practice of tying up is by far the best, and has many advantages over other systems. Every horse learns to know its place, and will go to it at a word from its master. This system also has the advantage that every horse will get its share of feed, and not be bossed from one end of the stable to the other by one or two unruly horses. The harness can be hung on a peg at each horse's place, and saves the necessity for running around the yard with a pair of winkers for a particular horse, or leading them to the harness-room. Not only does this method save one's own energy, but it teaches the horses to be quiet. Each horse should be thoroughly brushed and groomed before going to work; do not brush just the shoulders alone, go all over the animal, removing any sweat from the previous day. The little extra time involved is made worth while. It enhances the coat and helps to prevent them from rubbing one against the other in the team. When grooming, always speak to the horse before touching him; it may save you getting many a nasty kick—no matter how well horses are trained they do not like another horse interfering when they are feeding or resting, and the horse, feeling you touch him without speaking, may kick without realising it is not another horse. A straw stack near the stable may save a great deal of time when grooming, but do not let the straw stack do it all. A straw stack can also provide some shelter and warmth of a winter night.

The position of the water trough needs consideration. On no account should it be in the stable yard. It should be at least 2 or 3 chains away, situated where the horses pass it going to most of the paddocks. The advantage of having the trough as far away as it may seem is that the horses will not reach the trough with a mouthful of feed, as would be the case if it were in the yard. The dropping of food in the water is most objectionable and quickly contaminates the water, which may give rise to many stock ailments, especially if the trough is never allowed to become empty, as is the case with an automatic ball tap.

FEEDING.

The appearance and condition of the team depends very largely on the way they are fed, the amount given them, the time allowed for eating, and the quality of the feed. Always allow them time to eat first—1 hour at the morning and midday meal. A good measure for chaff is an old carbide tin; this is sufficient for two horses for one feed. At the evening feed they may be given three parts of a bin each, and overnight a bin

to four horses, plus a sheave of hay each, or if a paddock of greenfeed is available, they may be turned out over night; but always give a good feed of chaff before doing so if the horses are to work next day.

To the rations of chaff I have mentioned crushed grain—never whole grain—may be added, the amount depending upon the quantity of grain in the chaff and the work the horses are doing. Of crushed grains, I prefer barley, but oats are cheaper, and a crop of oats is advantageous to the land and at the same time provides grain for the team. For horses doing heavy work, such as seeding and ploughing, and fed on fair quality chaff, a half kerosene tin of crushed grain per horse per day can be fed with safety. The chaff fed should always be wholesome; it is not worth while to risk feeding that little bit of chaff that may have become hot through dampness, or even to risk putting an occasional mouldy or mousey sheaf through the cutter when chaffing: the result may be the loss of a horse or an ailing horse for a day or so.

GENERAL MANAGEMENT.

In the team careful management must be exercised. Have the team arranged so that it is easily handled, do not work more than nine horses abreast, except when harrowing, but for a team above that number use a tandem pull, and most certainly use the roller and chain type of equaliser. Be careful not to overload the horses. It is far better to put in an extra horse or two and have them walk along, than have the team straining. If a horse is inclined to be fast do not penalise him by tying his swingletree back to the main spreader or the implement, but give him a longer pair of chains. On the other hand, should a horse be slow the traces may be shortened. If a horse becomes slow, there is usually something wrong, an ill-fitting collar, tender feet, or some internal ailment, and the driver should find out what is wrong, otherwise the slowness may become a habit, and horses are prone to habits. The use of a whip on the team is not warranted; a well cared for horse does not need a whip, and the need of a whip reflects neglect for the horses on the part of the owner or driver.

Sometimes it may be found after the team has not worked for some time, that they may be inclined to be very free for a few rounds of the paddock, in this case do not let them go in the hope that they will steady down, but give them an occasional spell, and they will settle down to their usual gait in a very short time. On no account, allow the team or part of it to trot around a corner, it may result in them stepping on one anothers' feet, and it is not in the best interests of everything concerned if any of the swingle-trees should break. Be careful in the manner in which the reins are handled, a steady pull is all that is required. Jerking the reins only excites the horses, teaches them the nasty habit of throwing up their heads—not only one horse—but the whole team, and makes them generally hard to guide.

When finishing the day's work have the horses in the stable by sunset: it is better to have them out ½ an hour earlier in the morning than to come home after sunset, wet with sweat. Some drivers make a practice of allowing the horses to run home loose after the day's work; this may be in order providing they do not trot; if they are inclined to do this, drive them home, serious trouble may result to mares in foal through neglect in this manner.

TRAINING.

The "breaking in" or preferably the training of the young horses is important in the behaviour of the team. I prefer to use the term training instead of "breaking in" because farm-bred horses are not outlaws; they can be trained without any breaking process. Start to train the young horse for work at about 2½ years old, and do not make pets of foals, it spoils them for when they are ready for work. When they are handled they expect to be petted and the training may be a longer process than is usually the case.

When catching the 2-year old for the first time, try not to excite him; run him into a loose box if one is available, and with the aid of a pole, slip a lassoo around his neck, using a good strong rope, snubbing it around a stout post, and allow the horse to pull back but not choke down. Make a knot in the lassoo rope so that it does not pull too tightly and thus choke, but at the same time it must be tight enough to prevent the rope from slipping over the ears or its head, and on no account must the young horse get away once it is caught. Having a good pull on the rope will teach him to respect the rope, and after that first pull it is seldom he will try the strength of a rope again. For the first 2 or 3 days he should be taught to lead and stand, lift up his feet occasionally; it all helps to make a quiet horse.

The first time in the team, put him in the body of a tandem team on the near side, on pulley equalizers, with a good strong rope around his neck and tied to the spreader of the leading horse, a leading rope tied to the bit is advisable in case the harness is not as strong as it was thought to be. Hitching in the team, the young horse must take its share of the load, and respecting the rope he will not pull back to any extent, and he soon learns to walk along with the other horses. Be lenient with him; a couple of hours the first day is sufficient and gradually lengthen the time, and for the first 6 months if it is possible, only work him half days. It is not advisable to let the young horse into the main stable for a fortnight or so; it is much better to keep him in a loose box and tied up while feeding. After he has settled down he may take his place and be tied up in the main stable and then let run with the other horses, not forgetting to put a halter on him. This will help to avoid any trouble in catching him the next morning, and if tied up always in the same place, he will be like the other horses and soon learn which is his place. The main point in training is to teach the horse to obey commands, but at the same time not to be frightened of you and not to tremble when approached. A cool temper and patience exercised on the part of the owner will result in the training of a horse free from vices and of a good nature.

To keep the farm team healthy a certain amount of attention is required. If an animal contracts an illness call the vet. immediately. Give every horse a stable physic ball once a year, accompanied with bran mashes; just before seeding operations commence.

[*Papers Read at Conferences.*]

My reasons for this are that in all probability the horses are not working, or are on very light work, for when given a ball they should be spelled for a day or so, because the aperient affect has a tendency to weaken the animal for a short time; also they have been in the stubble paddocks for the previous months, and this is a suitable time to cleanse their systems; the horse will do better and improve his condition. If, the administration of a physic ball necessitates the calling of a surgeon, at the same time have the teeth of every animal examined; a horse with faulty teeth is rarely in good condition.

When starting to feed new season's hay it is advisable to mix it with old hay, half of each, and watch the horses carefully—new hay may bring about colicky pain in some horses, others it may affect in different ways.

The shoeing of farm horses is not a general practice, but do not neglect their hooves. Keep them well trimmed, using a saw, rasp, and if needed, a paring knife; cracking and splitting can in this way be prevented. Occasionally a horse may have to be shod when wheat carting or working on stoney land.

Sore Shoulders.

Sore shoulders are caused mainly by ill fitting collars. The collar may be too small or too large, or the harness poorly adjusted, but usually the relining of a collar is a sure remedy. Do not wait until a horse has a sore before having the collar relined. The check lining may be in good order, the collar hard and flat, if so have it relined. At times a horse has a tender shoulder and is prone to sores; but the saddler, will line the collar to a special shape to suit that horse. If a sore shoulder appears, and the collar cannot be repaired for a day or so, the use of a bag under the collar is helpful, but only until the collar can be repaired.

During summer, flies may cause a team to be very restless. Be considerate and provide each horses with a fly net. These can be very simply made from old binder twine, and are well worth the time taken to make them.

Once a year trim the manes and tails of the horses. It is an ideal job on a wet day. Comb out the hair with a blunt pocket knife, and the hair will pull out quite easily. With this method it can be thinned out and the tail made to look quite shapely. Usually horses do not object to this procedure, but be very careful with a mare in foal; do not trim her tail unless she is very quiet.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on May 29th, there being present:—Messrs. A. J. Cooke (Chairman), R. H. Martin (Vice-Chairman), A. J. A. Koch, S. Shepherd, F. Coleman, P. J. Baily, H. N. Wicks, J. W. Sandford, Hon. A. L. McEwin, M.L.C., and H. C. Pritchard (Secretary). Apologies were received from Professor A. J. Perkins, Dr. A. E. V. Richardson, and Mr. J. B. Murdoch.

Life Members.—The following names were added to the roll of life members of the Agricultural Bureau:—Brinkley Branch, H. D. Humphrey, A. B. Martin, and E. W. Pearson; Black Rock Branch, R. E. Kitto; Mount Pleasant Branch, E. J. Tapscott; Wepowie Branch, J. F. Burns; Mount Barker Branch, W. E. Daddow, E. P. Mappley, W. H. Cozier, and E. G. A. Tyrie.

New Members.—The following were approved as members of Branches:—Bute—Leonard H. Paterson, G. P. McDonald, J. G. Mohr, A. C. Brideson; Butler—Gilbert Wilford; Chandada—Joseph Carberry; Clarendon—Fred. Smart, Frank Mitchell; Coonalpyn—Chas. G. L. Tiller, Richard Sparnon, Alfred Chandler, Jas. O'Donoghue, F. F. Smedley, Syd. W. Smedley, Jack F. Smedley, Geo. R. Smedley, Roy Smedley, Albert Francis; Coonawarra Women's—Mrs. Frank Lynn; Goode—R. Mundy; Greenock—A. F. Giles; Mangalo Women's—Mrs. H. Olsen; Monarto South Women's—Miss D. Hartmann; Mount Gambier—C. G. Lucas, G. W. Langberg; Mudamuckla—S. D. Rohrlach, F. W. Dunstall, P. Flaherty; Narridy Women's—Mrs. J. W. Darley, Miss E. Darley; Palabie—Douglas Swanson; Pinkawillinie—G. C. Wake; Pinnaroo—Glen. M. Hawthorne, Alan D. Hawthorne, Les. Sheldon; Roberts and Verran—I. C. Cowley; Springton—A. N. Colebatch; Sandalwood—H. G. Neindorf, B. J. Curtin; Warramboo Women's—Mrs. O. M. Bayly, Miss L. E. Helberg; Wasleys—Harvey Venning, Gerald Ronan; Wasleys Women's—Mrs. H. Nield; Wirrabara Women's—Mrs. I. J. Harding, Mrs. B. A. Tucker, Mrs. J. Rafftry, Miss Rose Raffrty; Wirrilla Women's—Mrs. A. Woods, Miss E. Bauer; Wudinna—Martin Grocke.

Members of New Branches.—Whitwarta—F. J. G. Collins, Jack Kostera, P. P. Kostera, L. Kostera, H. L. Wachtel, W. Dunow, sen., W. Dunow, jun., E. W. Wilson, W. H. Hoepner, J. P. Hoepner, R. E. Maxwell, J. H. Wilson, A. J. Angel, R. E. Angel, G. M. Heaslip, J. Dunow, R. Wilson; Chapman's Bore—W. Whitehead, J. P. Krollig, C. Menadue, C. H. Buller, E. Buller, R. Ackland, R. Munroe, C. Calliss, A. C. Calliss, C. H. Randell, H. Kinlough, B. Wohfiel, W. T. Burbridge, H. E. Burbridge, S. Burbridge; Carey's Gully—F. W. Sharp, J. Burfitt, L. Neighbour, E. Hart, Hurtle Badenoch, Arch. Badenoch, C. Badenoch, L. Badenoch, A. Vierson, W. Cook, T. Jarrett, T. R. White, W. H. Edwards, L. A. Edwards; Coonalpyn Women's—Mrs. M. C. George, Miss E. E. George, Mrs. C. E. George, Mrs. P. Hayden, Miss Mary Hayden, Miss Veronica Hayden, Mrs. R. V. Potter, Mrs. J. O'Donoghue, Mrs. F. F. Smedley, Miss Mary Smedley, Mrs. Syd. Smedley, Mrs. W. Videon, Miss Esther Fox, Miss Una Fox, Mrs. G. Gibbs, Mrs. W. McCracken, Mrs. R. Sparnon.

New Branches.—Approval was given to the formation of new Branches at Whitwarta (17 members), Chapman's Bore (15 members), Carey's Gully (14 members), and Coonalpyn Women's (17 members).

Branches to be Closed.—It was decided to close the Neeta, Kanmantoo, Colton, and Rosy Pine Branches.

Margarine.—Resolution, Dairy Conference, Mount Barker:—"That we view with grave concern the serious effect margarine and all butter substitutes are having on the dairying industry, and that we urge both Federal and State Governments to take immediate

action to enforce at least 6d. per lb. levy on all butter substitutes manufactured in competition with dairy butter.'' It was decided to support this resolution, and bring it under the notice of the Minister of Agriculture.

Oiling Systems on Farm Machinery.—At the April meeting the Balumbah Branch asked that encouragement be given to manufacturers to improve the systems of oiling farm machinery. Mr. Shepherd stated that unless a personal inspection was made frequently it was difficult to deal effectively with the matter. Most engines have ample provision for oiling. Colonial ploughs, cultivators, and disc implements had the best oiling systems and grease caps. Nearly all windmills had a self-oiling bath which could not be improved, and most of the latest grass mowers, cream separators, portable forge blowers, and superphosphate broadcasters had perfect systems. Sheep-shearing machinery was equipped with ball and roller bearings needing only seasonal attention. Saw benches lacked good systems; corn-grinders were well catered for; wagons, trollies, and horse-drawn vehicles were ill equipped. Alemite and alemite zerk systems could be more generally used in combines, headers and harvesters. The sheaf binder requires a better system, many being unprotected with regard to sand, a matter which needed more attention. The alemite system was favoured, but its general application was not practicable. The wick system was costly. The quality and kind of oil for each machine was of great importance. The Secretary was instructed to forward a copy of Mr. Shepherd's comments to the Balumbah Branch.

IMPORTS AND EXPORTS OF FRUITS, PLANTS, ETC., DURING APRIL, 1935.

IMPORTS.

DAIRY AND FARM PRODUCE MARKETS.

MESSRS. A. W. SANDFORD & CO. LIMITED reported on 1/6/35:—

BUTTER.—The conditions for dairying during May continued generally satisfactory, and production, therefore, is steadily increasing. London values have advanced, and this is due to the decreased shipments that are going forward from both New Zealand and Australia, and a limited amount of purchasing by America of Latvia and Dutch butter is also assisting in firming values. Quotations to hand from London to-day are to the effect that choicest quality is increasing from 80s. to 81s. per cwt. Local values have receded somewhat during the month, and at present are:—Choicest creamery fresh butter in bulk, 1s. 2¾d. per lb.; prints and delivery extra. (This price is for local sale only, and, under the quota system, the equalised price manufacturers will receive will be 11d. per lb., on which basis payments to cream suppliers will be calculated). Separator lines, from 8d. to 11½d. per lb. for choicest; stores, 6d. to 8d. per lb. (These prices are subject to equalisation levies.)

CHEESE.—Fair quantities came forward from the South-East, but, under the influence of shorter supplies in the Eastern States, the market advanced sharply towards the end of the month, and values are 1d. per lb. higher than at the end of April. Production is increasing in the South-East, and in all probability the factories will commence exporting again within the next few weeks. London values for cheese are easier, owing to the heavy arrivals from New Zealand, and at present are 41s. 6d. to 42s. per cwt. for white and 41s. 6d. to 42s. 6d. for coloured. Present local rates are:—Large and medium, from 9½d. per lb.; loaf, from 10d. per lb. at store door, delivery extra; semi-matured and matured, 11d. to 11½d. per lb.

EGGS.—Under the influence of further shrinking in supplies prices advanced, but at present ample quantities are being received, and inquiry is not quite so eager. In the Eastern States markets fell during the last week of the month. Local rates are:—Ordinary country eggs, fair average quality, 1s. 2d. per dozen net; long distance rail or shipping eggs lower; selected new-laid clean eggs, full-sized, 1s. 5d. to 1s. 6d. per dozen net.

BACON.—There has been no alteration in prices. Fairly good trade is being reported in sides, middles and rolls, but hams are not in large demand. Values are:—Best quality sides, 9½d. to 9¾d. per lb.; middles, 10½d. to 11d.; heavy middles, 9d. to 9½d.; rolls, 9d. to 9½d.; hams, 1s. 1d. to 1s. 2d.; cooked, 1s. 2d. to 1s. 4d. per lb.

ALMONDS.—The demand for shell almonds is keen, and, although fair quantities are coming forward, floors are being cleared. Kernels, on the other hand, are slow of sale, and stocks are accumulating. Rates are:—Softshells and Brandis, 8½d. to 9½d. per lb.; hardshells, 5d. to 5½d. per lb.; kernels, 1s. 10d. to 1s. 11d. per lb.

HONEY.—The market continues dull, and the heavy stocks are not moving to any considerable extent. Even the temporary discontinuance of the inspection fees for interstate trade in this line has not had the desired effect of creating a demand. Values are without change, being:—Prime quality clear extracted, 2½d. to 3d. per lb.; lower grades, 1d. to 2d. per lb.

BEESWAX.—Manufacturers again purchased all available lots. Prices are steady at 1s. 4d. to 1s. 4½d. per lb., according to quality.

LIVE POULTRY.—Auction sales are held every Tuesday, Wednesday, Thursday and Friday at our sale rooms, which are in every way the best equipped in South Australia. Clearing sales arranged in any part of the State. A good demand has continued to rule for all prime quality, heavy-weight table birds. We advise consigning. Crates loaned free on application. The following are prices realised:—Prime roosters, 3s. to 4s.; nice-conditioned cockerels, 2s. 7d. to 2s. 11d.; fair-conditioned cockerels, 2s. to 2s. 5d.; chickens, lower; heavy-weight hens, 2s. 5d. to 3s.; medium hens, 1s. 9d. to 2s. 4d.; light hens, 1s. 4d. to 1s. 8d.; couple of pens of weedy sorts, lower; prime young Muscovy drakes, 3s. to 4s.; young Muscovy ducks, 2s. to 2s. 6d.; ordinary ducks, 1s. 2d. to 2s.; ducklings, lower; geese, 2s. 6d. to 3s. 6d.; goslings, lower; turkeys, good to prime condition, 8d. to 10d. per lb. live weight; turkeys, fair condition, 6d. to 7½d. per lb. live weight; turkeys, poor and crooked breasted, lower; pigeons, 3½d. each.

POTATOES.—New season's, 7s. per cwt.

ONIONS.—Brown Spanish, 8s. 6d. per cwt.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall at the subjoined stations for the month of, and to the end of May, 1935, also the average precipitation for May, and the average annual rainfall.

Station.	For May, 1935.	Av'ge. for May.	To end May, 1935.	Av'ge. Annual Rain-fall.

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator *v.* Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

LIFE MEMBERS OF THE AGRICULTURAL BUREAU.

At the May meeting of the Advisory Board of Agriculture the honour of Life Membership was conferred on Messrs. H. D. Humphrey, A. B. Martin, and E. W. Pearson (Brinkley Branch), R. E. Kitto (Black Rock Branch), E. J. Tapscott (Mount Pleasant Branch), J. F. Burns (Wepowie Branch), W. L. Daddow, E. P. Mappley, W. H. Croser, and E. G. Tyrie(Mount Barker Branch), in recognition of their having served the Agricultural Bureau for 20 years.

SOUTH-EASTERN DISTRICT.

MOUNT GAMBIER (Average annual rainfall, 30.55in.).

February 8th.—Attendance, 15.

Care of Seed.—Mr. E. S. Alcock, the District Agricultural Instructor, read the following paper:—"The greatest need in this district appears to be for more and greater care and attention to the selection of the seeds used for all classes of crops, also with regard to the annuals used for production of all kinds. This slackness appears to be universal throughout the world where good soils and favourable climate conditions prevail. The reason is probably owing to the favourable conditions. There never is any real adversity, and therefore the need for extra exertion is not necessary in order to secure some food. Some grass will grow somehow, whether the land is fertilised or not, and some crops will be harvested whether good, bad or indifferent seed is used. In examination of the rise and fall of production, disclosed by our factory returns, there is nothing to be proud of in such a fertile and favourable district as this. In other districts, where frequent adverse seasons are experienced, it has been found necessary to secure seeds of such varities as will suit those conditions. Take wheat for example. There are no varieties of wheat grown in the Commonwealth which have not been raised in Australia. A few years ago a salesman sold a good many bags of wheats from Denmark at very satisfactory prices to himself, but to-day you could not purchase a bushel of this variety locally grown at double the price, showing that it was not suitable for these conditions. The main points which suitable varieties have to maintain are as follows:—(1) Good yielders; (2) stand adverse seasons; (3) resist various diseases; (4) stand well and easy to harvest; (5) suitable for the purpose for which they are grown.

"The grower needs a variety which will yield well and give good returns of suitable produce of good sample and quality. This can be improved by the use of suitable seeds. If 100 grains of any cereal are sown, they will be found to vary very considerably, and this is where the selection of only the best will help to give improved results. This is the method adopted by plant breeders—individual selection for the improvement of the variety or breed. If we take examples of plants or animals we will find that they vary. This variation is called strain, and it is necessary to secure the best strain.

RESISTING ADVERSE SEASONS.

"In this district the need for varieties which have to stand dry seasons is not so apparent, but in the drier districts such precautions are necessary. In this locality, however, varieties are used for various purposes, such as providing early green feed or later varieties for hay or grain, or, in the case of potatoes, early ones which will be ready for digging when the old ones are done. These must possess sufficient hardiness to grow and produce prolific yields when required.

"Some diseases can be controlled by treating the seed before planting; others have to be kept under control by raising such varieies as show immunity to them. Rust and potato wilt are examples of such diseases. They can only be controlled in this manner. You have all experienced, perhaps never more so than this year, the difficulty of harvesting cereal crops that have lodged badly. Many will remember the older varieties of oats and wheat, which were much worse than many of the varieties grown to-day, but more in this direction can still be done by the selection of right strains suitable for the purpose. Very often one sees an unsuitable variety being used for a purpose, *e.g.*, many stockowners sow barley for early green feed when oats would fill the purpose much better. Early ripening varieties should be sown on the lighter lands, and the later ripening varieties on the heavier or later land. Some varieties of oats and wheat find more favour with the miller, and therefore are more readily sought after. The same remarks apply to both the barley and potato buyers.

CHANGE OF SEED.

"A change of seed seems to be the most popular method of improving all crops, not only in this district, but throughout the agricultural world. The belief is held that the continual growing of the same seed on the one farm leads to deterioration and is often spoken of as going wild. If this variety is to be kept pure and true to name seed must be secured from another area. Whenever this particular practice has been examined carefully the result is the reverse to the general belief. At Roseworthy College they have been growing the same seed of some varieties for the last 40 years and these varieties yield as well, and in some cases better than they originally did. Therefore if seed has deteriorated to such an extent that it needs replacing with fresh seed, it clearly shows that the seed has been neglected and it is not due to the continuous growing on the one farm. The same remarks apply to oats, barley, and potatoes, experiments having proved this to be the case.

"The advantages of growing your own seed are many. You do not introduce new weed seeds, neither is there the same danger of having to deal with new diseases which attack our crops, and this factor is a very great one to agriculturists.

HOW TO IMPROVE SEED.

"This can be done on the farm by those interested in this work, provided they are willing to go to a little trouble. First secure some suitable seed of a good variety, then when it is growing go through it carefully and take out all the strangers and foreign and diseased heads. This could be carried out on any farm so long as a suitable sized area was undertaken. Then you should have some seed reasonably true to name and free from other cereals. The seed obtained in this way can be sown the following year and then next year a much larger area can be hand picked, and so on until the whole area is reasonably clean and can be readily sown for seed purposes.

"The value of good seed is self evident. It means less seed is required for sowing, and good clean stands of vigorous plants are more certain. Poor seed means a poor stand, more seed is required, and weak, weedy crops result. Cheap seed is expensive and good seeds deserves a good price. Examine all seed carefully before purchasing and see that it is free from foreign weeds and seeds; thus avoid getting your paddock fouled with bad weeds.

GRADING SEED.

"Graded seed is almost unknown in this district, but since you depend a great deal on your crops for a livelihood they certainly deserve more attention than just sowing the seed as it comes from the thresher or harvester. The grader should remove all the weed seeds and also separate the largest and plumpest grains from the broken

and cracked and shrivelled ones. Grading has proved a profitable venture in all grain-growing countries and more than pays for itself. Increased crops result from the sowing of only the largest and best grains.

"Dr. N. A. Cobb, of the New South Wales Agricultural Department, tested this over a period of five years, using four varieties of wheats, and he reported as follows:—(1) The germinating power of the large seeds is greater than that of small seeds of the same variety and the same harvest. (2) Under similar conditions large seeds always give higher yields of both grain and straw. (3) The percentage of large grains from large seeds is always greater than from small seed. (4) The weight per bushel of grain produced from large seed is greater than that produced from small seed.

"The results of field experiments carried out with seed treated by grading machines make it appear as though the operation is worth an increased yield of about 2bush. per acre over and above that received from ungraded seed.

"Then allowing for the cost of plant and depreciation, loss on small cracked grain, and all payments necessary, it should not at any time cost more than 1s. per bushel to grade a bushel of grain even with the slowest machine on the market, and therefore it would not require a very great increase in the yield to pay for this extra work. Where graders are not available many men use the winnower and put their grain through several times with excellent results. Graded seed also runs more freely and evenly through the drill, which is a big consideration, as all will admit. Most of these results have been carried out with cereals, but nevertheless the same results are obtainable from potatoes.

"Perhaps one may ask, 'Why bother about these precautions with the low prices prevailing for cereals at the present time?' It is always necessary when prices are low to get your produce up well and make it attractive. Good seed of any kind commands attention and will always tempt the buyer to offer a little more." (Secretary, J. E. Morphett.)

● FULL MOON.

UPPER NORTH DISTRICT.

(PETERBOROUGH AND NORTHWARD.)

WIRRABARA (Average annual rainfall, 19.29in.).

3rd November.—Attendance, 12.

Mr. E. A. W. Harding read the following paper, entitled "Our School System and Agriculture":—"Our primary school provides education for children from 6 to 14 years of age. This is provided free of cost but is paid from general revenue of taxation. It is a debatable point as to whether a taxpayer without children should be asked to contribute for the education of other taxpayer's children. In larger schools an infant department forms a part of the school. Here much is done under the Montessori system. This plan of education was developed by Dr. Montessori of Italy and consists of much training in the form of play. Children up to the age of seven are trained by this system. The curriculum of the school, *i.e.*, the lessons to be given, is the same throughout the State. It may be argued that children of the cities need a training different from that given to rural children, but it has been found here that it is almost impossible to depart from our present plan to any advantage. The curriculum is almost identical for boys and girls; the only variation is in the manual work, as sewing is taught to girls and usually woodwork to the boys. Attendance at school from six years to 14 years within certain distances from school is compulsory by law. Children from six to seven years if within one mile of a school, from seven to nine years within two miles, and from nine to 14 within three miles are compelled to attend whenever school is open. After gaining a pass at the Q.C. Examination, students may branch off to various schools, namely, high schools, central schools, and technical schools. The high schools afford an opportunity to enter any of the professions, viz., doctors, law, engineers, dentists, science, &c. The central schools tend to a modified form of technical school having classes in woodwork, sheetmetal work, dressmaking, millinery, &c. The technical schools provide study for varying trades. The University is open to those who have passed certain subjects of the high school course. To matriculate a student is generally expected to pass the Leaving Examination. In the University various courses include medicine, dentistry, arts, music, engineering, forestry, law, &c.

It may well be asked in what way the State has provided an agricultural bias in education, since this is largely a farming community. This side of the education curriculum is being more attended to as time goes on. At present we have the Waite Institute as an adjunct to the University, and also the Roseworthy College. Only a limited number of students are catered for in these institutions. Lessons are being conducted in the majority of our primary schools where opportunity offers in elementary agriculture. The work here is more experimental than growing for profit. For instance, vegetables may be planted under varying conditions—different manures, rainfall variation, various soils, &c. These experiments prove forcibly certain facts to the boys doing the work. Boys are shown also the growth of various fodder plants under varying conditions. The better fodder plants for any particular district are thus discovered and can be grown more profusely. Certain high schools of our State also tend to an agricultural bias. Here the science of farming is more closely studied.

One of the most interesting aspects of our schools is the forming of Home Project Clubs. In these a boy or girl undertakes a particular work or project. It may be the rearing of a calf or a lamb, keeping bees, gardening, &c. The project worker aims at working for something at which he or she can get a profit. This seems a most admirable undertaking, as a boy may start with a calf and by studying the care and feeding he may later get a herd of cows and thus get a start in life as a dairy farmer. In one particular instance a lad at school started with half a dozen fowls and now at 19 years of age he is able to show a profit of about £100 a year, and has the start of a useful livelihood with an income. What is more, he is not unemployed. Another boy started with a hive of bees and now has the foundation of a very fine apiary. He also is learning the work connected with the honey at the right time, *i.e.*, when he is young. These boys get their start in life whereas others must have the stock bought for them and in these times very few are able to get that start. The project worker is expected to keep a record of the costs of his workings and to prepare a balance-sheet at the end of the year. He is thus able to determine whether there is a profit or loss on his undertaking. It is most probable that many farmers are unable to say exactly how they stand in this regard. Thus the project worker is taught the benefit of keeping proper, full, and true records of his transactions and workings. The project worker is expected to start off with as good a strain of stock as possible. He is made

to see that it costs no more to feed a cow of good breeding than to feed a mongrel; to feed 6 fowls laying 100 eggs each per year than to feed the same number laying double the quantity of eggs. But what a vast difference is the final result."

PREPARATIONS FOR SEEDING.—Paper by Mr. J. Bugg:—"If seeding is to be a success good clean fallow is essential. If the land is ploughed in August, cultivated in September and October, and cultivated and harrowed again in February and March, it should be ready for seeding in April if weather conditions are favourable. The seed wheat should be graded and pickled well beforehand, so that there are no hindrances when seeding is to be commenced. If the implements used are drawn by means of horses, the swings should all be overhauled and the chains put in pairs so as to avoid sore shoulders. A spare swing is always handy on the implement in case of any break which may occur whilst the seeding is in progress. The combine as we all know has one of the most important duties to perform, so it is necessary that the implement be in good order. In some instances it is used in fallowing as a cultivator, just filled up with the necessary seed and super, and the seeding is in progress, but this should not be. Whether the implement is used as a cultivator or whether it is put under cover after each seeding season is over, it should be thoroughly overhauled before each seeding is commenced.

The first thing to look at is the super box. All the stars should be taken out and the super scraped off, and then the bottom of the box itself should be scraped and cleaned properly, thus allowing the stars to work freely. I might mention that an old horseshoe rasp is a good tool for removing super from the stars. Next look into the grain box, which I have often noticed left half full of wheat. This, however, shows very poor judgment on the part of the driver, as he should be able to judge for himself the quantity of grain he requires to finish the paddock, thus finishing with an empty box. But if the box is not empty when the job is finished, it does not take many minutes to brush the box out when preparing for seeding again.

Next look to the cogs or chains, whichever the case may be, which drive the stars and seed discs. These, if they have been oiled, naturally get filled with grit, and should be thoroughly cleaned before the machine is put in gear for seeding. From the cogs we look to the sections and tines. The tines often get loose, especially when working

in rough country, and these, to make a good job, should be properly spaced and bolted up tight again, so that they are unable to shift. A good idea is to put them in their right position and put a chisel mark right against the tine on the section, so that if they do move at all while working, it can be adjusted in the paddock without a lot of time being lost in measuring to get it right.

The Wheels.—These with a little care do a lot of work, if the oiling or greasing is carried out in the correct manner each day. If oil is used, the big wheels should be oiled once a day, and if grease is used once every three days is sufficient, whereas the small wheels in front, if oil is used, should be done twice daily, and if grease is used once daily is sufficient.

If the combine is left out in the weather the boxes should be covered so as to keep out all dampness, and if the wheels have wooden rims, it is advisable to jack the wheels up on to stones, so as to stop the wood rotting. Of course, the best of all methods is to have a roomy shed, in which all implements could be housed as soon as their respective jobs are finished.'' (Secretary, B. W. Giddings.)

4th April.—Attendance, 20.

HOUSING OF PIGS was the subject of the following paper by Mr. T. A. Stanway:—''I sincerely think that anyone anticipating breeding and raising pigs, to obtain the best results or success should, as far as possible, have reasonable housing. I am no authority on this topic, and have not been away to see housing of pigs by any of our leading State breeders, but with what I have read and using my own ideas I will endeavour to express the method that I think should be helpful. Firstly I will deal with the beginning, namely, when a sow is brought in to farrow. The housing for this

should be a good clean healthy pen or sty, made up of stone and mortar and cemented over 4ft. high on the walls and with a cement floor. The size I recommend for the sty is 10ft. in width, 14ft. in depth, 8ft. in height at the back or western wall, and 6ft. high in the front, being a fall of 2ft. to the east for the roof, and covering 11ft. only of the pen. My reason for this is to allow for sunshine. The division walls should be 4ft. high with a railing front; the floor should have a 6in. fall for draining when hosed down. Approximately two-thirds of the way from the back to front of pen, about 8ft. or 9ft., reinforced concrete 4in. to 6in. high, with holes or drains should be made about 7ft. 6in. across the pen to hold bedding for the litter, the remaining 2ft. 6in. will act as a passage for a sow heavy in pig to come to the feeding trough, which would be placed between the concrete and front railing. The pens should have railing around three sides as far as the concrete that is built across the pen. As already stated, these should be 9in. from floor and 7in. to 9in. from wall to avoid squeezing the young against the wall. I also recommend escapes for the little pigs at the rear of the pen, so that they can go out into a small pen at the back and be fed to themselves when they take to feeding, about three to four weeks of age. This helps the little ones and also the sow, and it enables one to feed them on a ration suitable for little pigs, and the mother is unable to interfere. These little pens at the back should also have hard floors with light timber pens, about 4ft. to 6ft. in depth and 10ft. long, that is, the same size as the width of the farrowing pen. These pens should have a portion of the floor made of wood lying on the cement and movable, so that the sow and little ones could choose which to sleep on. This is essential, especially in winter. Housing of pigs in pens should be well ventilated; it is not necessary for them to be in a draught, but plenty of fresh air should blow over them, and not directly on them; especially a sow suckling little pigs, because they are tender and will more than likely catch a chill, and this is injurious to the mother and little ones. It is a good idea to have air vents in each pen about 4ft. long by 2ft. 6in. high well up over the pigs' heads, say 5ft. or 6ft. high, and reaching to the top, with flat or small-flute galvanised iron to be swung so that it should be either opened or closed with the aid of a small iron bar, according to weather conditions. This class of housing coupled with proper feeding gives quite good results. If small pasture fields are available it is desirable for the sow and young to be turned out on this when the little ones are about a month old, with a straw stack and fork uprights and straw for shelter. If pasture runs are not available, I would recommend keeping the little pigs in pens (design already mentioned) for about a month after weaning and give them a good start, and then let them into runs of several acres, where they can have free access to plenty of clean water to drink (ball-tap system) and self feeders, the feed to be under shelter from the weather.

The housing for paddock runs is a good straw stack and fork uprights covered with plenty of straw and well protected on the north and west, so that it will make good sleeping quarters and be warm during the winter months. I also think a concrete wash-pool helps to keep pigs clean of vermin where straw stacks and straw shelters are used for shelter in pig runs. Straw stacks should be burned about every two years to rid parasites, and fresh stacks built. This would help to keep the pigs healthier. Where pigs use the self-feeder, it should be placed if possible on a hard floor and well sheltered, keeping the grain ration from being dusted, also from getting wet or muddy around the feeders. It is advisable for the sleeping quarters to be some distance away from feeders in order to give the pigs some exercise. If pigs are kept under reasonable conditions and in shelters warm in winter and cool in the summer, in something like the housing I have tried to explain, it will help to give us a more profitable return for our labour.'' (Secretary, S. G. Chynoweth.)

Our Birds and Their Aid in Agricultural and Pastoral Pursuits.—The following paper by Mr. R. L. Myers was read by the Secretary:—''Many of the ills or hardships from which we suffer in our occupation as farmers and pastoralists are brought about

by the unbalancing of natural agencies, and among these agencies are the birds. It is said, and I think rightly too, that everything that Nature has brought into being has its function to perform in order to keep everything working smoothly and correctly. It is the interference by man of these laws of nature that often causes trouble. Birds are sent to act their part in the balancing of Nature's laws. Last season, many places suffered severely through the grasshopper plague. Who knows, but for the loss of many of our valuable birds such as the scrub turkey, plover, curlew, and others, through the introduction into the country by foolish unthinking individuals of that cunning and cat-like animal the fox, it might not have occurred. Reynard is not native to our land, therefore Nature did not intend him to be here. Then again man introduced the rabbit. In attempting to destroy the evil he had introduced, man has destroyed many useful birds and animals such as crows, opossums, and others, yet the rabbit, which he seeks to destroy, is as plentiful as ever, and according to late reports from northern pastoral areas, there is a grave danger that he will be the means of turning a great deal of that region into a barren wilderness.'' (Secretary, J. L. Vigar.)

WARRAMBOO.

April 12th.—Attendance, 6.

Mr. F. Chilman read a paper entitled ''A Review of the Past Year'' as follows: —''Taking last year on the whole it was very unsatisfactory from many points of view. We had early rains, a dry winter, good spring rains which were putting a good finish on a bad start. We had 5 points in January, 62 for February, 52 for March. These rains gave the weeds and grass a fair start, and that was the time when all fallow should be worked up, as working the fallow in early autumn, especially when we have early rains, tends to make all weeds germinate, as well as conserving moisture for the following crop. I am inclined to believe that too much time and working is put into fallows in this district in the spring and early summer instead of in the autumn. I admit that weeds must be kept down on fallow, but try and get sheep to do that. After any rain during late summer the fallows should be immediately harrowed, as that is when you conserve the moisture, not before summer. Seeding operations were mostly on the dry side, but with the early rains starting the weeds they were easily killed, and a fairly clean crop could be grown. During the last two years I have ploughed up some grass land at the end of the summer and worked it back at seeding time, and it has turned out as well as any I have put in. That working is against our experts' advice, so I would not advise you adopting that practice, but try a small plot. We had good rains the last part of the year which gave the crops a good finish, and although on the thin side, would have yielded well for the stubble as there was a good plump grain and good heads, but owing to a mild winter and good spring rains swarms of grasshoppers hatched out and sadly depleted the crops.'' SOUTH AND HILLS DISTRICT.

TWEEDVALE (Average annual rainfall, 35.97in.).

April 11th.—Attendance, 18.

SWINE HUSBANDRY.—Mr. L. H. Harrison, Manager of the South Australian Farmers' Union Butter Factory at Woodside, gave an address dealing with bacon curing and the care of pigs. In referring to the best type of pig to be kept, he said it was necessary to find the right pig for both the 90lbs.-100lbs. type for shop weights and also the 140lbs. pig for export. He favoured the cross from a Berkshire boar and a Tamworth sow, which produced a type of pig giving a good ham (for bacon factories), but without the thick shoulder and heavy jowl which was found in the pure Berkshire. The York was rather too thick in the head. Pigs should be allowed a large yard for exercise, but should be confined in a sty or pen for fattening. The fattening should occupy about six weeks. If concrete floors were used in the pens, a portion of the floor should be covered with boards for the pigs to sleep on, because concrete, in spite of an abundance of straw, would always be cold. (Secretary, B. Schapel.)

COOKERY AND FLOWER EXHIBITIONS.

SUCCESSFUL DISPLAYS BY WOMEN'S BUREAUX.

PINNAROO.

The members of the Pinnaroo Women's Agricultural Bureau have every reason to congratulate themselves upon the fine flower and cookery exhibition which they staged on 5th April. This was the occasion of the third annual function and proved to be even more successful than that of last year, The enthusiasm displayed in this function was remarkable, with the result that there was a very big increase in the number of entries, and much keener competition took place. The exhibition drew a large attendance, including many visitors from Parilla, Parilla Well, and other surrounding districts.

Mr. F. C. Richards (Assistant Secretary to the Advisory Board of the Agricultural Bureau) opened the show. Mrs. C. R. Mattiske presided during the afternoon.

Much praise is due to the organisers for their sterling efforts in providing such a fixture with such outstanding results. They were headed by the President and the Secretary (Mrs. C. H. Atze). The judges experienced an extremely difficult task in selecting the various prizewinners. One of the features of the display was the table decorations by girls (who are now admitted to the Branch). These were of excellent design and attracted a good deal of attention. The large array of cookery was a treat to see, while the flowers kept the gathering greatly interested. In all, the entries totalled 230, this being an increase of 96 on last year. The following were the judges:—Flowers—Miss Colwill, Mesdames A. W. Welden and C. Phillis; cookery—Mrs. A. Sands; preserves—Mesdames Johnston, Napper, and M. S. Davis.

PARILLA.

The outstanding activity of the Parilla Women's Branch is the annual Cookery and Flower Show, which this year was held on 17th April. This function always arouses very great interest, and is attended by a large number of people. Each year the number of entries has shown an increase, a record number being received for 1935. Much of the success of the show is due to the energetic committee of the Branch, particularly the Hon. Secretary (Mrs. Welden). The Assistant Secretary of the Agricultural Bureau (Mr. F. C. Richards) officially opened the show. Flowers and preserves were judged by Mesdames Atze, Fewings, and Mattiske, and the cooking entries by Mesdames Billing and Vaughan and Miss O'Loughlin. The judges spoke in very high terms of the exhibits, the preserves and some of the cake entries calling for the highest commendation. One of the judges in these classes stated that the articles exhibited would not disgrace any show in the State.

COONAWARRA.

The meeting of the Branch held on 16th April took the form of a Cake and Biscuit Competition, the entries being judged by Mrs. R. Black, of Penola. There was an attendance of 48, including visitors from Kalangadoo and Penola. The following are the recipes of the prize winners in the various classes:—*Sponge Sandwich* (Miss G. Seichleman).—4 eggs, ½ cup each cornflour and plain flour, ¾ cup sugar, 3 tablespoons milk, small piece of butter, 1 teaspoon cream tartar, ¼ teaspoon soda. Beat sugar and eggs until sugar is dissolved, add sifted flour, cornflour, cream tartar, and soda. Add warm milk and melted butter. Bake 20 minutes. *Pound Cake* (Mrs. R. Childs)—1lb. each butter, sugar, plain flour, currants, sultanas, ¼lb. each S.R. flour and peel, 8 eggs, and a few almonds. *Ribbon Cake* (Miss O. Lear).—½lb. butter, 1lb. each sugar and flour, 6 eggs, 1 cup milk, 2 teaspoons cream tartar, 1 teaspoon soda. Cream butter and sugar, add eggs, then milk, flour, &c. Divide into three parts. Flavour white with essence of lemon and pink with vanilla. Add 4 teaspoons of cocoa mixed with boiling water to the third. *Sultana Cake* (Mrs. R. Childs).—1lb. each butter, sugar, sultanas, and plain flour, ¼lb. S.R. flour, 8 eggs. *Jam Roll* (Miss D. Stafford).—4 eggs, small cup sugar, 1 teaspoon each butter and cream tartar, 2 tablespoons milk, ½ cup each cornflour and flour, ½ teaspoon soda. Boat sugar and eggs 20 minutes, add flour that has

been sifted three or four times. Stir well. Add butter and milk (boiling). Bake in a roll tin for 10 minutes in a hot oven. Roll on a damp cloth. *Biscuits* (Miss G. Seichelman.)—*Iced Dean Deans.*—½lb. S.R. flour, ¼lb. sugar. Rub into flour and sugar 4ozs. butter, mix to a stiff paste with 1 egg and a little milk. Roll on a floured board and cut into 2in. squares. Bake until lightly browned. When cold, spread a little jam down the centre of each biscuit. Ice each side of jam with 1 pink layer and 1 white, then sprinkle with cocoanut. *Chocolate Cream Biscuits.*—12ozs. flour, 6ozs. each sugar and butter, 2 eggs, 2 tablespoons cocoa, ½ teaspoon each carbonate soda and vanilla, 1 teaspoon cream tartar, 1 tablespoon milk. Cream butter and sugar, add well beaten eggs and milk, then flour, risings, and cocoa. Mix together, roll out, and cut into shapes. Join with 1 cup icing sugar, essence vanilla, and 1 tablespoon hot water and a small piece of butter. *Shortbread Biscuits.*—¼lb. butter, ½ cup sugar, 2 cups S.R. flour, 1 egg. Cream butter and sugar, add egg and flour. Mix, roll thin, cut out rounds and cut out the centre of half the rounds, making rings. When cool, join together with raspberry jam and sprinkle cocoanut on jam. *Shortbread Sandwich Biscuits.*—2 cups flour, 1 tablespoon cornflour, 2 teaspoons baking powder, ½ cup butter, 2 tablespoons warm milk and raspberry jam, soft icing. Mix dry ingredients together, melt butter in warm milk and stir into flour, &c. Mix well, roll out and cut into finger lengths. Bake to a golden brown colour. When cool join together with raspberry jam, ice tops, and sprinkle with chopped nuts. Mrs. R. Childs also read a paper on "Cake Making." (Secretary, Mrs. F. Skinner.)

THE AGRICULTURAL BUREAU.

Reading a paper on this subject at the first meeting of the Narridy Branch, which was held on 4th May, with an attendance of 23 members, Mrs. Reynolds (Vice-President) said the time was opportune to speak to members—and particularly those of the younger generation—on the benefits to be derived from a Women's Branch of the Agricultural Bureau. She held the opinion that one of its main objects was to train the future women so that they could keep abreast of the great questions of the present time. By conversation, lectures, and discussions, members would obtain valuable information and assist them to become useful and intelligent citizens. The chief reason for the increasing popularity of the Women's Branches, Mrs. Reynolds thought was due to the fact that members were united in a common interest, each member had a desire to learn, and those in a position to teach did so in a spirit of comradeship. Those members who put most into the Bureau would certainly get the most out of it. A perusal of the activities of other Women's Branches which were reported in the *Journal* would show what a wide scope of domestic activities was discussed by rural women. As in all community organizations, membership entailed responsibilities, and the most successful Branch would be that one with the greatest number of members taking an active interest in the work. (Secretary, Miss B. Reynolds.)

FEEDING CALVES.

Ten members attended the meeting of the Tantanoola Branch held on 1st May, when the following paper was read by Mrs. Wilson:—"Leave the calf with its mother for at lease 24 hours. The calf should be left 24 hours before being fed. To teach the calf to feed, run it into a corner of a shed or yard. The calf should be fed on whole milk for at least a fortnight. Half a gallon of fresh milk is sufficient for a feed for a young calf. This quantity can be given twice a day. A little salt can be added to each drink, it will help to keep the calf healthy and make it look forward to the next meal. As time goes on the whole milk can be diluted, each drink being supplemented with a small quanity of calf meal. From 10 days to a fortnight old the calf can be given the opportunity of getting a picking of green feed. If more than one calf is being handled, it is most important to see that each has a separate drinking vessel, so that those that are inclined to be "bossy" do not receive more than a fair share of milk. Kerosene tins cut in halves make very serviceable drinking utensils. The calves that are being fed should be kept apart until all danger of them sucking one another is passed. Calves that are dropped in winter should be given a little hay-chaff each day, and kept in a warm corner of a shed at night. By feeding the calves as they become older near the water trough, they will readily make a practice of drinking when thirsty. Calves should be hand fed for at least four months. When finally turned out they should be given the run of a good feed paddock which should be well fenced. Kept in a paddock enclosed with fences in a bad state of repair, the calves will soon become rogues. A supply of water to which they have easy access is most essential." (Secretary, Mrs. E. Telfer.)

SAVOURIES.

Mrs. Schmerl presided over an attendance of 16 members at the April meeting of the Auburn Branch when Mrs. B. Allen read the following paper:—"To most men-folk, savouries for lunches are more acceptable than sweets. Sandwiches are both easily and economically made, as butter and bread are not expensive. Stale cheese and scraps of meat can be utilised when mixed with tomato sauce or mayonnaise. *Sandwich Fillings.*—3ozs. shredded Kraft cheese, 1 dessertspoon butter, 1 egg, salt, cayenne, and 1 tablespoon milk. Put all ingredients together into a small pan and stir over hot water until well blended and quite smooth. Put in a jar and use instead of Kraft cheese. This can be used for sandwiches with shredded cucumber, chopped celery and walnuts, shredded lettuce, chopped olives and gherkins, hard boiled eggs, chopped candied ginger, dates or spring onions. *Rainbow Sandwiches.*—Take a square tin loaf; half or quarter according to how many sandwiches are required; cut off the crusts all round. Cut into 4 equal slices the whole length of the loaf. Spread the first slice with butter and then tomato. Butter the next slice on each side and place over the tomato. Cover this with egg and lettuce then add the third slice of bread buttered on both sides. Beetroot makes the last layer. Spread the fourth slice on one side only and place on to the beetroot. Wrap firmly in a slightly damp cloth and place under a weight for 1 hour. Then slice down with a very sharp knife. For parties, cutters may be used to cut the sandwiches into various shapes, hearts, diamonds, clubs and spades. *A Savoury.*—To 1 cup of seeded lexias or sultanas, add 4 to 6ozs. of cold minced ham, 2 to 3 tablespoons of pickled cucumbers, pickle, salt and pepper to taste. Stir in sufficient cream or mayonnaise to bind and spread easily. Serve on triangle of toast as a savoury, or serve on lettuce leaf for a luncheon. It can also be served between thin slices of brown bread as a sandwich.

Thirteen members and a large number of visitors attended the meeting of the Wilkawatt Branch which was held on 21st May, at Mrs. F. Koch's residence. The hostess read the following paper:—"To those who do not like making sandwiches—which must be dainty to be attractive—savouries should commend themselves. They are increasing rapidly in popularity for suppers and afternoon teas, because most of them can be served cold, which is a point that will commend itself to most housewives. In many recipes the foundation for the savoury mixture is short or puff pastry, cream puff cases, fried bread, toast, bubble bread, home made sao biscuit and for the one who

prefers something still easier, there are the numerous unsweetened biscuits which can be purchased. Many of the recipes for the savoury mixture include those kept in the usual household store: Sardines, anchovy paste, cayenne pepper, beet, parsely, cheese, eggs, celery, watercress, lettuce, ham, tongue, potted meats or fish, whipped cream with the addition of minced chicken, salt and mustard. All recipes are free from sugar. Another good standby is boiled salad dressing or mayonnaise. *Boiled Salad Dressing.*—¾ cup each sugar and water, 1 tablespoon each S.R. flour, mustard and butter, 1 teaspoon salt, 1 cup milk, and ½ cup vinegar. Mix dry, sugar, flour, and mustard in a saucepan, then mix milk and water with the yolks of 2 eggs added to the dry ingredients. Add the butter melted and finally vinegar and salt. Stir continually while bringing to the boil. When just on the boil, remove from the fire, allow to cool, then bottle.

Sao Biscuits.—2 cups flour, 3 tablespoons butter, enough milk to make a stiff dough; ½ teaspoon of salt will improve the flavour. Roll out very thin, then cut into shapes and bake in a very hot oven.

Puff Pastry.—2 cups plain flour, 1 cup each dripping and boiling water. Rub fat into flour, add boiling water and mix well, then stand aside for several hours until very cold. Roll and spread very thinly with butter. Fold over to 3 thicknesses, roll and spread again, with butter. Fold and roll again and a third time roll and cut into shape.

Bird's Nests.—Take round biscuits, butter them thinly and put 3 or 4 boiled green peas in the centre. Whip some cream—mixed with a little salt and mustard to taste—stiff enough to put through the icing pump. Pipe this around the outside to form a bird's nest.

Chicken Puffs.—Take ordinary cream puff pastes and fill with a mixture of cold chopped chicken, mixed with a little mayonnaise and a flavouring of chopped celery, tomato or cucumber. If preferred hot, the chicken may be mixed with a good cream sauce. Brush over with beaten egg or melted butter and sprinkle with chopped parsley.

Bubble Bread.—1 cup of plain flour, piece of butter the size of an almond, 2ozs. grated cheese, pinch of cayenne and salt, and enough water to make a pastry mixture. Roll out as thin as paper and cut into desired shape. Bake in a moderate oven. Do not cook quickly. (Secretary, Mrs. W. Pritchard.)

THE WINTER VEGETABLE GARDEN.

Paper read by Mrs. H. Schwarz at the May meeting of the Maltee Branch, attended by 10 members:—"The cultivation of vegetables in the home garden will result in a considerable saving of household expenses. Where there is a good water supply and time available to devote to their proper attention, vegetables can be grown right through the year. Cabbage and cauliflower seeds should be sown late in December or at the beginning of January. Enfield Market and Sugar Loaf are two good early varieties and for late sowings Succession and Drumhead are recommended. Early Greenleaf and Autumn Giant with Phenomenal for later crop are the best cauliflowers. The seedlings should be set out into permanent beds in February or March, choosing a cool and cloudy day for the work. A fortnight before planting, dig up the beds and heavily manure the soil. The following varieties of other vegetables are recommended:—Lettuce, New York, Beetroot, quick growing Egyptian Turnip-rooted. Later sowings—Derwent, Globe and Obelisk. Small sowings of turnips, swedes and radish should be made every few weeks; turnips—Early Wonder, White Stone and Orange Jelly; radish, Long Red and White Icicle, and Turnip-rooted. Carrots, Early Shorthorn, Ox Heart and Intermediate. A bed that has previously been well manured and carried a crop of cabbages is best for root vegetables. Land that is to be sown to Beans or Tomatoes can be prepared just a ew days before sowing. Wood ashes scattered over the beds before raking will be a help to the plants. Best results will be obtained in dry weather if seeds are sown in shallow drills, then filled with water and left for a few hours before sowing. The seeds should then be sown thinly covered with soil, keeping it moist. Lettuce can be sown in the same way and the plants thinned out to the desired distances apart. The best variety of Silver Beet is that with the curly leaf. Good varieties of Peas are William Hurst and Yorkshire Hero. Do not forget a small plot of Parsley. If enough space is available, a bed of herbs including Sage, Thyme and Marjoram should be included. No vegetable garden is complete without Onions—White and Brown Spanish are two good sorts. Celery is easily grown and if only required for flavouring, only a few plants will be necessary. Keep all beds free from weeds and the soil frequently loosened by constant hoeing. Save wood ashes and store them in a dry place until required. Soot from the stove may be forked into the land around Carrots and Onions. If the soil becomes sour through continuous cropping, dig it up roughly, scatter air-slaked lime over it and leave for a fortnight. It can then be manured again and prepared for planting. All growing plants will benefit by an occasional application of liquid manure." (Secretary, Miss L. Bassham.)

KYBYBOLITE (Average annual rainfall, 22in.).
March 19th.—Attendance, 23.

Exhibition of Pickles and Sauces.—The following recipes accompanied the exhibits:—*Apricot Sauce.*—6lbs. apricots, 4 large onions and garlic, 3lbs. sugar, 3 pts. vinegar, handful cloves, handful whole ginger, 1 tablespoon white pepper, ¼lb. salt, cayenne to taste. Boil all one hour. Strain and bottle when cool. Cork tightly. *Fig Conserve.*—4lbs. figs, 3 cups water, 4lbs. sugar, juice of 4 lemons. Boil sugar and water together, add figs and lemon juice, boil 3 hours. *Clear Mixed Pickle.*—Break cauliflower into sprigs, cucumber in pieces, or gherkins. Peel onions and leave whole, and put in a basin with a few chillies. Make a strong solution of salt and boiling water and pour over vegetables and allow to get cold. Then strain and leave to dry on sieve for 1½ hours. Then fill bottles with vegetables and pour over boiling vinegar seasoned with peppercorns and cloves. Cover when cold. *Tomato Relish.*—6lbs. ripe tomatoes, 9 large onions, 2 tablespoons curry, 2 tablespoons mustard, 1½lbs. sugar. Peel tomatoes, cut, sprinkle with salt, leave over night. Cut onion in separate bowl. In morning pour off liquid, cover with vinegar, add salt and pepper. Boil 30 minutes. *Worcestershire Sauce.*—1gall. vinegar, 4lbs. treacle, 2ozs. garlic, 1 bottle (8ozs.) anchovy sauce, 2ozs. cloves, 1oz. cayenne, 2 small handfuls salt. Put garlic and spices in a bag and boil all together for 1 hour. Bottle when cold. Ready for immediate use. *Tomato Sauce.*—12lbs. tomatoes, ½lb. onions, 2lbs. apples, ¼lb. garlic, 1oz. mace, 1oz. turmeric, 4 tablespoons salt, 1 to 1½ bottles vinegar, 3lbs. sugar, 6 chillies, 2ozs. whole ginger, 2ozs. allspice, 2ozs. peppercorns, ¼oz. cayenne pepper. Boil 3 hours, strain and bottle. *Plum Sauce.*—Take 3lbs. of plums (dark), 1½lbs. sugar, 1¼ pints vinegear, 1 teaspoonful salt, ½ teaspoonful cayenne, ¼ teaspoonful cloves, ½ teaspoonful of ground ginger. Put the vinegar and spices on to boil, add fruit, and keep boiling steadily until nice consistency. Strain through colander. Put in dry bottles and cork securely. (About 2 hours to cook.) *Ripe Tomato Chutney.*—12lbs. tomatoes, ¼lb. salt, 3lbs. sugar, 1½ onions, 4 apples, ½oz. cayenne, ½oz. cloves, ½oz. allspice, 1½ pints vinegar. Peel tomatoes, boil until soft with the onions and apples. Cut up finely, then add the other ingredients and boil 5 hours. Bottle when cold. *Preserved Meat.*—Cut some cutlets from a leg of mutton. Roast them in the oven until nicely cooked. Have ready some stock or gravy. Mix ¼oz. gelatine to 1 pint stock. Fill the bottles with the meat and stock. Put on rings, covers, and clips; then put in sterilizer and bring to the boiling point (200 deg.). Let stand at that for ½ hour; lift out and stand aside for 48 hours, then repeat. Bring to 200deg. for ½ hour. Do not remove clips until after the second sterilization. *Tomato Chutney.*—6lbs. tomatoes, 2lbs. onions, 1 or 2 apples, 1 cup treacle, 1oz. whole ginger (bruised), 1oz. cloves, ½ teaspoonful cayenne, 1lb. sugar, 1 pint vinegar. Cut up tomatoes and onion, sprinkle with salt and let stand over night. Strain off liquid and put in preserving pan with all ingredients. Put ginger and cloves in muslin bag. Boil for ½ hour. Then thicken with 2 tablespoons of cornflour, mixed with cold vinegar. Allow to boil for a few minutes, then remove from the fire. Bottle when cold. *Tomato Relish.*—10lbs. ripe tomatoes, 1½lbs. apples, 1½lbs. onions, ½lb. sultanas, 3lbs. sugar, 1 quart vinegar, ¼lb. salt, 1oz. cloves, 1oz. ground ginger and allspice, ½oz. cayenne. Boil tomatoes in pan for 1 hour. Strain through sieve and put spice, &c., in muslin bag. Mix all ingredients and boil ½ hour. *Tomato Pulp Soup.*—Take 12lbs. of firm, ripe tomatoes, 4 sticks celery, 1 cup sugar, and 2 large onions. Cut up roughly, place in preserving pan (enamel) with 1 teaspoonful salt to each pound of tomatoes. Boil slowly 25 to 30 minutes, until all juice is out of them, and strain and measure. To each quart of pulp add a level teaspoonful of carbonate soda and boil 5 minutes. Bottle boiling hot in preserving bottles with glass lids and put into sterilizer. Bring to 180degs. and drop back to 160degs. and keep there for 1 hour. This may be thickened before bottling if liked. Have the water in the sterilizer a little more than warm when placing the bottles in it, in order to avoid breaking them. This recipe makes sufficient soup for 16 persons. (Secretary, Mrs. W. D. Kekwick.)

LAURA BAY, April 9th.

Hints.—Paper by Mrs. J. Blumson:—1. Equal parts of glycerine and methylated spirits mixed together and rubbed well into the feet, morning and night, will banish corns, callouses, and even bunions, if persevered with, and fatigue will disappear. I found castor oil cured callouse on soles of feet, and after four years they have not reappeared. 2. When plucking a fowl add ½ teaspoon washing soda in the water in which it is scalded. The feathers will become so loosened that the labour of plucking will be minimised. 3. When cooking anything with an onion in it always add a teaspoon of sugar. This prevents the onion from "repeating." 4. Mix dates with your favourite jam, and a little dessicated cocoanut, and you will have a delicious filling for tarts. 5. Cabbage water should never be thrown away, as it contains valuable mineral salts. If not wanted for soup, use it for making gravy. 6. Use half milk and half cream in mixing a butter sponge cake. It makes the sponge twice as nice. 7. The healing properties of mutton fat cream, so often recommended for chapped hands, are enhanced by the addition of 1oz. Friar's balsam to each 1lb. of fat. Add balsam when

the mixture is just about to thicken, then stir in thoroughly. 8. When frying tomatoes, add a little sugar and a pinch of carbonate soda. 9. Cook "seven-year-old" beans with lid off the saucepan, and they do not lose their usual green colour. 10. To remove iron rust from cotton goods, dissolve 1 dessertspoon of cream of tartar in 1 quart of water. Put in the articles, which should be well washed and still wet, and boil till rust is removed—probably half an hour. 11. When using preserved eggs, always break the shells near the pointed end. The yolks are less likely to break. 12. Leave a thread in a needle when the latter is pushed into the pincushion. The needle will be less likely to slip through the cover, and should it do so, it can easily be pulled out by the thread. (Secretary, Mrs. R. W. Burke.)

O'LOUGHLIN.

March 21st.—Attendance, 12.

A collection of 3d. per nominee was taken for the purpose of providing prize-money for a competition on "Useful Household Hints," to be judged at the next meeting. Miss T. Hasting read a paper, "Home Nursing," in which she stated that since the depression many people could ill afford to pay a doctor's consultation fee or to pay for patent medicines. As a result in many cases very simple home remedies had been tried with excellent results. Great precautions should be taken to avoid all germs in the case of an epidemic. That could be done by means of lysol baths; also by dabbing the hair with lysol and thoroughly washing the hands. Germs could easily be killed in a home where there was an infectious case. The house should be fumigated by burning sulphur in the rooms, all windows and doors being closed and all ventilators and fireplaces blocked. Fireplaces could be closed by gluing a large piece of paper in front of each. An old bucket or piece of tin with some burning coals in it could be placed in the room, and about ½lb. of sulphur sprinkled on the coals. This should be left in the room for at least two hours, and would kill all germs. A simple way to check the spread of germs in a house was to saturate old rags with phenyle, and hang them over doors, windows, beds, and any other furniture. During the summer months, or after a long dry spell, all water should be boiled and only cold water drunk. Where a patient was very sick and refused food, the only strengthening and nourishing food was barley water. Where the patient could eat, the breakfast should be of light and digestible food, such as milk foods or stewed fruit, an egg lightly boiled or poached, or steamed fish with a little bread and butter. The mid-day meal could include clear broth, ample fresh green vegetables, a little grilled or roast meat and stewed fruit or egg custard. For the evening meal steamed chicken, brown bread and butter, a glass of milk and fresh fruit were recommended. In a case of diarrhoea, the patient should have only plain food, barley water and milk. If the milk was scalded, it should be only sipped, because drinking it fast often caused it to curdle into big lumps and so cause constipation. In cases of bleeding throats or any internal haemorrhage, only ice-cold drinks and ice-cold soft foods should be given, since the ice would chill the wound and clot the blood. *Simple Home Remedies.*—Severe nose bleeding could be stopped by placing a piece of butter on the head and then a cold wet cloth over the butter. The remedy had never been known to fail, even with the worst attacks. When a child or adult experienced the first symptoms of a cold or of influenza, immediate treatment should be given, in the form of a hot mustard foot bath, 2 aspirin tablets, and a hot lemon drink to which an eggcupful of rum or brandy had been added. If the throat was sore a cold compress should be applied to the neck and covered well with oiled silk and cotton wool. The patient should remain in bed for two days and be kept warm, in a room which was well ventilated. If the patient was restless, an onion sandwich or an onion inhaled would often produce sleep; lettuce would answer the same purpose. A good laxative for children was a warm drink sweetened with brown sugar. Another simple remedy for constipation in bottle-fed babies was to sweeten the food with a little golden syrup instead of sugar. A distressing cough could often be relieved by taking a tablespoonful of hot lemon and honey; if lemons were not available, vinegar would answer the same purpose. Pure lard was one of the best things to use in cases of burns and scalds; several applications would heal the wound. Sprains of similar swellings should be bathed frequently with hot salt water and massaged with methylated spirits and olive oil. (Secretary, Mrs. E. R. Pfeiffer.)

BOOR'S PLAINS (Average annual rainfall, 15.6in.).

April 4th.—Attendance, 20.

BUTTER MAKING.—Paper by Mrs. G. E. Rodda:—During the making of butter cleanliness is the most important part of the process. The hands should be washed before milking, also cows' teats. All dairy utensils must be kept very clean with soda washings. Always rinse in scalding water; put buckets and separator out in the sun—an excellent germ killer and sweetener. Before separating put through a little hot

water. Always turn the separator at the same pace; if not you will get different tests. Do not mix hot and cold cream together. You must wait until it has gone cold, then mix and stir all. Keep cream in a cold, draughty place. To have good butter, cream should be made into butter while it is fresh—allowing for weather conditions, about twice a week. Fairly thick cream gives the best results. Put salt with the cream into the churn at the rate of 1lb. of salt to every 10lbs. butter. Of course salting is a matter of taste. Work it until it reaches the crumbly stage. Add 1gall, or so of cold water. Work again, pour off, and repeat until the water is quite clear. Put in more salt if needed. The butter is then ready for pounding. Allow 1oz. to every pound of butter for shrinkage. An easy way to cover butter with paper smoothly is to dip the butter-papers in cold water before wrapping. (Secretary, Miss L. Stanway.)

PARILLA (Average annual rainfall, 14.01in.).

March 20th.

The subject of the meeting was "Vegetable Salads." The following recipes were collected:—*Carrot Salad.*—½lb. new carrots, 2 or 3 spring onions, 1 lettuce, 1 egg, mayonnaise sauce. Boil some new carrots. The number depends on size, but aim at about ½lb. in weight. Then place them on a dish to drain and cool. Skin, top, and tail the spring onions, and choose the best leaves of a cos lettuce. Boil the egg hard and wait for it to cool. Next slice the carrots, spring onions, and lettuce leaves, and blend with mayonnaise sauce. Put in a salad bowl and garnish with sections of hard-boiled egg. *Cabbage Salad.*—¼ heart of cabbage, 2 apples, 1 teaspoon capers, 1 tomato, 1 cooked potato, few lettuce leaves, mayonnaise sauce. This is an "All British" recipe, suggested by the Empire Marketing Board. Slice the potato, apple, and tomato. Shred the cabbage, pour over the mayonnaise, add the capers, and blend thoroughly. Serve on a bed of crisp lettuce leaves and decorate with half-slices of tomato. *Parsnip Salad.*—3 or 4 parsnips, parsley, salad dressing, 1 beetroot. Use cold cooked parsnips and similarly with the beetroot. Slice both and sprinkle with sprigs of parsley. Make a salad dressing of equal quantities of salad oil and vinegar. Mix with a spoonful of dry mustard and add a little pepper and salt. This salad is admirable when served with cold boiled meat and poultry. *Asparagus and Lettuce Salad.*—1 bundle of asparagus, mayonnaise sauce, 1 egg, 1 or 2 lettuces. First boil the egg hard and set it aside to cool.

Then cook the asparagus. When it has been cooled down, remove the portion of the stalks which cannot be eaten. Pick over and wash the lettuces. Select the light, crisp leaves and spread them on a dish. Arrange the asparagus on them and pour the mayonnaise sauce over them. Cut the hard boiled egg into sections, one for each person, and place them on a dish. It is not a bad plan to arrange the salad on several small platters, one for every person at the meal. *Bean Salad.*—Boil some French beans in salted water, cut in pieces, and garnish with tomato and parsley. Pour over boiled salad dressing. *Orange Salad.*—Cut some oranges in thin slices, also some onions. Arrange in dish and garnish with celery. Pour over French salad dressing. *Green Peas and Almond Salad.*—2 cups cold green peas, 1 cup of shredded blanched almonds. Fill cups of lettuce leaves with them, and pour on top a little American salad dressing, on top of which shred a very little finely chopped mint. *Waldorf Salad.*—Cut the apples after paring and coring in thin slices, and shred; add equal quantity of white, crisp celery. Cut in thin strips, too; chop up a handful of walnuts. Mix all well together, and cover with American salad dressing. *Beetroot and Macaroni Salad.*—Take equal quantities of cooked macaroni and cooked beetroot. Cut them into pieces, dress them with pepper, salt, oil, and Tarragon vinegar. It is well to arrange this dish some hours before it is wanted, so that the macaroni may become pink from standing with the beetroot. *German Salad.*—Slices of cold boiled potatoes, beetroot, carrots, tomatoes, shreds of lettuce; in short, all kinds of vegetables in season, all mixed together and covered with this salad mixture. Pound in a mortar the yolks of four hard boiled eggs (with a dessertspoonful of dry mustard if liked), adding drop by drop six tablespoonfuls of oil and three of vinegar. Work all together till smooth like cream. Add a little salt and pour over the salad. (Secretary, Mrs. R. E. Welden.)

All communications to be addressed:

"The Editor, Journal of Agriculture, Education Building, Adelaide."

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences—1935.

Southern, at Mount Compass, Thursday, August 15th (Chas. E. Vercoe, Secretary).

Hills, at Lenswood, Thursday, August 22nd (B. F. Lawrance, Secretary).

Murray Lands (East), at Alawoona, Tuesday, October 1st (A. J. Pengilly, Secretary).

Fruit (Non-irrigated), at Lyndoch, Tuesday, November 5th (J. S. Hammat, Secretary, Williamstown).

Each Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda of the Conference in their respective districts.

Agricultural Shows.

We have been advised by Secretaries of Agricultural Show Societies that their shows will be held on the following dates:—

North-Western, Crystal Brook, Wednesday, September 4th.
Snowtown, Wednesday, September 11th.
Laura, Wednesday, September 25th.
Eudunda, Wednesday, September 25th.
Gawler, Saturday, September 28th.
Balaklava, Saturday, September 28th.
Waikerie, Saturday, September 28th.
Karoonda, Wednesday, October 2nd.
Streaky Bay, Wednesday, October 2nd.
Murray Bridge, Friday and Saturday, October 4th and 5th.
Kapunda, Saturday, October 5th.
Peterborough, Saturday, October 5th.
Kadina, Saturday, October 5th.
Jamestown, Wednesday, October 9th.
Loxton, Wednesday, October 9th.
Strathalbyn, Wednesday, October 9th.
Penola, Wednesday, October 9th.
Blyth, Saturday, October 12th.
Moonta, Saturday, October 12th.
Pinnaroo, Wednesday, October 16th.
Saddleworth, Wednesday, October 16th.
Mount Remarkable, Wednesday, October 16th.
Maitland, Wednesday, October 16th.
Clare, Saturday, October 19th.
Minlaton, Wednesday, October 23rd.
Mount Gambier, Wednesday and Thursday, October 23rd and 24th.
Burra, Wednesday, October 23rd.
Southern, Port Elliot, Saturday, October 26th.
Tatiara (Bordertown), Wednesday and Thursday, October 30th and 31st.
Millicent, Saturday, November 2nd.
Kingscote, Thursday, November 7th.
Kalangadoo, Saturday, November 16th.
Angaston, Saturday, February 29th, 1936.
Mundalla, Wednesday, March 4th, 1936.
Mount Pleasant, Thursday, March 19th, 1936.

Rabbit Poisons.

Replying to questions on the action of various poisons used for the destruction of rabbits, Mr. W. T. Rowe (Director of Chemistry) says:—

Strychnine is generally called a nerve poison and causes twitching of muscles, followed by convulsions and arched stiffening of the body. Death in a few minutes if poisonous dose absorbed.

Potassium Cyanide.—Death results from paralysis of the central nervous system. It also affects the red blood corpuscles, rendering them useless as oxygen carriers. It is very rapid in action, death taking place in a few minutes.

Arsenic is an irritant poison, and generally causes a painful death. Vomiting and diarrhoea are usual symptoms.

Carbon Monoxide.—This gas is absorbed by the red blood corpuscles and quickly renders them unfit to carry oxygen to the tissues. Death comes quickly and painlessly. It is the presence of carbon monoxide in coal gas that makes it poisonous. It is also contained in the exhaust gases from motor car engines.

Carbon Bisulphide is a liquid at ordinary temperatures, but gives off fumes which, in a confined space, are poisonous. The vapour of carbon bisulphide acts on the red blood corpuscles like carbon monoxide, although it is slower in action.

Calcium Cyanide in the presence of moisture emits prussic acid gas (*hydrocyanic acid*) and this acts in the same manner as potassium cyanide. Of course, if the solid calcium cyanide were swallowed, its action would be similar to potassium cyanide.

Arsenate of Lead—Analyses of Samples.

The Director of Chemistry has requested us to correct a mistake which occurred in a report from his Department in the figures showing the Five Minute Suspension Test of Arsenate of Lead Powders as published in the December, 1934, issue of this *Journal.* The Five Minute Suspension Test for "Orchard" brand of Arsenate of Lead powder should have been 77.3 per cent. instead of 27.3 per cent. The report should have read as follows:—

"The samples (6) of arsenate of lead powders, received on 12th November, 1934, No. 517, have been analysed with the following results:—

No.	Brand.	Moisture.	Total Lead. (PbO)	Total Arsenic. (As_2O_5)	Water Soluble Arsenic. (As_2O_5)	Suspension Test. Five Mins.	Suspension Test. Thirty Mins.
		%	%	%	%	%	%
1.	"Vallo"	0.52	64.0	30.9	0.11	32.8	10.7
2.	Hemingway's	0.53	64.4	31.4	0.14	83.0	60.3

6.	"Palmprest"	0.25	64.6	32.0	0.17	35.2	9.1

Weevil in Oats.

A delegate at the recent Ceduna Conference mentioned that there was a belief among some farmers that weevils did not cause much harm to oats from a germination point of view. Mr. R. C. Scott (Supervisor of Experiment Work) stated that, generally speaking, the *germ* in a weevil-attacked grain was not necessarily destroyed. If the damage was not severe, this portion might not be injured and was still viable. However, if the other material in the grain, which normally supplied foodstuff for the young plant until its own roots could function, had been consumed by weevil, then there must be very weakly development. The result was that, although these lightly-attacked grains might germinate, a high percentage would fail to survive and form healthy plants. On the other hand, in a badly damaged grain, the germ was totally destroyed, and, naturally, in such instances, no germination was possible. Consequently, for planting purposes, the result was much the same in both cases, and a grain attacked by weevil had practically no value for use as seed.

Publications Received.

The Library of the Department of Agriculture has received the following publications:—

"Variations in the Composition of Milk," Bulletin No. 16 (6d.).

"Green Peas," Bulletin No. 81 (1s. 6d.).

"Pests and Diseases of Sugar Beets," Bulletin No. 93 (1s. 6d.).

Published by the Ministry of Agriculture, England.

Manual of Grasses of U.S.A.—A. Hitchcox (1 dollar 75 cents).

AGRICULTURAL INQUIRIES.

Dissolving Bones for Manure.

"Miltalie" asks the following questions:—"Is there any economical method of dissolving bones for manure; if so, what is the process and would such manure be equivalent to fine bone dust weight for weight?"

Reply—There is no economical farm method for the production of "dissolved bones" or "bone superphosphate" for manure. If it is desired to produce "bone superphosphate" on the farm the following is the proportion in which the materials are used:—40lbs. bone ash, 10lbs. (1gall.) water, 15lbs. of strong sulphuric acid (S.G. 1.832). Pour the water into a wooden or lead-lined trough, and add the sulphuric acid slowly with stirring. (If the water is poured into the acid an explosion will result.) Gradually add, with stirring, the bone ash. A doughy mass forms, and this will dry in several hours to a friable bone superphosphate which will break up finely. Burning the bones to form bone ash is the only method which could be used on the farm to remove all the fat completely. If the fat is not removed from the bones the action of the sulphuric acid is interfered with and a slimy mass very difficult to dry and handle results.

On the farm, excluding labour, carriage of the acid (which is very high), and the materials used other than the acid, £4 will buy sufficient sulphuric acid for one-third of a ton of 50 per cent. bone superphosphate. On the other hand, at present market rates, £4 will buy 1 ton of 45 per cent. superphosphate. Average bone dust sold on the market contains about 40 per cent. ordinary or tri-calcic phosphate and 3.5 per cent. nitrogen. The tri-calcic phosphate of bone-dust is less active than the water soluble mono-calcic phosphate of bone superphosphate. In addition, the nitrogen of bone dust only slowly becomes available as compared with, say, the nitrogen in sulphate of ammonia.

Thus, on weight, considering only the phosphate content, 1½ tons of bone dust would be equivalent to 1 ton of the bone superphosphate. On heavy soil in spite of its nitrogen content, bone dust shows no superiority over bone superphosphate containing an equivalent amount of phosphate, either in immediate or residual effect. On lighter soils not well supplied with lime, bone dust is superior to bone superphosphate for intense culture.

Oats *v.* Wheaten Hay Chaff for Sheep.

"How many bushels of oats would be equivalent to 1 ton of best green wheaten hay chaff for hand feeding sheep where the roughage in the paddock is sufficient for handfeeding with oats?"

Reply—The following are the analyses of green wheaten hay chaff and oats:—

	Digestible Protein. Per cent.	Digestible Fat. Per cent.	Digestible Fibre. Per cent.	Digestible Carbohydrate. Per cent.	Starch Equivalent. Per cent.
Hay	4.0	.4	12.9	29.9	31.4
Oats	8.0	4.0	2.6	44.8	59.7

From these analyses it can be seen that the best green wheaten hay chaff would have approximately half the feeding value of oats. Thus with a sufficiency of roughage —the paddock 28bush. of oats could be used in place of 1 ton of the best green hay chaff for hand feeding sheep.

Viability of Oats.

"Will seed oats keep their germinating powers for, say, 2 years under slightly damp conditions in an underground silo?"

Reply—Under these conditions due to fungal and/or weevil development, there would be a decrease in the germinating power of oats, the decrease depending on the extent of this development. A common site of fungal devlopment is the soluble sugar layer around the germ. Development here would kill the germ resulting in non-germination. Such conditions are conducive to weevil attack which may result in a proportion of germ injury, thus further decreasing the germinating powers of the oats.

Feeding Value of Pie Melons.

"What food value to stock is there in pie melons and what is the percentage of water?"

Reply—Pie melons contain about 91 per cent. water and 9 per cent. dry matter. The dry matter contains about 1 per cent. digestible protein, 5.8 per cent. digestible carbohydrate, and .3 per cent. digestible fat. This would have a starch equivalent of about 7.4. Thus it has about one-eighth the feeding value of, say, oats which has a starch equivalent of 59.7.

[Replies supplied by Mr. R. C. SCOTT (Supervisor of Experimental Work).]

Preparing Land for *Phalaris tuberosa*.

"Milang": "What soil preparation is necessary for 'Phalaris tuberosa'?"

Reply—This crop is best planted alone on a well prepared area of land which is free from weeds. *Phalaris tuberosa* is very delicate in its early stages of growth, and will not withstand competition from either weeds or other pasture plants sown in conjunction with it. However, when once established it can withstand both competition and heavy

grazing. Very satisfactory stands have been secured in this State by planting *Phalaris* by itself and adding clover in the second year.

The food value of this fodder is quite good, and stock do well on it, although it is sometimes reported that it is not particularly palatable to the animals at first. In planting the crop, old clover land is preferable to relatively infertile areas and at least 1cwt. superphosphate to the acre should be applied.

Phalaris tuberosa is a perennial plant, and a well established stand will persist for many years.

Nauru Phosphate Rock.

The Secretary of the Black Springs Branch of the Agricultural Bureau asks: "How is the phosphate rock on Nauru formed?"

Reply—The generally accepted theory regarding these deposits is that original guano in the form of bird excreta, &c., must have been deposited many thousands of years ago. It has been proved that the islands have been submerged on a number of occasions and fish bones, shark teeth, &c., are frequently discovered.

Because of the inundations all impurities have been washed away, and practically only the pure phosphate remains, some of which is hard and rock like, but the majority is in the form of a light brown friable material.

The chief difference between this and our local phosphate rock is that the latter is relatively impure, containing a low percentage of phosphoric acid.

VETERINARY INQUIRIES.

[Replies supplied by Veterinary Officers, Stock and Brands Department.]

Secretary Agricultural Bureau, Wasleys, reports mare whose foals suffer from constipation from birth.

Reply—There is no specific way of treating the mare before foaling, excepting that it is advisable to see that her diet should be laxative. With respect to the foal, it is very important that the young animal should be got to suck quickly after being "dropped," as a good drink of the colostral milk of the mare is essential to promote proper bowel functioning in the foal. Should a definite constipation arise, the most satisfactory way of treating the foal is to give repeated copious enemas of warm soapy water into which some olive oil has been well mixed. The injections must be made very carefully in order to avoid seriously injuring the bowel wall; the best appliance to use is an ordinary Higginson's rubber bulb enema syringe. The young animal could next be given a dose of 1oz. each of castor and olive oils—mixed together—adding a dose of brandy if a stimulant is indicated.

Secretary Palabie Agricultural Bureau reports cows chewing wood.

Reply—Depraved appetite in cows is usually a sympton of want of sufficient nourishment, chiefly proteins and mineral matter. Supply better feeding, and give 2ozs. of following mixture in feed daily:—Dicalcic phosphate, 40 parts; salt, 60 parts.

Secretary Blachheath Agricultural Bureau reports pigs losing the use of their hind legs,

Reply—This is due to a deficiency in their diet of a vitamin, and will respond to the following treatment:—If possible, supply affected pigs with cow's whole milk—not separator milk—in addition to the grain rations. In any case, give one dessertspoon of cod liver oil per day to each pig for at least fourteen days. If any carrots are available, slice them longways and give once a day. The following mineral mixture should be available at all times:—Sweet bone meal, 10lbs.; charcoal, 10lbs.; common salt, 1lb.

THE RELATION OF PASTURE DEVELOPMENT TO ENVIRONMENTAL FACTORS IN SOUTH AUSTRALIA.

[By H. C. TRUMBLE, M.Agr.Sc., Agronomist, Waite Agricultural Research Institute.]

(Paper read before Section K of the Australian and New Zealand Association for the Advancement of Science, Melbourne Meeting, January, 1935.)

1. Introduction.

The development of natural and seeded pastures has received material investigation in South Australia during the last five or six years, and the present would seem a suitable opportunity to review some of the results obtained and to attempt their interpretation in the light of several basal controlling factors.

The data concerned, while to some extent diverse, has been obtained entirely within the State of South Australia. It is possible, however, that the results may have some bearing on other portions of the Commonwealth, especially where related conditions of climate and soil prevail.

The botanical nature and productivity of pastures in South Australia are governed, as in all regions, by immediate climatic, soil and biotic circumstances. It is exceedingly difficult, if not impossible, to obtain a single measure of all the factors concerned. A composite reflex of the native environment may be found, however, in the type of vegetation which has naturally developed to a comparatively stable or climax condition with the passage of time. It is reasonable to suppose that a close inter-relation will exist between the type of climax vegetation induced by the native environment and the types of natural and seeded pastures produced by essentially the same climatic and edaphic conditions, although by very different biota. The practical and utilitarian value of such a relation lies in the indication which the climax vegetation supplies regarding the types of pasture for which the land is suitable.

Much information collected by botanists, explorers, pioneer-farmers and surveyors has been systematized by Prescott (3) who has related the major types of vegetation in Australia to soil and climatic conditions. From the grassland point of view, however, little has been done to relate natural and seeded pastures to climax vegetation types or to environmental factors.

The climatic conditions of South Australia are distinctly less favourable than in most other regions where pasture development has progressed. The western, northern, eastern and central areas of the State are arid, the mean annual rainfall in most places being substantially less than ten inches. These areas consist of desert, semi-desert with mulga and myall, saltbush, bluebush, various scrub types and some mallee. Indigenous species predominate, with exotics providing comparatively little of the fodder supply. The arid portion outside the 10in. isohyet covers 83 per cent. of the State and carries 21 per cent. of the sheep, 18 per cent. of the cattle and 5 per cent. of the horses maintained by the whole.

The area receiving more than 10ins. per annum is 65,000 square miles. Only 15,000 square miles receive 18ins. or more; less than 5,000 square miles receive 25ins.

The climatic conditions of the southern area are essentially of the Mediterranean type. The rainfall occurs mainly in winter; the winter temperatures are mild and the summers hot and dry. It is of interest to note that the majority of exotic species found in southern grasslands—most of them annuals, with a moderate sprinkling of perennials—are indigenous to Mediterranean countries or to

the Cape Province of South Africa. Common examples are silver grass (*Festuca myuros*), barley grass (*Hordeum murinum*), cape weed (*Cryptostemma calendulaceum*), wild geranium (*Erodium* spp.), cat's ear (*Hypochaeris radicata*) and many of the annual clovers and trefoils.

2. Location and Nature of Grazing Areas.

The location of grazing areas may be indicated fairly precisely by dot dispersions of livestock. These indicate not only the limits of the pastoral and agricultural holdings but the relative intensity of stocking from point to point.

The separate distributions of wheat, sheep and cattle were plotted for Australia by Thomas (5) as early as 1922. The distribution of livestock as a whole, for any portion of Australia, however, has not previously been plotted on one map; nor has this distribution been correlated with the natural vegetation. In the present instance the distribution of sheep, cattle and horses, prepared from the official statistics for district councils, hundreds and pastoral holdings has been superimposed on a map of the major vegetation associations of South Australia, from the recent work of Prescott (3) and of Wood (7). The preparation of a composite map was prompted by the necessity for a delineation of the grazing areas within each major type of vegetation and the provision of a basis for the study of the pastures of these areas in relation to their environment. Owing to the reduction in size of the original copy of the accompanying plate, the distribution of sheep only is shown. A limited number of enlarged copies of the original may be obtained on request to the Waite Institute.

For suitable treatment from the pasture viewpoint, nine major types are defined:—

(1) *Desert*—consisting mainly of sand, with porcupine grass (*Triodia* spp.) and ironstone gravel.

(2) *Semi-desert with Acacia scrub*—mulga, myall, gidgea, with associated saltbush, spear grass, Mitchell grass, etc.

(3) *Saltbush steppe*—dominated by saltbush and bluebush shrubs. In South Australia the saltbush and desert scrub areas carry 1,900,000 sheep, or 25 per cent. of the total, 61,000 cattle (20 per cent.), and 13,000 horses (7 per cent.).

(4) *Mallee*—characterized by comparatively dense associations of dwarf *Eucalyptus* scrub. The mallee areas of South Australia are important agriculturally and support 23 per cent. of the sheep, 20 per cent. of the cattle, and 44 per cent. of the horses of the State.

(5) *Dry savannah woodland*—a savannah type intermediate between the parklike formation of a typical savannah woodland and mallee scrub. The dominant species is *E. odorata* (peppermint), but the trees possess the typical mallee habit of branching at the base.

(6) *Savannah woodland*—comprising *E. odorata* and *E. leucoxylon* (blue gum) associations.

(7) *Sclerophyll forest*—*E. Baxteri* and *E. obliqua* (stringy bark), *E. fasciculosa* (pink gum), *E. rostrata* (red gum), etc.

(8) *Heath and sclerophyll scrub*—an edaphic sub-climax of sclerophyll forest and mallee.

(9) *Irrigation and "soak" areas*—these include the River Murray irrigation areas and areas of natural soakage where the accumulation of underground water enables deep-rooted herbage plants, such as lucerne, to be grown.

The areas of sclerophyll forest, savannah and dry savannah woodland, together with the irrigation and "soak" areas carry the greatest intensities of livestock, particularly sheep and cattle. These areas together support approximately half the sheep and horses and rather more than half the cattle of the State.

The numbers of livestock located within each main type of environment during the 1932-33 season are given in the following table:—

TABLE I.—*Showing numbers of sheep, cattle, and horses in the areas of Acacia scrub, saltbush, mallee, dry savannah woodland, savannah, sclerophyll forest, heath and irrigated cum "soak" areas in South Australia during the* 1932-33 *season.*

	Number of Livestock.			Percentage of Total.		
	Sheep.	Cattle.	Horses.	Sheep.	Cattle.	Horses.
Acacia semi-desert scrub	890,000	51,000	9,000	11·5	16·3	4·7
Saltbush	1,010,000	10,000	4,000	13·1	3·2	2·1
Mallee	1,780,000	63,000	84,000	23·1	20·2	44·3
Dry Savannah woodland	910,000	32,000	27,000	11·8	10·2	14·2
Savannah	1,120,000	74,000	36,000	14·5	23·6	19·0
Sclerophyll forest	1,390,000	55,000	16,000	18·0	17·6	8·4
Heath and sclerophyll scrub	160,000	2,000	1,000	2·1	0·6	0·5
Irrigation and " soak " areas	450,000	26,000	13,000	5·8	8·3	6·8

3. Fluctuations in Numbers of Livestock.

Over the 1913-33 period the numbers of sheep have increased, apart from temporary seasonal fluctuations, by a real amount of approximately two millions, despite an increase of 2 million acres in the area cultivated for cereals. Cattle have decreased slightly, and the number of horses has decreased materially.

These fluctuations have not tended to take place uniformly over all parts of the State. The areas of forest, woodland and mallee have increased in both sheep and cattle, whereas, apart from the north-western area, much of which has been opened only recently, the saltbush and desert-scrub areas have tended to decrease in all three classes of livestock.

Least fluctuation in the numbers of livestock from year to year occurred in the central and south-eastern areas of forest and savannah, whereas the greatest relative fluctuations have occurred in the saltbush and desert-scrub areas.

4. Nature of the Main Pasture Types.

The indigenous flora provides the principal pasturage for stock in the areas of desert scrub and saltbush steppe. The perennial species appear to be necessary for stability and sustained production in these areas. Under continued grazing and the depredations of rabbits, the effects of which are particularly serious in drought years, much country that formerly supplied good pasture has reverted or is reverting to desert. A flush of herbage usually follows infrequent liberal rains but this is short-lived in nature. The exotic species which occur are mainly of the desert ephemeral type, a notable example being "Arabian grass" (*Schismus barbatus*) which is said to have been introduced into Central Australia by Afghan camel drivers and has spread thence to various parts of the Commonwealth. The grass is dwarf, short-lived and free-seeding, yielding numerous seedlings which form a dense carpet of short pasture in early winter. It appears to be best suited to the lighter soil types. Whilst this species is an inferior grass compared with many other exotic annuals, it provides pasturage where otherwise feed would be absent, and has spread rapidly in recent years, over much mallee and saltbush-mallee country in South Australia. It may now be found over a great deal of the Murray mallee, and must be regarded as a valuable grass in these areas.

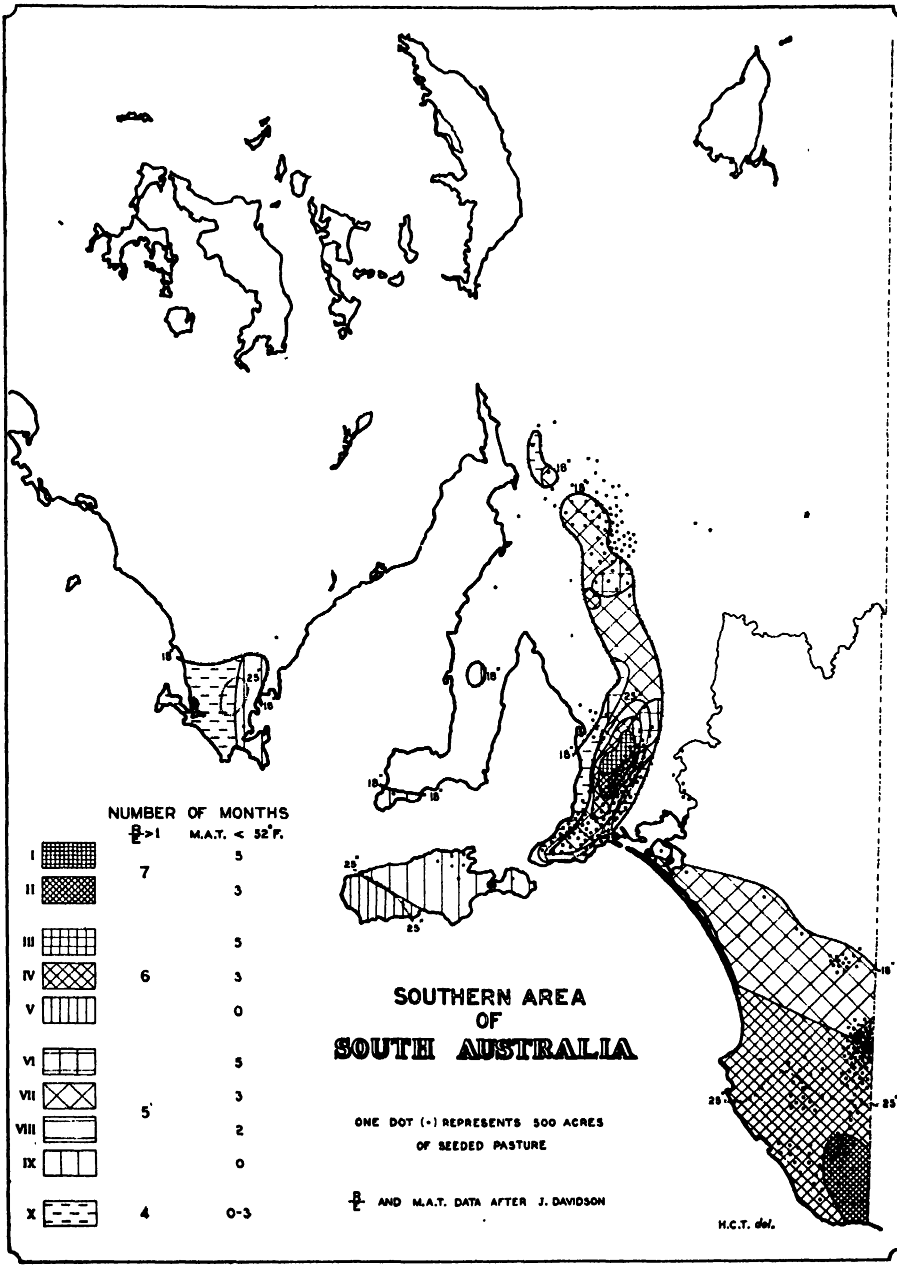

Figure 1.—Southern area of South Australia, showing the relation of seasonal moisture and temperature conditions to the distribution of seeded pastures. The length and nature of the growing season are largely dependent on the total rainfall (indicated by the 18in. and 25in. isohyets), the period over which rainfall exceeds evaporation, and the degree of coldness in winter (indicated by the period over which the mean air temperature is less than 52°F.).

Apart from the ecological work at Koonamore, which has been carried out in some detail, these areas have been little investigated from the pastoral point of view and there appears to be little immediate scope for economic pasture improvement. In general, deterioration has occurred fairly widely in the older settled areas.

The pastures of the *Eucalyptus* areas, including the mallee, savannah and forest types, have been derived mainly as a result of clearing. In the areas of peppermint (*E. odorata*) and the various mallee types (*E. oleosa, E. dumosa,* etc.), *Stipa-Danthonia* associations are common in the natural grassland formation, but under agricultural conditions, rapidly give way to exotics of the ephemeral type.

In the areas of sclerophyll forest (*E. obliqua, E. cosmophylla, E. Baxteri,* etc.) and blue gum (*E. leucoxylon*), kangaroo grass (*Themeda triandra*) is common after clearing but soon disappears under grazing; survivals are conspicuous in areas protected from stock. The erect sparsely-tillered spear grasses (*Stipa* spp.) and *Agropyrum scabrum* also disappear fairly rapidly. Wallaby grass (*Danthonia* spp.), *Microlaena stipoides* and *Eragrostis* spp. are capable of withstanding considerable grazing from sheep owing to their capacity for tiller production, and, in the absence of cultivation or the competition factor, frequently dominate the sward.

The carrying capacity of the perennial indigenous pastures varies in general from a sheep to four acres to two sheep per acre. *Danthonia* types occur throughout all of the woodland areas. The *Stipa* types become less important with increasing rainfall, however, whereas *Eragrostis* and *Microlaena* occur mainly within sclerophyll forest. The *Danthonia-Eragrostis-Microlaena* type of pasture is associated with a long season of moisture excess, and carries up to two Merino sheep per acre in the natural state. The pasture frequently remains green throughout the year, the period of minimum production being in winter.

5. Investigations of Unfertilized and Top-dressed Natural Pastures.

Natural pastures of the *Danthonia* type have been investigated in much detail at the Waite Institute, Glen Osmond, and at Kybybolite in the South-East, the greater portion of the work having been caried out by Davies, Scott and Fraser (2). At Glen Osmond, a typical indigenous pasture of the foothills, when allowed to remain in an unfertilized but grazed condition for ten years has been found to vary in *Danthonia* content from 20 to 65 per cent., at the completion of growth in November. At Kybybolite, with a longer growing season, but a much poorer soil, the content of perennial grasses (principally *Danthonia*) in November varied from 36 to 55 per cent. over four seasons. At each centre, the percentage of indigenous perennials was materially higher in the earlier part of the season.

At the Waite Institute, natural pastures were found to carry one Merino sheep per acre per annum, the mean annual return over a three-year period being 13.9lbs. of 64's quality wool per sheep and per acre. Where the pasture was top-dressed with superphosphate at the rate of 185lbs. per acre per annum, the carrying capacity was increased to 1.6 sheep per acre per annum and the wool production per acre to 22.1lbs. of 64's quality wool per acre, the yield of wool per sheep remaining the same as on the unmanured pasture. At Kybybolite, the production of wool per acre averaged 8.2lbs. for two seasons on unfertilized pasture and 19.5lbs. on pasture top-dressed with superphosphate. The further addition of lime increased the wool yield per acre to 26.5lbs. per acre. In all cases the increases in wool yield were directly due to increases in carrying capacity and not to any increase in production per sheep.

At both centres the original *Danthonia* pasture became dominated by miscellaneous annual plants, many of which are of doubtful value and poor stability. Examples are silver grass, geranium, barley grass, the bromes and the poorer annual clovers. An annual pasture of this nature tends towards poor autumn and winter production with a marked flush in spring. At Kybybolite, superphosphate increased the yield of pasture only 5 to 7 times in July compared with 10 to 20 times in November. In terms of carrying capacity, superphosphate increased the stock carried per acre from 0.75 sheep to 2.5 sheep in five years; that is to say, the number of sheep carried was slightly more than trebled. During the first three years of top-dressing, however, only 1.2, 1.8 and 2.1 sheep were carried during each successive season.

6. The Effect of Rainfall Incidence on the Yield of Natural Pastures.

The total yield produced by a natural pasture, whilst limited initially by low soil fertility, and under top-dressing by its botanical nature, is closely dependent on rainfall, and in particular on autumnal rains.

At the Waite Institute, the annual yields from both unmanured and top-dressed natural pastures over the 1925-34 period have been correlated with (*a*) total rainfall, (*b*) various types of seasonal rainfall, taken in groups of six, three and two months. The results are given in Table II.

TABLE II.—*Correlation coefficients (corrected) for the annual yield of* (a) *unmanured natural pastures,* (b) *top-dressed natural pasture, with annual and seasonal rainfall.*

Significance of the correlation coefficient—

* $P < \cdot 01$ ** $P < \cdot 02$ *** $P < \cdot 05$

NOTE.—Thanks are due to Mr. E. A. Cornish, B.Agr.Sc., for assistance with the determination of the "r" values. The seasonal trend of the correlation coefficient is of considerable interest and will be dealt with in a further publication.

The results of this examination point very strongly to the significance of the autumnal rains in determining the annual yield of the untreated and top-dressed natural pasture. The commencement of these autumnal rains is termed the "break" of season in South Australia, and most frequently occurs in early May. The importance of rains in autumn lies in their coincidence with relatively warm

soil temperatures, resulting in rapid growth prior to the cold temperatures of winter. A secondary effect occurs during the winter itself, when materially greater development is made possible by the greater range of root exploration resulting from vigorous early growth. The advantage of deeper and more abundant root development during winter is at least three-fold, permitting root activity in a region of more favourable soil temperature, affording greater opportunities for the assimilation of partially leached nitrates and giving increased scope for respiration. The advantages of early rains are well known in respect to crops sown for grain. They apply to temporary and permanent seeded pastures, both of which benefit greatly from early seeding, provided competition from weed development is not too severe. It is probable, of course, that spring rains will prove of greater importance with seeded pastures owing to the longer growing season.

It is of interest to note that the mean rainfall for the April-June period, over a sequence of ten years, is 8.03ins. Investigations of the water requirements of the pasture species concerned, carried out at the Waite Institute, show that the transpiration ratio for these plants approximates to 400.

Applying this value to the mean April-June rainfall figure of 8.03ins, the quantity of air-dry herbage produced would be 45.37cwts. per acre, which is slightly in excess of the mean yield per acre (42.90cwts.) actually obtained on the top-dressed plot over a period of ten years. The mean rainfall occurring in the April-June period, whilst only one-third the mean annual rainfall, thus provides the transpiration requirements of the mean yield of herbage recorded, and much of the rain which falls after June must be of very little use to unmanured or top-dressed natural pastures in the Waite Institute type of environment.

7. The Trend from Indigenous to Exotic Pastures.

General observation within the agricultural areas indicates that cultivation tends inevitably to eliminate the indigenous grassland species. Additional agents of suppression are the close grazing habits of European animals and the plant competition factor, provided by numerous introduced plants. The latter is stimulated by the application of soluble phosphate, resulting in the rapid reduction and frequent elimination of indigenous types from top-dressed land.

Owing to the marked tendency of the indigenous grasses to disappear with agricultural progress, and the readiness with which the areas of maximum stock concentration have become populated by exotics, the herb-flora of foreign winter rainfall areas, and the Mediterranean region in particular has assumed a special significance in the development of pastures in South Australia.

Unfortunately, most of the naturally occurring exotic species are decidedly inferior, as judged by our accepted standards for cultivated pasture plants. It has been shown conclusively that the productivity of top-dressed natural pastures is greatly limited by the nature of the exotic species which compose them. In order to increase production to a higher level, it is necessary to employ plants of greater vigour and better quality. It goes without saying that plants of high productivity and good quality are best adapted to soils of moderate to good fertility.

Pre-eminent amongst our limited supply of superior herbage plants in South Australia is subterranean clover of the Mount Barker strain. This is well adapted to much of the South-East except on the black rendzina soils, where its place is taken by strawberry clover. On the Murray swamps it is replaced by white clover, on the Booborowie flats by lucerne, and at the Waite Institute and other areas where the spring conditions are normally too severe for ordinary subterranean clover, its place has been successfully taken by the early maturing Dwalganup strain. Legumes appear to be vitally necessary as the basis for pasture improvement in South Australia. This is because most soils of the

higher rainfall areas tend to be deficient in total nitrogen, whereas even the less common soils of good natural fertility tend to become deficient in available nitrogen in the absence of cultivation or a suitable pasture legume.

Both scientific investigation and practical experience have shown that the continuous growth of a pure legume year after year is not only inadvisable from the viewpoint of animal health, but is also an impossibility in practice owing to the increasing nitrogen level of the soil, and its increasing suitability for grasses and other non-leguminous plants. We thus find invariably in a pasture sown to pure clover, a conspicuous influx of naturally occurring weedy grasses and other plants within three or four seasons, and it is impossible to prevent these plants from entering the sward. This indicates the necessity for superior grasses such as the rye-grasses and *Phalaris tuberosa.* The particular value of these plants lies in their capacity to grow in association with subterranean clover, lucerne, white clover or strawberry clover, and to make use of the nitrogen accumulated by the legume, at the same time doing much to keep out inferior plants.

8. The Relation of Pasture Type to Environment.

Leaving out of consideration the areas of desert-scrub and saltbush, in which little improvement of the pastures has occurred, we are left with the irrigated and "soak" areas, and the natural forest, savannah and mallee types. From the agricultural point of view, this country may be classified into four broad classes:—

(*a*) Irrigated areas, capable of yielding a wide variety of products, watered chiefly from the Murray River.
(*b*) Areas of soakage or of high water table, well adapted to the growth of lucerne, and located principally in the Booborowie-Mount Bryan area.
(*c*) The well-defined areas of subterranean clover (Mount Barker type), which coincide closely with the areas of forest and blue gum savannah.
(*d*) The areas of cereal cultivation, located mainly within the peppermint, savannah and mallee types of vegetation.

(a) *Irrigated Areas.*

The only irrigable areas of any extent in South Australia are the flats bordering the Murray River. The reclaimed swamps of the lower reaches have attracted most attention from the grazing aspect, and until recently lucerne has been the principal fodder grown. The work of Trumble and Davies (6) has shown that a simple mixture of perennial rye-grass, cocksfoot, white clover and red clover is satisfactory for these areas and is more productive than lucerne under the conditions of a typical reclaimed swamp. It has been demonstrated that 20 sheep per acre per annum can be carried on a pasture of this type. Other species which have attracted attention are *Phalaris tuberosa,* sown with *Poa pratensis* and white clover, Yorkshire fog on low-lying and over-grazed areas, and suitably permanent strains of prairie grass. Up to the 1932-33 season, only 3,000 acres of seeded pasture had been established on these areas, many stock being supported by temporary forage crops.

(b) *Areas of soakage or of high water table.*

These areas are situated principally in the Booborowie-Mount Bryan district, east of the Flinders Range, approximately 100 miles north of Adelaide. There are also restricted areas in the Adelaide plains region, the upper South-East and isolated portions of the State. The majority of the lucerne is located in country receiving 15 to 20 inches mean annual rainfall. Maintenance of the stand appears to depend in most cases on subsoil moisture accumulated from the falls of previous seasons or from outside catchments, as the amount falling in one season is frequently insufficient to promote the growth obtained.

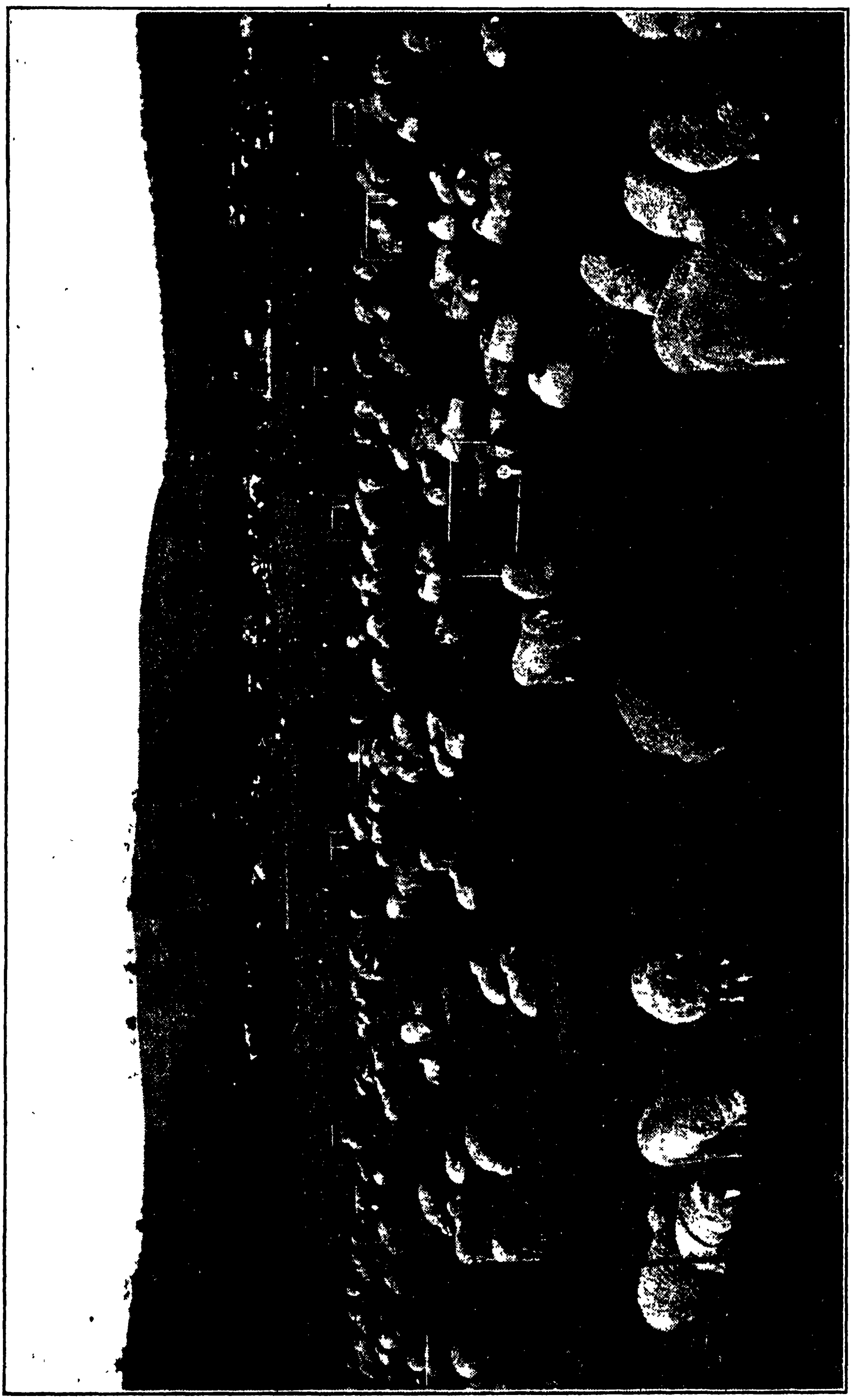

Figure 2.— Sheep grazing on a seeded pasture of *Phalaris tuberosa* and early flowering Subterranean Clover, at the Waite Institute, in the second year of the pasture, August, 1933.

DISTRIBUTION OF SHEEP IN SOUTH AUSTRALIA IN RELATION TO VEGETATION TYPES

VEGETATION TYPES AFTER J.G. WOOD AND J.A. PRESCOTT

H E POWELL GOVERNMENT PHOTOLITHOGRAPHER ADELAIDE

The development of lucerne from seed is usually slight in the first year but production is moderate to high in subsequent seasons. After two or three years, intrusion by barley grass and other non-leguminous annuals is usually evident particularly under grazing, and is probably a consequence of the increasing nitrogen level of the soil. There is scope for including light seedings of the more valuable non-legumes such as *Phalaris tuberosa* and the rye-grasses, with the initial seeding of lucerne. There is evidence that the lucerne stands in the Booborowie area are deteriorating owing to material reduction in the water table.

(c) *The areas of Subterranean Clover.*

Subterranean clover in conjunction with the use of superphosphate has provided the key to pasture improvement in the areas of sclerophyll forest and blue gum savannah. This plant was first exploited at Mount Barker, in an area of rolling savannah country on the eastern slopes of the main Mount Lofty Range. Since its introduction about 1880, it has spread naturally over much of

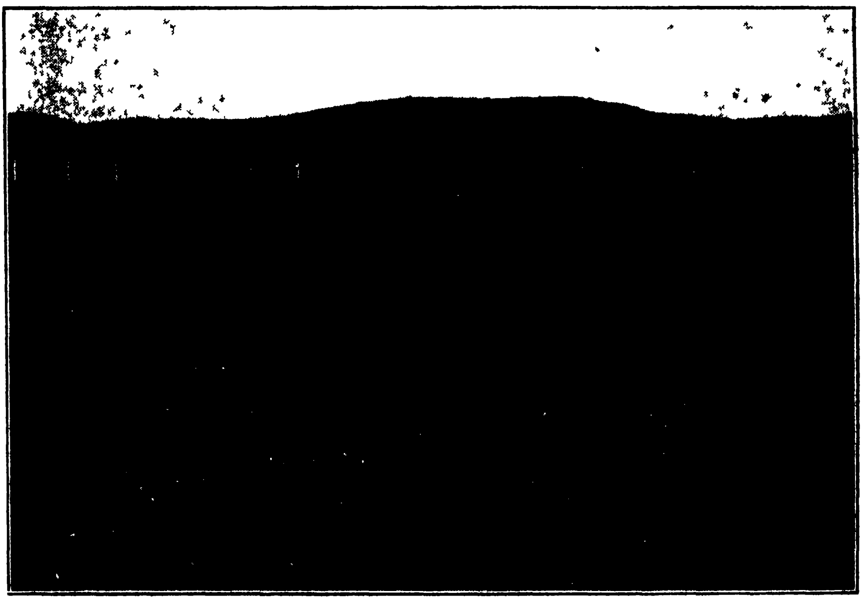

Figure 3.—General view of experimental plots at Mount Compass in the third season of the experiment, November, 1934.

the stringy bark-blue gum region, and attempts to establish it have been made in many grazing areas of the State. Its present distribution coincides closely with the limits of sclerophyll forest and blue gum savannah.

The most important factor in the development of subterranean clover has been the increased use of superphosphate. The soils of these areas for the most part tend towards the podsolized type and are low in both nitrogen and available phosphorus. Following two to four years of clover, a marked increase in non-leguminous annuals is evident as a result of an increased nitrogen level due to the clover. Silver grass (*Festuca myuros*) is the most common species and one of the first to appear. Others of frequent occurrence are soft brome (*Bromus hordeaceus*), barley grass (*Hordeum murinum*), wild oats (*Avena fatua* and *A. barbata*), shivery grass (*Briza minor*), Cape weed (*Cryptostemma calendulaceum*) and geranium (*Erodium* spp.).

B

In the Mount Barker district, where subterranean clover has been grown for many years, the pastures after passing through the annual phase have become populated to some extent by perennial rye-grass (*Lolium perenne*) and rib "grass" (*Plantago lanceolata*). Perennial rye-grass also occurs in the lower South-East particularly on the volcanic soils of good fertility and on soils improved by several years' growth of subterranean clover. *Poa pratensis* occurs along roadsides and in pastures in the forest and blue gum areas. These grasses, especially perennial rye-grass, were sown by early settlers of the State. In the limited areas of good soil fertility they have persisted. On the poorer soils they have tended to disappear temporarily but have increased during recent years on soils improved by clover.

Certain areas in this region have not grown subterranean clover satisfactorily. These are the black rendzina soils and glacial or quartzite sands of low moisture retentivity. Subterranean clover appears to be at its best on light, well-drained soils of good subsoil retentiveness. The swamp soils appear to grow strawberry clover (*T. fragiferum*) well. *Selliera radicans, Hypochaeris radicata* and *Hordeum maritimum* are also common on these soils.

A recent development in this region has been the establishment of sown grasses in association with subterranean clover. Suitable strains of perennial rye-grass, Wimmera rye-grass, and *Phalaris tuberosa* have proved adaptable to the climatic conditions of this area, and associate satisfactorily with the clover, tending to exclude to a marked degree the common inferior annual types. Yorkshire fog and *Phalaris* have established and grown satisfactorily with subterranean clover on podsols in wet districts (Figures 3-5).

(d) *The areas of cereal cultivation.*

Cereal cultivation in South Australia is carried out chiefly in the areas of peppermint (*E. odorata*), savannah and mallee (*E. oleosa, E. dumosa*). The soils vary from grey soils and red-brown earths to the lighter mallee soils. In the more productive wheat areas the soils are of good general fertility, with retentive clay or marl subsoils, but are comparatively low in available phosphate.

The rainfall conditions of these areas are less favourable than those of the forest and blue gum areas so far as pasture development is concerned. The total rainfall is rarely above 20ins.; the area of most intensive cereal development receives a mean annual rainfall of 16ins. to 20ins. The growing season is shorter than in the areas of subterranean clover; the months of September and October in particular tend to be definitely more arid.

The areas of peppermint-savannah may, from the pasture viewpoint, be regarded as neo-subterranean clover areas. This species when sown in these areas has usually failed to persist. At the Waite Institute, which is situated on the line of transition from peppermint to blue gum, very close to the 25ins. isohyet, systematic attempts to establish the clover have failed, whereas within the blue gum area less than two miles distant, subterranean clover grows naturally.

The reason for the failure of the clover in the cereal areas appears to be connected with the coincidence of its flowering and seed ripening—September to November—with a period of rapidly increasing temperature and increasing saturation deficiency.

Compared with the exotic annual species of the cereal areas, subterranean clover possesses an extended period of growth, involving in particular a long period from flowering to seed-maturity—approximately two months. Furthermore, its rate of transpiration is high during the post-flowering period, large quantities of soil moisture being required at that time. A deficiency of soil

Figure 4.—Close view (November, 1934) of a pasture seeded in 1932 with a mixture of Subterranean Clover and Yorkshire Fog, at Mount Compass.

Figure 5.—Close view (November, 1934) of a pasture seeded in 1932 with a mixture of Subterranean Clover and *Phalaris tuberosa*, at Mount Compass.

moisture within the root zone of the clover during the post-flowering period tends to inhibit normal development and promote death of the individuals before seeds are formed in sufficient quantity for satisfactory regeneration.

The solution to the growth of pasture legumes in the cereal areas appears partially to be provided by the use of earlier maturing strains of subterranean clover and, in certain areas, lucerne. The Dwalganup type of early subterranean clover, which first gave promise at the Waite Institute in 1929, has since proved a suitable type at several centres within these areas. This strain has been thoroughly tested and found to be persistent over a range of five seasons at the Waite Institute, Gepp's Cross, and Saddleworth, and has also shown a high degree of persistence following unfavourable spring conditions at Roseworthy College on the peppermint-mallee fringe.

Of the grasses, Wimmera rye-grass and *Phalaris tuberosa* appear to be the most suitable types. Additional non-legumes which have given good results in small trials at the above centres are perennial veldt grass (*Ehrharta calycina*), selected *Danthonia* strains and creeping saltbush (*Atriplex semibaccatum*). In the case of *Ehrharta* and *Danthonia*, however, practical disabilities arise in the fluffiness of the seed, which necessitates broadcasting by hand, and in the slow establishment of these grasses from seed. The types of seeded pasture which have tended to develop are grass *cum* legume combinations of early subterranean clover, lucerne, *Phalaris tuberosa*, Wimmera rye-grass. Low seeds rates of the order of 1lb. to 4lbs. per acre have given satisfactory results with these species.

Natural pastures in these areas are composed mainly of annual ephemeral types. Common amongst these are *Medicago* spp., principally *M. denticulata* (burr trefoil) which commonly develops on stubble, following the use of superphosphate with cereal crops. Barley grass (*Hordeum murinum*), wild oats (*Avena* spp.), wire weed (*Polygonum aviculare*), cape weed (*Cryptostemma calendulaceum*), the annual thistles and crucifers, and sour sob (*Oxalis cernua*) are common on cultivated land. These pastures are of a temporary nature and are frequently supplemented by the feeding down of crops and the use of grain, chaff, hay, and silage.

Throughout the dry savannah and mallee areas are found stretches of land not usually cultivated. Lack of cultivation may be due to a poor soil type, a steep or stony surface or distance from suitable transport facilities. *Stipa-Danthonia* associations are characteristic of these areas when cleared. Portions of this country could be ploughed once if suitable pasture types were available for establishment.

The ephemeral type appears to be well adapted and the early Dwalganup strain of subterranean clover is the most promising of the types at present available.

9. The Relation of Seeded Pastures to Climatic and Soil Factors.

The area of artificially seeded pastures is small in proportion to the total area of land grazed. Up to the 1932-33 season, 208,418 acres had been sown. Material increases in the area established have occurred since 1923-24, principally since 1928-29.

The distribution of sown pastures in relation to total rainfall, seasonal rainfall-evaporation ratio and mean air temperature is shown in Fig. 1 (page 1463). The rainfall isohyets are taken from the most recent data of the Commonwealth Meteorological Bureau; the rainfall-evaporation and temperature data are taken from C.S.I.R. Bul. 79 (1); the writer is indebted to Dr. Davidson for the use of his original graphs.

The dot dispersions for seeded pasture fall into two main groups:—

(1) Subterranean clover pastures: located principally within the areas south and east of Adelaide (34.9°S.).

(2) Lucerne: located principally north of Adelaide and most particularly in the Booborowie-Mount Bryan area.

There are also limited areas of permanent seeded grass mixtures along the Murray River and in the subterranean clover districts.

The area sown to subterranean clover is greater than that sown to lucerne and grass-clover mixtures combined. The main areas are in the South-East of the State principally in the Kybybolite, Kalangadoo, and Mundalla districts, and in the Mount Barker, Woodside, Meadows, and Myponga areas of the Mount Lofty Ranges.

These areas receive an average rainfall of 25ins. or more in the Mount Lofty Ranges and 18ins. or more in the South-East. In all cases rainfall exceeds evaporation for September (the month of maximum flowering of the clover) and in many cases for October as well. At least five months of the year are characterised by an excess of rainfall over evaporation. A favourable balance between available soil moisture supply and transpiration as influenced by the atmospheric environment appears to be indispensable during the post-flowering period of the clover. Favourable conditions usually obtain in the established clover areas but the balance is adverse during September and October in the cereal areas. In the latter the earlier strains of subterranean clover, by flowering in early August, secure favourable moisture relations during their post-flowering period and are able to produce sufficient seed for regeneration. In both the late and early strains, provision against unusually adverse seasons is made by the production of an appreciable proportion (10 to 40 per cent.) of hard seeds resulting in delayed germination and a series of seedling plants establishing over several seasons, from one year's seed production.

It is of interest to note that the areas of maximum subterranean clover development have relatively warm winter conditions. Thus in the majority of cases only three months of the year are characterized by a mean air temperature of less than 52°F. Where this period extends to five months in the Mount Lofty Ranges there is a falling off in subterranean clover concentration.

There are certain areas north of Adelaide, through Kapunda and Saddleworth, in which the general climatic conditions as indicated in Fig. 1 closely resemble those of the Mundalla area, in the upper South-East. Subterranean clover has not developed in these northern areas, however, and the reason is closely associated with soil conditions. The soils of the agricultural areas north of Adelaide are either relatively heavy in texture or tend to set when dry, or are granitic with poor moisture retentiveness. On the other hand, the South-Eastern soils are lighter and more friable, with excellent subsoil retentivity. The September-October conditions are also rather more favourable in the Mundalla area, although the monthly rainfall-evaporation gradations employed in Fig. 2 are not sufficiently fine to bring out this difference.

The lucerne areas are more independent of immediate climatic influences depending more on subsoil conditions and particularly the presence of sufficient free moisture at a reasonable distance from the soil surface.

It is significant that the two species which have provided the basis for pasture development in South Australia are both legumes and have both depended on liberal dressings of soluble phosphate for their success. The leaves of both species are typically mesophytic and the transpiration rate of each is high. This applies also to *Phalaris tuberosa*, one of the most promising and most drought-resistant of the non-legumes.

It would appear that the use of a suitable strain of one or both of the legumes as a basis, the application of soluble phosphate, the presence of a suitable associate grass such as *Phalaris tuberosa*, Wimmera or perennial rye-grass, and favourable subsoil conditions are necessary for the satisfactory development of pastures with the material now available. Furthermore, apart from areas with underground soakage, there is as yet no definite evidence that these species can be grown successfully and permanently in South Australia below annual rainfall conditions of 17 to 18ins.

10. The Inter-relation of Phosphatic and Nitrogenous Manuring with Competition Effects and Productivity in Pastures.

Extremely little information is available concerning the response of seeded pastures to fertilizer treatment under South Australian conditions The indispensability of superphosphate is generally recognized, but a lack of quantitative data is evident. Nitrogenous fertilizers have been found to increase the grass-clover ratio rather than to increase production materially, and economic responses have not been obtained.

The greatest responses to fertilizer treatment are to be expected on the podsolized soils, which are associated with high winter rainfall and an extended growing season. These soils provide much scope for pasture development in view of their physical suitability for subterranean clover and the comparatively favourable and reliable moisture conditions associated with them. Two relevant problems are concerned with (1) the provision of suitable permanent non-legumes in combination with subterranean clover and (2) the optimum fertilizer dressing for these soils.

To obtain preliminary information regarding these questions, an experiment was carried out in the Meadows district, during 1934, on a podsolized soil representing the *Meadows sand* type (4). The surface horizon consists of a greyish white sand extending to approximately 12ins., with pH = 6.4, P_2O_5 = 0.006 per cent. and loss on ignition 1.47. per cent.* Below this is reddish yellow clay. The mean annual rainfall is 35ins., of which 25ins. falls between April and September. Rainfall exceeds evaporation for 7 months of the year. The rainfall for 1934 was 26ins., distributed as follows:—

Jan.	Feb.	Mar.	Apl.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Total
1.20	0.31	1.03	3.42	1.09	1.25	1.64	4.52	3.72	3.56	3.00	1.34	26.08

The rainfall distribution would appear to be almost ideal for subterranean clover.

The natural vegetation is of the sclerophyll forest type (Fig. 6), with pink gum (*E. fasciculosa*), tea-tree (*Leptospermum myrsinoides*), scrub oak (*Casuarina distyla*) and a little *Banksia* and *Xanthorrhoea*. The dominant native grasses are *Microlaena stipoides, Danthonia setacea, Pentapogon quadrifidus, Neurachne alopecuroides* and *Stipa pubescens*. *Festuca myuros* and *Aira caryophyllea* are the common annuals.

An area of approximately one acre, which had been burnt, was cleared of scrub and ploughed in March 1934. On 17th April, 100 plots, each 20 x 25 links, were laid out in the form of a 10 x 10 Latin square and all were sown with subterranean clover 5lbs. per acre and *Phalaris tuberosa* ½lb. per acre. The 10 treatments employed were nil, 1, 2 and 4cwts. superphosphate per acre at seeding, 2cwts. superphosphate 12 weeks after seeding, basic slag and rock phosphate equivalent to 2cwts. superphosphate at seeding, 2cwts. superphosphate + 56lbs.

* The writer is indebted to Mr. C. S. Piper, M.Sc., and to Mr. R. E. Shapter, A.A.C.I., for the analyses of the "Clear Hills" soil.

sulphate of ammonia, 2cwts. superphosphate + 1cwt. sulphate of potash, and 2cwts. superphosphate + 5cwts. slaked lime, all at seeding.

12 weeks after seeding (10th July) the no manure and rock phosphate plots were particularly poor. Seedlings of both subterranean clover and *Phalaris* were yellowish and retarded in development. Well developed nodules were present on numerous clover roots that were examined.

1cwt. superphosphate produced greatly superior development, with 2cwts. superphosphate again superior. There appeared to be no further development with 4cwts. superphosphate. Basic slag appeared to give a similar response to the equivalent quantity of superphosphate. Neither potash nor lime showed any evident response over and above 2cwts. superphosphate.

The addition of 56lbs. sulphate of ammonia, however, produced a marked response on the part of both clover and *Phalaris*, and the nitrogen-treated plots were outstanding at that stage, being at least three times as vigorous as the

Figure 6.—General view of experimental area at "Clear Hills," Meadows, prior to clearing, 1934.

2cwts. superphosphate plots. The nitrogen-treated plots were the only plots to show a normal healthy development. In all other cases, both clover and *Phalaris* appeared yellowish or retarded in growth.

The effect of the small dressing of nitrogen on the clover is of considerable interest and has been confirmed in pot cultures. In the early stage of clover development, the nodule organisms are actively colonizing, and the nitrogen fixed is probably largely utilized in their own expansion and the development of the clover root system, with the result that comparatively little is available for the growing portions of the leaves. It is probable that the small quantity of additional nitrogen supplied at this stage provides the excess required for the more active development of the top portion.

Establishment counts were made (20 per plot = 200 per treatment) using a 4 sq. link mesh, on the nil, 2cwts. superphosphate and 2cwts. superphosphate + 56lbs. sulphate of ammonia treatments. The results are given in Table III.

TABLE III.—*Showing the seedling establishment of subterranean clover (5lbs. per acre)* + Phalaris tuberosa (*½lb. per acre*) *sown at Meadows (S.A.) with* (a) *no fertiliser,* (b) *2cwts. superphosphate,* (c) *2cwts. superphosphate* + *56lbs. sulphate of ammonia.*

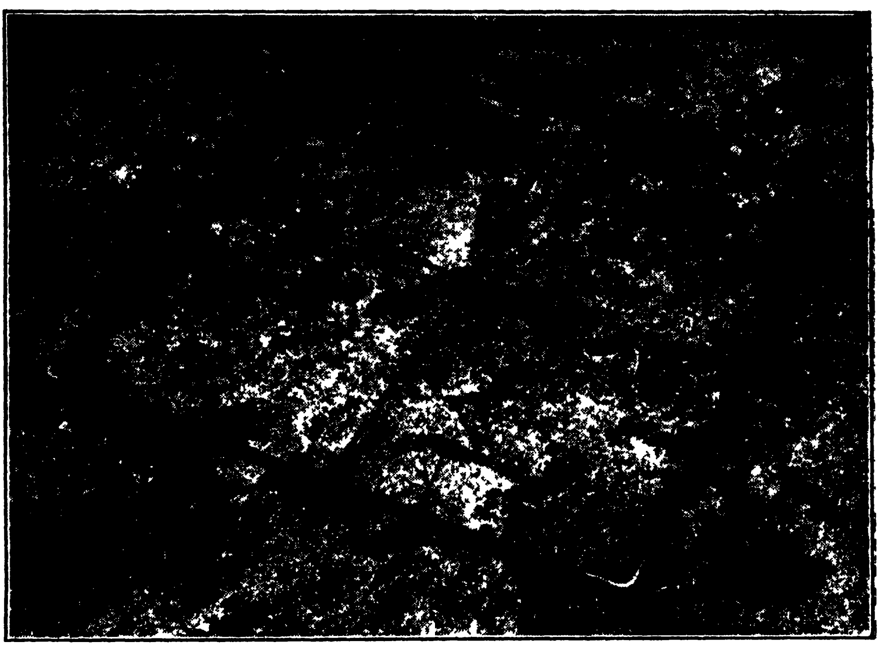

Figure 7.—Close view of plot receiving no fertilizer, at "Clear Hills," Meadows, 12 weeks after seeding, 1934.

The establishment rate is unusually high for both these species and is due probably to the favourable physical soil conditions and the absence of competition. Superphosphate significantly increased the establishment of both species, whereas sulphate of ammonia in addition further increased, significantly and materially, the establishment of subterranean clover. Photographic records of the effect of nitrogen on establishment and early growth are given in Figs. 7-10.

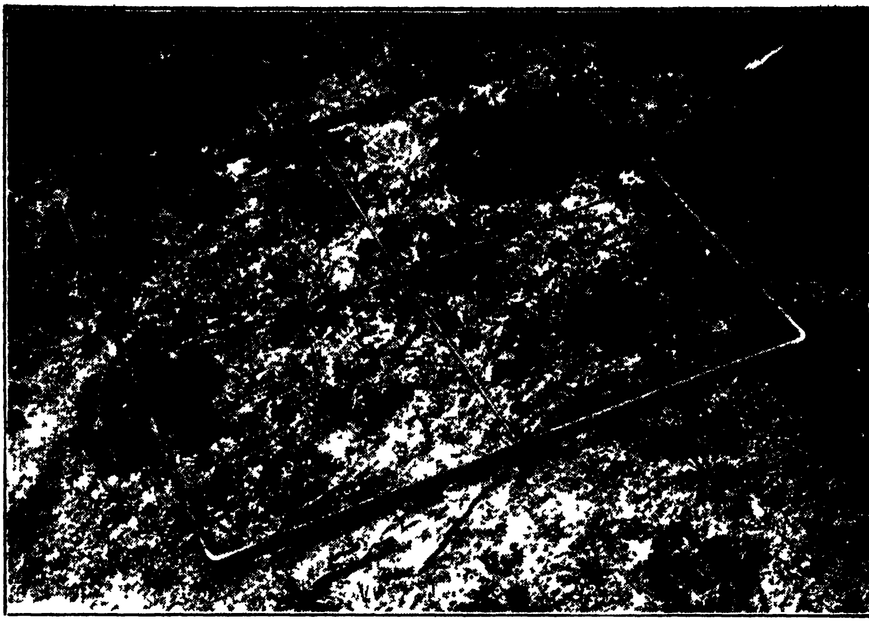

Figure 8.—Close view of plot receiving 2cwts. superphosphate per acre, at "Clear Hills," Meadows, 12 weeks after seeding, 1934.

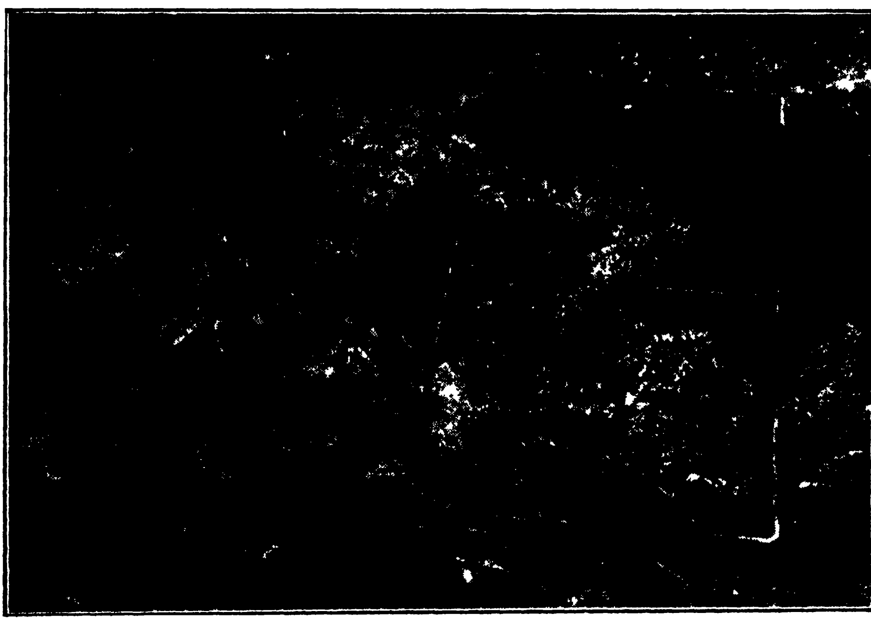

Figure 9.—Close view of plot receiving 2cwts. superphosphate + 56lbs. sulphate of ammonia per acre, at "Clear Hills," Meadows, 12 weeks after seeding, 1934.

Yields were obtained from all plots on 15th November by taking four samples 5 x 2½ links from each plot, or 40 samples per treatment. Each sample was cut to ground level with a sheep-shearing machine, and the four samples for each plot were bulked. The samples were air dried and botanically analyzed *in toto* by the method of percentage estimation by weight. The estimations were preceded and checked, in the case of each laboratory worker, by the hand separation of small samples. The results, based on air-dry weights, are given in Table IV. Photographs of typical plots at harvest are shown in Figs. 11-15.

TABLE IV.—*Showing the yields of air-dry herbage obtained with varying fertiliser treatment on a first year subterranean clover*-Phalaris tuberosa *pasture at Meadows (S.A.)*, 1934. *All yields are in cwt. per acre.*

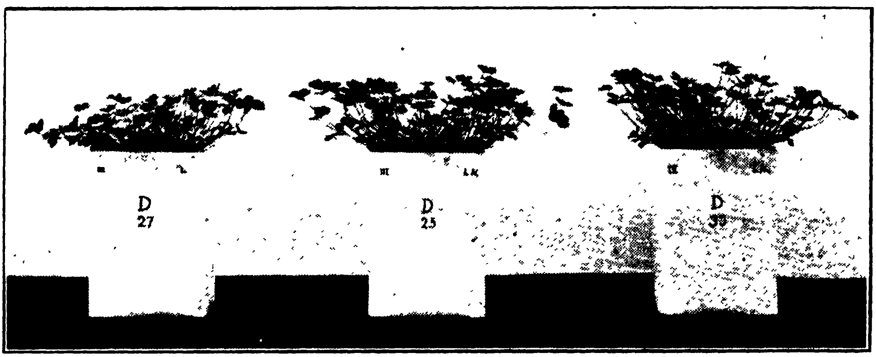

Figure 10.—The effect of soluble nitrogen on the development of Subterranean Clover in pots at the Waite Institute, 12 weeks after seeding. D27—no nitrogen; D25—0.25 gm. $NaNO_3$ per pot; D33—1.0 gm. $NaNO_3$ per pot. All pots received a basal dressing containing abundant nutrients other than nitrogen.

The increase in the yield of subterranean clover due to increasing phosphate dressing is striking, and significant increases were obtained up to 4cwts. superphosphate per acre. The yields of subterranean clover plotted aganst the quantity of superphosphate applied fall almost exactly on the calculated Mitscherlich curve (A = 37.40cwts., K = 0.33). This curve is shown in Fig. 16. From the graph log (A — y) plotted against x, the maximum dressing would appear to be 5.8cwts. superphosphate per acre.

In view of the desirability of rapid establishment from seed and of obtaining both a vigorous development of clover and a satisfactory development of the sown grass in the first season, a dressing of approximately 2cwts. superphosphate per acre with the seed is indicated. Neither lime nor potash produced any material or significant increase on the total yield or the yield of subterranean clover, although both additions significantly increased the development of *Phalaris tuberosa*.

Figure 11.—Close view of plot receiving no fertilizer at "Clear Hills," Meadows, 16th November, 1934.

Figure 12.—Close view of plot receiving 1cwt. superphosphate at "Clear Hills," Meadows, 16th November, 1934.

Figure 13.—Close view of plot receiving 2cwts. superphosphate per acre at "Clear Hills," Meadows, 16th November, 1934.

Figure 14 —Close view of plot receiving 4cwts. superphosphate per acre at "Clear Hills," Meadows, 16th November, 1934.

Basic slag produced yields comparable with the equivalent dressing of superphosphate, but rock phosphate was much inferior and gave little increase over and above the control.

The effect of 56lbs. sulphate of ammonia was not nearly so apparent at the final harvest as at an earlier growth stage, the clover of the superphosphate only plots having made good the leeway to a material degree. Of the ten treatments,

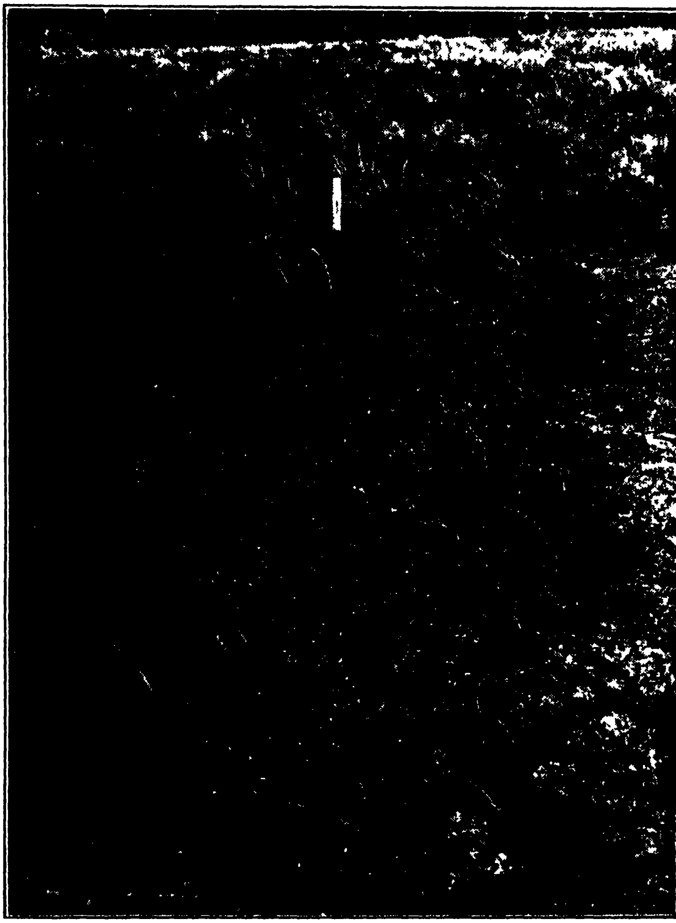

Figure 15.—Mixture of 5lbs. Subterranean Clover + ½lb. *Phalaris tuberosa* per acre; left—receiving 2cwts. superphosphate per acre; right—receiving no fertilizer; "Clear Hills," Meadows, 16th November, 1934.

however, the superphosphate + nitrogen plots were second only to the plots receiving 4cwts. superphosphate. From the Mitscherlich curve it is calculated that the yield of subterranean clover obtained with 2cwts. superphosphate + 56lbs. sulphate of ammonia would have been obtained with 2¾cwts. superphosphate, which is a cheaper dressing by approximately 3s. 6d. per acre. As against that, however, there is an increase of more than 50 per cent. in the development of the associate perennial grass during the first season, which may prove a material advantage.

The competitive effect of the subterranean clover is exemplified in the case of the 4cwts. dressing, as a result of which the miscellaneous annuals present have been depressed and the rate of increase of *Phalaris* has been slightly retarded. *Phalaris* appears better able to withstand competition from subterranean clover than many other plants, owing to its capacity for tallness. The tendency to dominance on the part of the clover appears to be most evident under conditions of maximum phosphate and minimum nitrogen supply.

At the Waite Institute, a basal dressing of 2cwts. superphosphate per acre has been used in all seeded pasture experiments and has proved entirely satisfactory. The application of sulphate of ammonia, however, has not tended to improve the development of seeded pastures, and in this habitat tends to depress clover materially when two dressings of 1cwt. per acre each are applied, one in autumn and one in late winter.

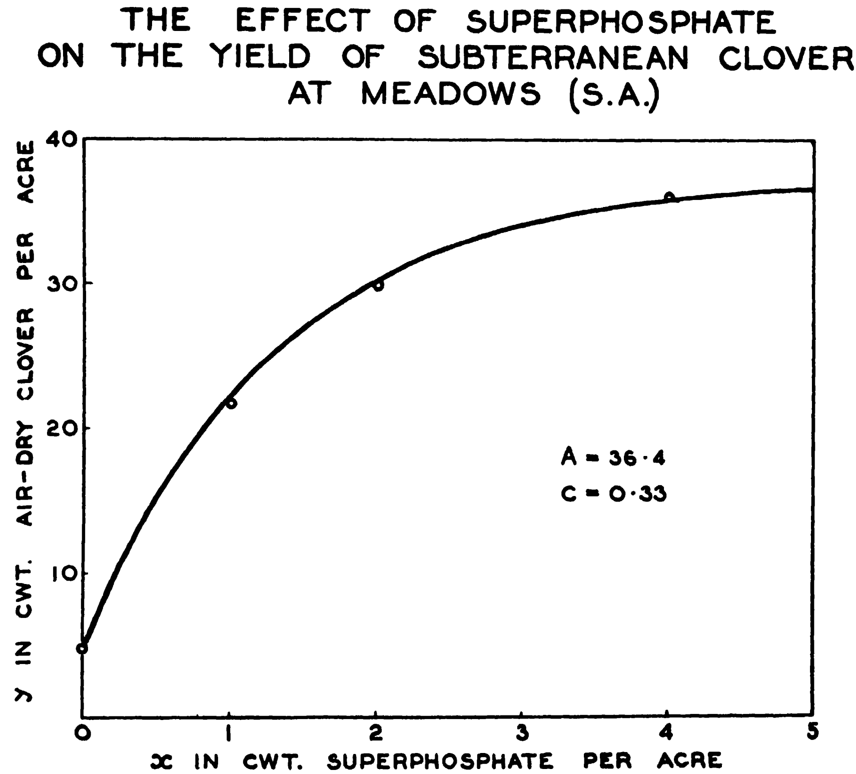

Figure 16.—Curve showing the relationship between the yield of Subterranean Clover and the quantity of superphosphate supplied, "Clear Hills," Meadows, 1934.

During the 1930 autumn, a series of seeded pasture plots was established on a soil typical of the red-brown earth class, on peppermint country at the Waite Institute. This series included pure plots of Wimmera and perennial rye-grass of the Hawke's Bay strain, *Phalaris tuberosa* and a selected mixture of *Danthonia* strains. It also included a pasture mixture of Wimmera rye-grass (5lbs.), perennial rye-grass (10lbs.), *Phalaris tuberosa* (10lbs.) and Dwalganup subterranean clover (5lbs.). Each set of plots received a basal dressing of 2cwts. superphosphate per acre, but was top-dressed with sulphate of ammonia (2cwts. per acre) on every alternate pair of plots, following the ABBA system with eight replications.

Whereas the pure grasses without exception responded to nitrogen, the pasture mixture was depressed by the nitrogen dressing in the fourth and fifth seasons, and over a five years' period nitrogen showed practically no total response.

The total yields under grazing for the three years' period 1931-33 are given in the following table.

TABLE V.—*Showing the response of pure grass swards to the application of 2cwts. sulphate of ammonia per annum over a three year period,* 1931-33.

Grass.	Total Pasture Yield (cwt. per acre).		Increase Due to Nitrogen.	
	No Nitrogen.	Nitrogen.	Cwt. Per Acre.	Per Cent.
Wimmera rye-grass	62·94	125·22	62·28	99
Perennial rye-grass	81·06	115·17	34·11	42
Phalaris tuberosa	99·43	133·97	34·54	35
Danthonia	70·94	90·16	19·22	27

The order of fertility requirement as indicated by the percentage response to nitrogen is in agreement with practical experience with these grasses.

The pasture mixture, after establishment, was subjected to (1) rotational grazing, (2) systematic mowing, (3) annual cutting for hay. The pasture, which was sown on fallow, was dominated by Wimmera rye-grass in the first year.

In the second season, perennial rye-grass assumed almost complete dominance. During the third and fourth seasons, *Phalaris tuberosa* and early subterranean clover increased materially, *Phalaris* becoming dominant on the area cut for hay and clover assuming dominance under systematic mowing. In the fifth year of the experiment, perennial rye-grass disappeared almost entirely, and all three classes were dominated by *Phalaris tuberosa,* with approximately only one plant of the latter to 4 sq. ft. throughout.

The responses to nitrogen over four seasons are given in the following table:—

TABLE VI.—*Showing the response to nitrogen* (*2cwts. sulphate of ammonia per acre per annum*) *of a seeded pasture mixture at the Waite Institute,* 1930-33.

	(Cwt. air-dry herbage per acre).				
	1930.	1931.	1932.	1933.	Mean.
Systematically cut	+3·25	+10·74	−3·24	−5·97	+1·19
Cut and grazed	+3·93	+10·23	+3·86	−3·25	+3·69
Cut as hay	+6·88	+20·62	−1·38	−3·74	+5·59

The botanical composition on the "grazed" and "hay" sections in the fourth seasons was as follows:—

TABLE VII.

	"Grazed" Area.			"Hay" Area.		
	Lolium.	*Phalaris.*	Clover.	*Lolium.*	*Phalaris.*	Clover.
1. Yield in cwt. per acre—						
No Nitrogen	9·45	9·38	6·00	13·65	51·52	0·38
Nitrogen	14·66	5·43	1·07	21·68	39·86	0·27
2. Percentage composition—						
No Nitrogen	37·6	37·3	23·8	20·8	78·6	0·6
Nitrogen	67·0	24·8	4·9	35·1	64·5	0·4

The productivity of the pasture has been maintained at a high level as indicated by the yields on the no nitrogen plots which were as follows:—

	1930.	1931.	1932.	1933.	Mean.
Grazed Area (cwt.)	28·09	32·41	41·80	25·13	31·86
Hay Area (cwt.)	30·44	24·96	63·74	65·55	46·17

The influence of nitrogen, whilst producing no increase in productivity after the second season was responsible for pronounced changes in botanical composition, as indicated in Table VII. In general, the effect of nitrogen was markedly to increase perennial rye-grass which in turn depressed both *Phalaris tuberosa* and subterranean clover. It is considered that this depressing effect is largely due to root competition. Temporary dominance by perennial rye-grass is not desirable in areas liable to severe summer drought, owing to the thinning effect which this species has on species better adapted to withstand (1) the drought period, and/or (2) inevitable temporary declines in available soil nutrients. Much mortality with perennial rye-grass occurs during the winter months, when the rye-grass commonly assumes a yellow unthrifty appearance. *Phalaris tuberosa* established alongside the rye-grass is frequently a deep green colour and vigorous in development under the same conditions. An explanation for this difference may be found in the materially deeper root system of *Phalaris* which may be capable of picking up leached nitrates removed from the rooting zone of the rye-grass.

It appears fairly evident that the only established fertilizer for South Australian conditions as yet is superphosphate at the rate of approximately 2cwts. per acre for the first two or three years. Dressings of sulphate of ammonia of the order of 1 to 2cwts. per acre appear to be out of the question on the experience so far gained but there is scope for the further investigation of lighter dressings such as 56lbs. per acre. There is also scope for the investigation of management in respect to established seeded pastures. The problem of competition in pastures as affected by seeds rates, management, and manuring also merits further investigation.

Above annual rainfall conditions of 17 or 18ins., there appears to be a satisfactory range of plants in the rye-grasses, *Phalaris tuberosa*, subterranean clover and lucerne, with white clover, strawberry clover and cocksfoot for the irrigated areas and the temperate areas of the lower South-East. *Phalaris caerulescens* and *Atriplex semibaccatum* are both possible pasture species for country too arid for *Phalaris tuberosa*. The most desirable addition to this list would be a perennial winter-growing legume of the strawberry clover or white clover type.

So far as improvement within the species is concerned, strain investigation of *Phalaris tuberosa* and perennial rye-grass is being carried out at the Waite Institute. Additional species which would merit further investigation from this point of view, under South Australian conditions, are strawberry clover, in which there is much variation, subterranean clover and *Bromus unioloides* (Prairie Grass). Other species of importance are Kikuyu Grass—as an associate with subterranean clover on bracken country, and on areas which tend to remain moist in summer—and *Paspalum distichum* on swampy land. On the Murray swamps *Paspalum dilatatum* is being used where conditions of soil or management are not suitable for the more desirable rye-grass, cocksfoot mixture.

11. Seeded Pasture Mixtures Adapted to Particular Climatic and Soil Conditions.

As a result of the natural distribution of certain plants such as perennial rye-grass, cocksfoot, white clover and subterranean clover, which have been seeded over much of South Australia in past years, and as a result of many formal and private trials carried out in different parts of the State it is now possible to indicate

with a certain degree of confidence, a number of pasture mixtures as being suitable for specified types of environment. A tentative classification is given in the following table.

TABLE VIII.—*Showing pasture mixtures suitable for specified conditions of moisture supply and general soil type.*

	Conditions of Moisture Supply.		Soil Conditions (General soil type).	Suggested pasture mixtures.
	Total Rainfall (Ins.).	No. of Months R>E.		
1	Irrigation		Drained swamps	(*a*) Perennial rye-grass, cocksfoot, white clover, strawberry clover, red clover.
2	25	7	Volcanic soils and fertile loams	(*b*) *Phalaris tuberosa*, *Poa pratensis*, white clover, strawberry clover.
3	25	6–7	Poorly drained and highly leached soils	Yorkshire fog, white clover, subterranean clover.
4	20	5–6	Black rendzina soils and flats with soakage	(*a*) Perennial rye-grass, strawberry clover. (*b*) *Phalaris tuberosa*, (*Poa pratensis**), strawberry clover.
5	20	5–6	Loams, flats, and improved soils	(*a*) Perennial rye-grass, subterranean clover. (*b*) *Phalaris tuberosa*, subterranean clover. (*c*) Wimmera rye-grass, subterranean clover.
6	20	5–6	Unimproved podsols ...	Subterranean clover (very light seedings of Wimmera rye-grass and *Phalaris tuberosa*).
7	18	4–5	Red-brown earths, grey soils, mallee soils	(*a*) Wimmera rye-grass, early subterranean clover. (*b*) *Phalaris tuberosa*, early subterranean clover. (*c*) Lucerne (Wimmera rye-grass, *Phalaris*).
8	18	5	Light heath country with deep or retentive subsoils	(*a*) Lucerne, *Phalaris*, early subterranean clover. (*b*) Evening primrose.
9	Underground soakage		Friable surface soils with retentive subsoils	Lucerne (*Phalaris tuberosa*).

* Grasses given in brackets for certain conditions have not been fully investigated under the particular conditions noted but appear to be promising.

This brief survey has been very general, and in some respects, far from precise. As one becomes more precise in this type of work, one frequently becomes far less certain of one's ground. Biological work in general is characterized by a lack of that neat precision so readily obtainable in the physical or chemical laboratory; this is certainly true in agriculture, and is particularly true in grassland ecology. The main difficulty in pasture work is the lack of cogent and concrete entities. In the final event, the test of a pasture is in the quantity and value of the animal products obtainable from it per acre, and this can only be measured on a comparatively large scale. Much can be learnt, however, by accurate observation and reasoning, together with extended trials of an exploratory nature, provided these are backed by critical experiments designed to supply accurate data concerning specific problems.

ACKNOWLEDGMENTS.

The author desires to thank Mr. Norman Brookman, of "Burbrook," Meadows, for his ready and efficient co-operation in carrying out the "Clear Hills" experiment, near Meadows. To Mr. Basil Proctor, "The Glens," Mount Compass, grateful acknowledgment is also due.

Able assistance has been rendered at various times by Messrs. C. M. Donald, B.Sc.Agr., H. K. Kemp, B.Ag.Sc. (Hons.) and C. A. N. Smith, B.Ag.Sc., and this has been much appreciated.

The photography was in all cases carried out by Mr. A. D. Cocks.

Summary.

1. The nature and productivity of grassland associations are closely dependent on the climatic, edaphic and biotic factors of the immediate environment. It is not unreasonable to expect a close inter-relation between climax vegetation and the types of natural and seeded pastures which develop under essentially the same climatic and soil conditions.

2. The location of the grazing areas of South Australia and the intensity of stocking from point to point have been indicated by the combined dot distributions of sheep, cattle and horses, and these have been superimposed on a map of the major vegetation associations of the State. This delineates the grazing areas within each major type of vegetation and provides a basis for more detailed ecological studies.

3. Agronomic investigations have been confined mainly to the limited areas of forest and savannah; the indigenous grasslands here tend to be dominated by *Danthonia* spp., with *Microlaena-Eragrostis* co-dominant in areas of high and extended rainfall, and *Stipa* spp., co-dominant to dominant as the "mallee" type of environment is approached.

4. *Danthonia* pastures in South Australia appear to have developed chiefly on soils deficient in available phosphate and frequently low in available nitrogen as well. Superphosphate when applied to these pastures improves sheep-carrying capacity and wool production per acre to a material degree, but the utility of the resulting pastures is severely restricted by the generally inferior nature of the annual species which in turn become dominant.

5. The productivity of unfertilized or top-dressed natural pasture at Adelaide is limited primarily by low soil fertility and an inferior botanical nature but is also closely dependent on autumnal rains. It is much less dependent on winter rainfall and is little dependent on spring rains. This is indicated by high significant correlations between the yield of natural pasture and various types of autumnal rainfall, whereas there is little or no correlation between yield and late winter or spring rainfall.

6. Future progress in pasture improvement appears to depend very largely on the efficient use of superior species and strains of exotic herbage plants, even in the areas of dry savannah woodland and of mallee.

7. Legumes seem to be essential as the basis for pasture improvement in South Australia. This is because most soils of the higher rainfall areas tend to be deficient in total nitrogen, whilst even the less common soils of good natural fertility tend to become deficient in available nitrogen in the absence of cultivation or a suitable pasture legume. The legumes of established value for permanent pasture under South Australian conditions are Mount Barker and Dwalganup subterranean clover, lucerne, white clover and strawberry clover. The necessity for permanent associate grasses is now very obvious. The grasses of proven value are Wimmera rye-grass, perennial rye-grass and *Phalaris tuberosa*, with cocksfoot and *Poa pratensis* under irrigation.

8. The area of artificially seeded pasture is as yet small in proportion to the total area of land grazed. Up to the 1932-33 season, 208,418 acres had been sown. Material increases in the area established have occurred since 1923-24, principally since 1928-29.

9. The distribution of seeded pastures in South Australia has been mapped in relation to total rainfall, seasonal rainfall-evaporation ratio and mean air temperature. The dot dispersions for seeded pasture fall into two main groups:—

(*a*) Subterranean clover pastures, located principally south and east of Adelaide on podsolized soils or red brown earths with retentive subsoils.

(*b*) Lucerne, grown principally north of Adelaide. This species is much less dependent on immediate climatic influences than subterranean clover. The physical conditions of the subsoil and the presence of underground reserves of moisture are of paramount importance for lucerne under South Australian conditions.

10. Satisfactory establishment and a high order of productivity have been attained on a podsolized soil at Meadows, using a seeded mixture of 5lbs. subterranean clover + ½lb. *Phalaris tuberosa* per acre. Superphosphate and sulphate of ammonia both significantly improved the establishment of the pasture.

11. The yield of subterranean clover plotted against the quantity of superphosphate applied was found to fall almost exactly on the calculated Mitscherlich curve ($A = 37.40$cwts., $K = 0.33$). The maximum dressing appeared to be 5.8cwts. superphosphate per acre and the most economic dressing in practice approximately 2cwts. per acre. The addition of ½cwt. sulphate of ammonia to the superphosphate dressing increased the yield of clover by a further 3.4cwts. per acre, and *Phalaris* by 1.2cwts. per acre.

12. Pure grass swards at the Waite Institute, on a typical red-brown earth were found to respond very materially to artificial nitrogenous dressings, the order of response being Wimmera rye-grass, perennial rye-grass, *Phalaris tuberosa, Danthonia.* On the other hand, a seeded pasture mixture containing clover, after showing a good response to nitrogen in the second year of establishment, was depressed by nitrogen treatment in succeeding years and over a four-year period the total increases due to nitrogen treatment were negligible.

13. A list of pasture mixtures tentatively suggested for specified environmental conditions is given.

IMPORTANT WEEDS OF SOUTH AUSTRALIA.

[By G. H. CLARKE, B.Sc., Botanist at the Roseworthy Agricultural College.]

No. 15.—SLENDER THISTLE.

Carduus tenuiflorus, Curtis.

There are some thirteen species of true thistles in this State, all of which have been introduced, and several of these have been already described in the present series of articles. Regarded as weeds, the character common to all of these plants is the presence of prickles or spines, sometimes confined to the flower-heads, but more usually present also on the stems and foliage. Taken in conjunction with their capacity for rapid multiplication by seed, this character makes the thistles objectionable as a group, rendering them unsuitable as feed for stock, difficult to handle, and liable to cause wounding. Of those naturalised in South Australia, five are on the list of noxious weeds; four—namely, the Star Thistle, the Yellow Cockspur, the Saffron Thistle, and the Canada Thistle—being proclaimed for the entire State, and the remaining one—the Variegated Thistle—for the district of Mount Gambier only. In addition to the importance of certain thistles as individuals, a degree of importance is to be attached to the group as a whole, so that it is desirable to be able to distinguish them, one from another. Certain species, not listed as noxious, are therefore deserving of brief description in this series of "Important Weeds."

The Slender Thistle (*Carduus tenuiflorus*) affords an example of a relatively unimportant member of an important group of weeds. It is an annual or sometimes biennial thistle, easily distinguishable from others by its diffuse, spindly habit, and by having the slender branching stems bordered by spiny wings and terminating in small clusters of flower-heads with pink or purple florets. The individual heads are small and slender as compared with those of other local thistles; they are not more than an inch in length, and much less than this in breadth, their narrow appearance being accentuated by the fact that the surrounding and protective involucral bracts, though numerous and sharp-pointed, do not spread outwards as they do in some other thistles. The whole plant is of a whitish-green colour, due to the presence of a felt-like covering of woolly hairs, most abundant on the under surfaces of the leaves.

Botanical Name and Classification.—Carduus, Latin *Carduus,* a thistle) is an important but rather ill-defined, genus of thistles. Willis gives the species as 35, but remarks that scarcely any floras agree in the species assigned to this and to the nearly related genera *Cnicus* and *Cirsium.* The Variegated Thistle (*Silybum Marianum,* Gaertn.) is included, by some authors, within *Carduus* as *C. Marianus,* L. The detailed structure of the florets present in the head is very similar in both *Carduus* and *Silybum,* but the staminal filaments are free in the former genus and united to form a tube in the latter. The species *tenuiflorus* (literally "slender-flowered") is characterised by having slender, relatively small, clustered flower-heads falling off when mature, by the shape of the surrounding bracts, and by having spiny decurrent wings along the entire length of the stems. *C. tenuiflorus* is synonymised by Ewart ("Flora of Victoria") under *C. pycnocephalus,* Jacq., a very similar species of which the type differs from *C. tenuiflorus* in having fewer and larger flower-heads and stems not winged at the summit. It is possible that the two are not specifically distinct. Some local forms approach *C. pycnocephalus* in having stems which, though spiny, are not conspicuously winged at the top, and a good deal of variation is found as regards the number and size of the flower-heads in a terminal cluster.

Slender Thistle (*Carduus tenuiflorus*, Curtis).
A.—Flower head. B.—Floret. C.—Achene from front. D.—Achene from side.

Botanical Description.—An erect annual or biennial, 1ft. to 4ft. high; stems simple or branched, spiny-winged and leafy up to the summit; leaves sinuate or pinnatifid, white-tomentose especially below, armed with strong spines, the upper ones decurrent and continuous with the winged spiny margins of the stems; heads small, slender, sessile, arranged in clusters, caducous; involucre oblong-cylindrical; bracts numerous, tapering into slender outwardly curved spines, the inner ones equalling or surpassing the purple florets; florets tubular and bisexual; receptacle hairy; achenes oblong, glabrous; pappus of simple bristles. In flower: October-January.

The Slender Thistle occurs along roadsides and waste places, and to a less extent on cultivated ground. It forms large amounts of seed which germinate readily, and dense growths of the weed are sometimes met with, especially in moist situations. Fortunately it does not appear to be aggressive in pasture land, and, not being perennial, does not present a difficult problem of eradication.

PRUNES FOR OVERSEAS MARKETS.

[*Below is a statement recently made by the Minister of Agriculture (Hon. A. P. Blesing, M.L.C.) with reference to the size and variety of prunes for export overseas.*]

Since the new regulations have been put into force under the Dried Fruits Act, it has been evidenced that the proportion of the South Australian production which weighs more than 100 prunes to the pound is in the proximity of 40 per cent. of the whole production, and prunes of this size cannot be marketed overseas at prices which will return the cost of production to the grower. During the last year or so, large Californian prunes have been sold in London and Glasgow shops at 6d. per pound, and there does not appear to be any immediate prospect of the market rising to any great extent. While such fruit is to be bought, the oversea housewives will not purchase small prunes at any price.

The Minister is appealing to the growers to take such steps as are necessary by pruning and thinning the fruit on trees to raise the South Australian quality, and is soliciting the assistance of the Agricultural Bureau in growing areas to this end.

The South Australian Prune-growers' Association in its report to members states:—

"Your executive is concerned as to the fate of growers of small prunes, as throughout the world the demand is principally for large fruit. Cultural improvements aiming at an increase in the size of South Australian prunes are the most urgent necessity facing the industry to day. Overseas orders for large prunes are now being lost owing to the shortage in the supply of this type, whereas small prunes are only saleable overseas at prices which would hardly pay the charges. On the Australian market the offerings of small prunes have been proved to have a detrimental effect on the total consumption, housewives looking askance at prunes after once having bought small prunes at low prices."

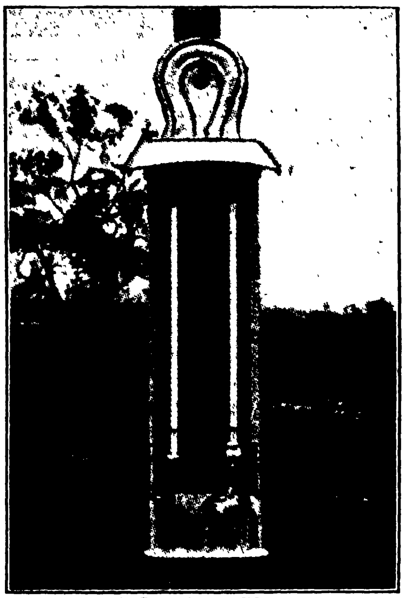
The Minister is advised that the time is fast approaching when it will be in the interest of growers who are producing varieties of prunes which are not in general demand to replace these by varieties which sell more readily. The varieties most easily saleable are:—(1) D'Agen, (2) Robe DeSargent, (3) Splendour. Such varieties as French, German, Fellemberg, and Sugar are increasingly difficult of sale while such large quantities of D'Agen and Robe DeSargent are being placed on the Australian market from New South Wales, and their inferior keeping quality makes a definite risk in shipping overseas.

FROST PREDICTION.

[By A. G. STRICKLAND, M.Agr.Sc., Deputy Chief Horticultural Instructor.]

Inquiries have been received regarding the use of a wet and dry bulb thermometer for the purpose of frost forecasting, and brief notes on procedure are here appended. With the aid of this inexpensive instrument, it is a simple matter for fruitgrowers to advise themselves with reasonable accuracy during the evening of the risk of frost on the following morning.

The instrument comprises two thermometers side by side, the bulb of one being kept constantly moist by means of a wick which dips into a small reservoir of water. The thermometer should be affixed to a convenient post at a height of



Wet and Dry bulb Thermometer.

4ft. to 5ft. from the ground, and shaded, preferably by installation in a shelter of the type described by Mr. J. B. Harris in his bulletin on "Frost Prevention by Orchard Heating."

On calm nights heavy frosts are far more likely when the air is dry, *i.e.*, when the temperature of the wet bulb thermometer is far below the dry bulb temperature, than when the air is moist, or the wet bulb temperature closely approaches the dry bulb temperature.

Translation of differences between the wet and dry bulb temperature readings into terms of frost danger involves some calculation, but by means of a simple chart devised by a Viennese instrument-maker—Kappeler—such calculation may be avoided.

A modification of Kappeler's chart was published by the Victorian Viticulturist, Mr. F. de Castella, in the Victorian *Journal of Agriculture* some years ago. This chart is now reproduced, together with notes from de Castella's article, for the benefit of those growers who wish to utilise the wet and dry bulb thermometer for frost prediction.

Readings are taken on the wet and dry bulb scales about sunset, due recognition being given to the fact that if a strong wind is blowing at the time, the observations will not be reliable; wind will cause excessive evaporation of the surface of the wet bulb which evaporation will have a cooling effect, and result in an abnormally low wet bulb temperature reading. Having obtained reliable readings, the above chart is consulted with the object of determining the locality of the point of intersection of lines proceeding respectively from the observed wet and dry bulb readings. If this point of intersection falls between the two dotted lines running diagonally across the chart, there is danger of frost; if the point

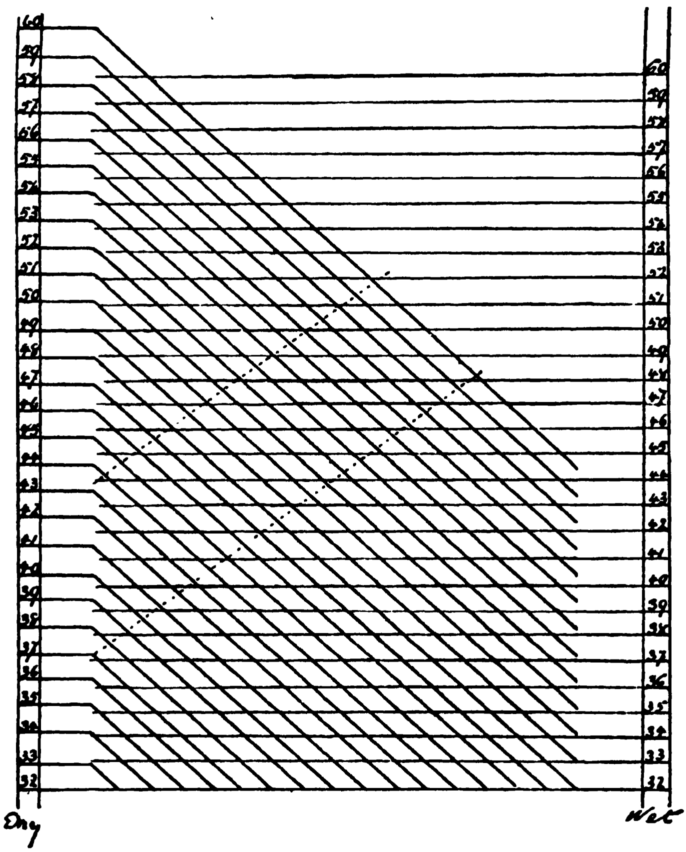


Diagram for prediction of frost.

falls above the uppermost dotted line, there is no danger; and if the point is below the lower dotted line, frost is certain unless cloud or wind develops very rapidly.

Three hypothetical cases are given below in order to illustrate the use of the chart.

Dry Bulb Temperature.	Wet Bulb Temperature.	
52°	49°	Safety.
50°	45°	Danger.
50°	42°	Certain frost.

Irrespective of whether an automatic frost alarm thermometer is installed or not, a wet and dry bulb thermometer used in conjunction with the chart accompanying this note will give very valuable preliminary information to growers.

AGRICULTURAL BUREAU CONFERENCES.

RIVER MURRAY.

The Annual Conference of River Murray Branches of the Agricultural Bureau was held at Moorook on 20th June. The attendance included members of Branches at Moorook, Renmark, Barmera, Monash, Berri, Ramco, and Waikerie. Mr. F. J. Petch presided and Mr. J. B. Murdoch, representing the Advisory Board of Agriculture, delivered the opening address. The following papers were read:—"The Source of Castor Oil" (Mr. M. J. Herbert, Moorook); "Ailments of Stock" (Mr. F. J. Petch, Moorook); "Why is the Currant Deteriorating?" (Mr. L. A. Chapple, Berri); "Irrigation and Drainage" (Mr. F. R. Arndt, District Horticultural Instructor); "The Economic Value of Australian Birds" (Mr. S. Saunders, Jun., Moorook); and "Green Manuring" (Mr. P. M. Wilksch, Berri). Professor Perkins (Director of Agriculture), Messrs. A. G. Strickland (Chief Horticultural Instructor), N. S. Fotheringham (Manager of Berri Experimental Orchard), and H. C. Pritchard (General Secretary) were also present to reply to questions and to assist in discussions. In the evening Mr. Strickland gave an illustrated address on "Fruit Setting."

It was decided that the next Conference be held under the auspices of the Block E Branch.

EYRE'S PENINSULA (WEST).

The Branches situated in the west districts of Eyre's Peninsula held their Conference at Ceduna on 3rd July, when the Goode Branch was responsible for the arrangements. This was one of the best attended and one of the most successful Conferences which these Branches have held during recent years. While no papers were submitted by members, the agenda was comprised mainly of questions which had a direct bearing on agricultural practices of the district.

The Hon. A. L. McEwin, M.L.C., opened the proceedings and Mr. C. P. Linke presided

In reply to a question asking for an explanation of Goyder's Line of Rainfall, Mr. R. C. Scott (Supervisor of Experimental Work) read a statement which had been prepared by Professor Perkins (Director of Agriculture), who was unavoidably absent. Mr. Scott also dealt with questions relating to the best method of pickling wheat, the milling qualities of wheats in the district as compared with those of the South-East, sheep on fallowed land in mallee districts, mustard seeds found in superphosphate, and the effect of weevils on the germination of seed oats. In the evening, Mr. Scott addressed the meeting on "Suggestions for Improving Returns on Eyre's Peninsula." Mr. H. B. Barlow explained the working of the Dairy Produce Act and Mr. C. A. Goddard gave a demonstration of woolclassing. Messrs. W. H. Brownrigg (District Agricultural Instructor) and H. C. Pritchard (General Secretary) also attended and assisted in the discussions.

The following resolutions were carried:—"That in view of the favourable condition of the State's finances and the unfavourable reports in respect to agricultural operations in these districts, the Government be requested to give relief from motor registration"; "That the Federal Government be asked to remit the tax on petrol"; "That the Federal Government be asked to form a compulsory pool so as to raise wheat to a payable price"; "That we consider there is a very urgent need for reticulating the water on Upper Eyre's Peninsula where farmers are carting water from existing mains"; "That the next Conference be held at Ceduna under the auspices of the O'Loughlin Branch."

GLYCERO-BORIC BLOWFLY DRESSING.

The work of the Council for Scientific and Industrial Research on the blowfly problem has been mainly directed towards the discovery of means of preventing the attack of sheep by blowflies, but the problem of cleaning up blowfly strikes when they occur has also received considerable attention. Numerous dressings commonly used by pastoralists, and also many other substances, have been tested by the Council's Division of Economic Entomology at Canberra, but, until a few months ago, no dressing was found to have all the desirable properties.

To be satisfactory, a blowfly dressing must not only kill the maggots present, but must also help to heal the wound and render it no longer attractive to blowflies. Most dressings commonly used kill the maggots, but many of them also injure the delicate skin of the sheep, and this has been shown to increase the susceptibility of the treated area to blowfly strike. The few dressings commonly used which do not damage the sheep's skin have been found to be unsatisfactory for other reasons.

When investigating the effect of various chemicals on the attractiveness of baits, Mr. M. R. Freney, the biochemist of the Council's team of blowfly research workers, found that baits treated with glycerine or boric acid did not attract blowflies. For various reasons it was thought that a combination of these substances might form a satisfactory blowfly dressing. Dr. I. M. Mackerras, Dr. M. J. Mackerras, and Mr. Freney then carried out over a hundred tests with this dressing under rigorous conditions in the insectaries at Canberra with most promising results.

This new dressing is a colourless, odourless, rather viscous fluid which is easily rubbed into the shorn area of a strike, and adheres readily to the fleece and skin. A few minutes after application the unpleasant normal odour of the strike is changed and becomes much less unpleasant. The maggots are killed rather slowly, 24 to 30 hours often elapsing before all are dead, but they cease to worry the sheep immediately the dressing is applied. Temperature records of struck sheep clearly show the relief afforded, the fever temperature (106° to 108° F.) quickly falling to normal (102° F.) after application of the dressing. The effect of the dressing on the strike wound is decidedly beneficial. The extension of damage to the skin is immediately arrested, and inflamed, but unbroken, skin becomes soft, flexible, and healthy, without any sign of crust. So far it has been found impossible to produce an experimental restrike on a dressed area, even after liberal wetting, but the testing of this point is not yet completed.

In many respects the tests already carried out in insectaries are more rigorous than field tests, but the proof of the value of the dressing must ultimately depend upon the results of extensive tests under normal station conditions. Because of the promising results already obtained, however, the Council has decided to make the new dressing known to pastoralists at this stage, although final proof of its satisfactory large-scale applicability has not yet been obtained.

A relatively simple dressing, which has given quite good results, may be prepared as follows:—Take 1gall. (13lbs.) of glycerine and add 3lbs. of powdered boric acid (commonly known as boracic acid). A thick paste is formed which is then heated and stirred until all the boric acid is dissolved. This results in the formation of various borates of glycerine. After cooling, the clear solution should be kept in well corked bottles or tins, and should be used without dilution.

Better dressings may be made by using more elaborate methods of preparation. For example, preparations containing a higher proportion of boric acid and which have been subjected to temperatures of about 300° F. have given excellent results, but these would be difficult to prepare on a station. If the tests in progress ultimately prove these preparations to be decidedly better than the simple dressing described above, then a means of producing them in bulk at a reasonable price will no doubt be found.

At present prices of the pure chemicals, the cost of the dressing is 11s. per gallon, which works out at about 2d. for each sheep dressed. Tests are being made with crude glycerine, and if it should prove that this can be substituted for the pure product, costs will be about halved.

It is hoped that some pastoralists will try the glycero-boric dressing during the coming season, and that they will let the Council know what kind of results they obtain. Communications should be addressed to the Division of Economic Entomology, P.O. Box 109, Canberra City, F.C.T.

INFECTIOUS ENTERO-TOXAEMIA OF SHEEP.

[At the Ceduna Conference of the Agricultural Bureau, a member of the Petina Branch asked for a résumé of toxaemia poisoning which has been the cause of death of so many sheep in the district. The appended summary was supplied by the Veterinary Branch of the Stock and Brands Department.]

Infectious *entero-toxaemia* is a common disease in this State, affecting grown sheep and lambs running on cultivated paddocks or top dressed pastures. Common names for it are "Stinkwort Poisoning," "Braxy-like Disease," and "Pulpy Kidney of Lambs."

The disease is in the nature of a rapid poisoning set up by the absorption into the animal's system of a powerful toxin (or poison) produced in the bowel by the rapid growth therein of a germ known as the *Bacillus ovitoxicus.*

The disease occurs mainly during the Autumn, Winter, and Spring months. It may appear after the first Autumn rains where the flocks are on cultivated paddocks containing a profuse growth of stinkwort—elsewhere it follows on the establishment of good green feed. Losses from it are usually greatest in the late Autumn and again in the Spring, when lambs more particularly are affected. Good seasons with abundance of green feed are generally bad seasons for infectious *entero-toxaemia.*

Animals of any age from three weeks upwards and of either sex may be affected, and affected animals are almost invariably those in good condition. Sheep in store condition are rarely affected.

Mortalities are usually greatest on farms or in districts where the disease occurs for the first time. In areas where the disease is well-known the death rate is usually lower on the average, excepting amongst sheep that have been newly introduced from areas where the disease in unknown.

Symptoms.—The period of sickness being short (2-4 hours), symptoms are more often than not not observed by the owner, the animals generally being just found dead of a morning near where they camped overnight. Sick animals may be observed when the flock is moved about—they lag behind and develop a staggering gait, with knuckling over of the front limbs. They soon go down, and either just lie quietly until death occurs, or they may struggle violently. Frothing at the mouth and champing of the

jaws are frequently observed, and bloating may become marked prior to death. The losses from infectious *entero-toxaemia* are, as a rule, never great at any one time, but appear more gradually spread over a period of weeks.

Post Mortem.—The carcass is almost invariably that of a well-nourished animal. It is blown up, the skin frequently showing a dark-bluish discolouration. The paunch and small bowel are found to be full of gas and contain less solids than usual, and, on slitting the bowel open, its lining appears redder than usual. A variable quantity of pale-coloured fluid may be found present in the abdominal and chest cavities and in the heart sac. The kidneys are frequently soft and pulpy, especially in lambs (hence the name "Pulpy Kidney").

Predisposing Factors.—The germ of infectious *entero-toxaemia* is a soil inhabitant, and sheep may take it into their digestive tract along with the feed and water. Under normal conditions it occasions them no harm, but if conditions are favourable for its rapid proliferation in the bowel, it becomes pathogenic. Sluggishness of the bowel, induced by lack of exercise, coupled with feeding on abundance of green feed low in fibre content, is very favourable for the production of the disease. Early morning grazing on pasture while it is wet with dew or frost is also dangerous. Injury to the lining of the bowel wall, caused by the pappus hairs of stinkwort, also provides conditions favourable to proliferation of *Bacillus ovitoxicus* in the bowel and the production of the disease.

At times the disease will occur where conditions appertaining to the property are such as are likely to lead to heavy contamination of the soil with the causal organism, viz., cultivation, heavy stocking, and sheep carcasses frequently left lying about to act as incubators for the germ. On such properties grazing sheep, especially if they have to graze "close," may take in through the mouth massive doses of the germ sufficient to set up the disease.

Treatment.—Medicinal treatment is not practicable.

METHODS OF CONTROL.

1. *Vaccination.*—Protective vacination of flocks against infectious *entero-toxaemia* has given very promising results in Western Australia, and this treatment is available for application in this State. Vaccination should be carried out some few weeks before the infectious *entero-toxaemia* season begins. Arrangements have now been made for stockowners to obtain necessary supplies of vaccine direct from the Commonwealth Serum Laboratory, Parkville, Victoria, *providing they first obtain from the Chief Inspector of Stock, Adelaide, a written permit, which must be forwarded with their order to the Laboratory.*

2. *Exercise.*—Compulsory exercise has been found to be beneficial in controlling the disease, and some sheep men claim to be able to prevent it by "dogging" the sheep round the paddock daily.

3. *Feeding of Fibre.*—Curtailing the grazing on green feed to some extent and supplementing this with hand-feeding of chaff is often found beneficial in preventing and checking the progress of the disease. A change on to a rougher type of pasture is also often beneficial.

4. If possible, close grazing should be avoided.

5. Where young lambs mostly are being affected, weaning of them will almost invariably check the progress of the disease immediately. Yarding the ewes and lambs for 24 hours once every four to seven days has given very good results.

6. *Disposal of Carcasses.*—The germ multiplies in carcasses of sheep which have died from this disease, and heavy contamination of the soil results from this source. All carcasses should, therefore, be effectively destroyed as soon as possible to prevent this contamination occurring.

FEEDING TESTS AT PARAFIELD POULTRY STATION.

[New Series of Tests by C. F. ANDERSON, Government Poultry Expert.]

In continuing the experimental feeding tests at Parafield Poultry Station, a new series o tests commenced on 1st April, 1935. Five tests each of 50 white Leghorn pullets were selected. The pullets were chosen as nearly even in age, type, and maturity as was possible.

In order to gain further information on the various methods of feeding, some of the tests are similar to the series which concluded on 31st March, 1935.

The following are the methods to be adopted, together with the results from 1st April to 30th June.

Feeding Tests commenced on 1st April, 1935.

1. Wet mash, composed of crushed barley and crushed wheat, with greenfeed and meatmeal; 2ozs. wheat per day.
2. Standard bran and pollard mash, with greenfeed and meatmeal; 1½ozs. wheat per day.
3. Bran and crushed wheat mash, with greenfeed and meatmeal; 2ozs. wheat per day.
4. Mash of crushed oats and crushed wheat with greenfeed and meatmeal; wheat, 2ozs. per day.
5. Commencing with a crushed barley and crushed wheat mash, greenfeed, meatmeal and then the feeding to be changed according to the season of the year.

	No. Eggs Laid 1st April, 1935, to 31st May, 1935.	No. Eggs Laid Month of June, 1935.	Total Eggs Laid 1st April, 1935, to 30th June, 1935.

THE STATE EXPERIMENT ORCHARD, COROMANDEL VALLEY, NEAR BLACKWOOD, SOUTH AUSTRALIA.

[By GEO. QUINN, Chief Horticultural Instructor.]

(*Concluded from page* 1391.)

ROOTSTOCKS—FOR PEACH TREES.

As has been the case in all other warm temperate parts of the globe, the peach tree has proved adaptable to a very wide range of the soils and climatic conditions found in this State. In fact, the only absolutely restraining factors to its well-being here would appear to be the excess of winter cold and moisture experienced in limited areas of the extreme south-east, and Mount Lofty Ranges, and the excessive dryness of the hot, low rainfall areas of the interior, where water suitable for irrigation purposes is seldom available.

Brigg's Red May on Almond Stock.

In so far as soils are concerned, it has been found to thrive best where there is a depth of from one to more feet of a well balanced loam containing sufficient sand and organic matter to render it friable and retentive of moisture when subjected to appropriate annual tillage operations. The subsoil should afford an efficient, yet not too rapid, means of drainage relief from any temporary excess of rain or irrigation water.

As previously remarked in this report, the principal subsoils of much of our orchard land consist of deep bands of clay varying in their degrees of resistance to water penetration in different localities, whilst in others the sublayers consist of limestone crusts or calcareous marls, often of

E

Elberta on Almond Stock.

Salwey on Almond Stock.

considerable depths. In the coastal non-irrigated areas, these marls are sometimes more or less blended into the clay substrata. It has only happened when planting certain varieties of peach trees under these latter conditions of soils and subsoils that a limited resort has been made to the use of rootstocks of a different species of prunus—chiefly the almond. At the time these trials were initiated, the growing of peaches on a commercial scale was receiving a good deal of attention in many districts in this State. Plantings were extending into the drier localities north of Adelaide, in the irrigation areas along the valley of the Murray River, as well as creeping up into the wetter and more elevated parts of the Mount Lofty Ranges. In the great majority of these plantations, the rootstocks used consisted of seedling peach trees raised from the stones or "pits" of many varieties. These were usually obtained by the nurseryman in large quantities from the jam making and fruit preserving factories.

Brigg's Red May on Myrobalana Plum Stock

In the drier unirrigated districts where calcareous subsoils were much in evidence, and yellow-fleshed peaches were being grown for canning purposes, the seedling hardshell sweet almond stock was resorted to by some growers. This departure had its warrant in that in parts of Europe and on the Pacific slope in America—chiefly in California—this stock had been used extensively for peach trees. In Europe, rootstocks of the St. Julien, Black Damas, Myrobalan, and common Mussel, and in America, the St. Julien and Damson plums also had been long in use when propagating peach trees for planting in heavy and fairly cold soils.

With these facts before him, the writer, in 1909, when formulating the trials outlined herein, decided to include amongst the rootstocks all of the species or varieties of same which were locally available, of those kinds used in other countries, to see which of them might possibly afford some information relative to their compatibility with certain representative commercial varieties of peaches then in favour in this State.

Elberta on Myrobalana Plum Stock.

Salwey on Myrobalana Plum Stock.

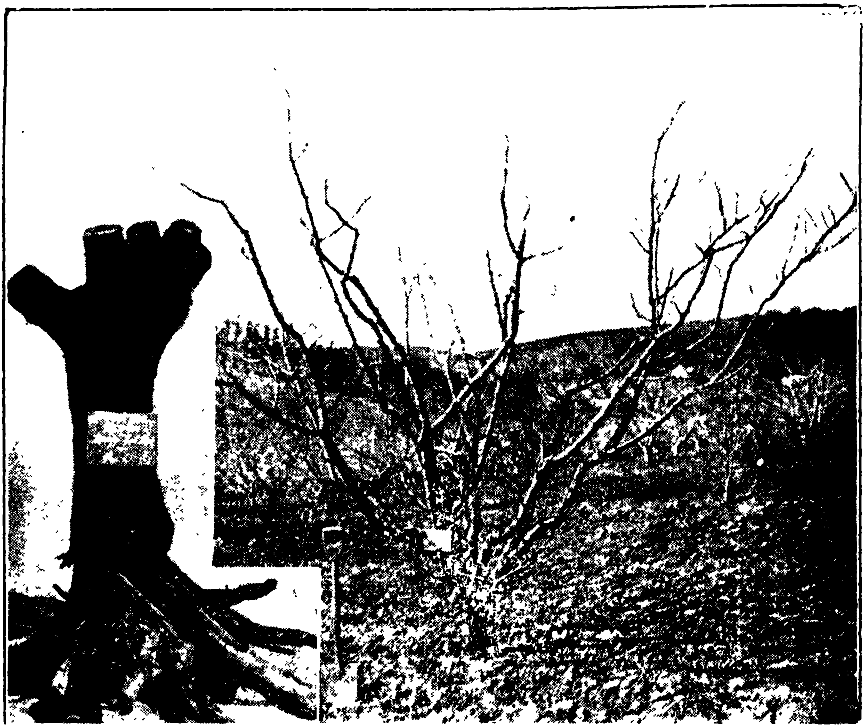
To this end, seedlings were procured from a reliable local fruit tree nurseryman of peach, apricot, almond, Myrobalana plum, and of a chance cross deemed to have taken place between an almond and a peach tree. This latter tree bore foliage midway in appearance between that of a peach and almond, in that its leaves had the colour and texture of the leaf of the former, but the smooth flatness of surface similar to that displayed by the leaves of most varieties of cultivated almonds. The fruits were not so rounded or spherical in shape as those of the cultivated peaches, but possessed a highly coloured epicarp or skin over a thick, almost flavourless mesocarp which, when about to ripen, split open sufficiently to reveal an endocarp or stone, the exterior of which was covered with the deep fret-work of pittings typical of the peach stone. The seedlings of this tree were stout and vigorous in habit. As a limited number only of trees of each of these kinds of stocks were to be used, it was possible to select for budding only those which bore evidences of healthy even development. In addition to the five kinds of rootstocks named above, a combination stock consisting of an almond seedling with an intermediate stem-piece of the hardy, robust growing Salwey variety worked upon it, was used. Upon this in turn the selected varieties of peaches were budded.

These varieties comprised Brigg's Red May, representing the shy bearing earlier ripening types of white fleshed semi-freestone dessert peaches; Elberta, the most widely planted mid-season ripening yellow flesh freestone variety grown for dessert and drying purposes, and at that time, very freely used in local canneries; the Salwey, a late ripening yellowish-green, tough fleshed freestone variety regarded as the most popular canning peach at that period when the clingstone varieties were not favoured by local fruit preserving factories.

The fourth sort, Nicholl's Orange Cling, is a late ripening, large fruited, richly flavoured and highly coloured clingstone variety, representing that type only then being talked of for canning purposes in Australia. This was prior to the introduction of those varieties of clingstone which carry no colour around the stone. The seedling stocks are recorded as having been worked in the nursery at the Blackwood Orchard by the then Manager (Mr. C. G. Savage) in October, 1909, and the trees planted out into the trial plot during August, 1910. (Most of the trees used in the early plantings of stone fruits in this orchard were bench grafted seedlings, using the simple form of splice or whip graft—not whip and tongue —and moulding the raffia-tied union over with clay prior to planting the grafts out into the nursery beds. By adopting this method, a season was saved in preparing the trees.)

The plot of land devoted to these trials is contained in Block D, as shown on the orchard plan. It is located on the upper portion of the slope near to the south-western corner of the orchard area. It immediately adjoins the pear rootstock trial plot on its southern and uphill side. Its greater length extends for 150ft. along the slope from east to west, and its full width is 86½ft. The surface fall to the westward is approximately 33¼in. along the upper side, and 25⅝in. along the lower margin per chain. The fall to the north along the eastern end is 79¼in., and down the western end, 55in. per chain. It will be seen, therefore, that the surface of this portion of the land falls rapidly to the north, thus presenting a very sunny aspect to the trees planted thereon.

The soil in general character, is similar to that described in respect to the adjoining plot carrying the pear rootstock trials. Four test holes were sunk in fairly even order of distribution over the slope. Along the lower— which is the northern half—in the vicinity of the western end where trees



Brigg's Red May on Peach Stock

Salwey on Peach Stock.

Nicholl's Orange Cling on Peach Stock.

on apricot and peach x almond stocks were planted, about 11in. of a dark-brown coloured, somewhat intractable clay loam rests on 18in. of bluish coloured, gritty marl. Below this is 6in. of a dry, calcareous mixture, which crumbled and readily fell away from the auger. At this depth (35in.), the sublayers became very consolidated without actually reaching the local rock. On the lower eastern portion occupied by almond and plum stocks, only 8½in. of this brown clay loam covered a layer of yellowish marly clay 8½in. thick, but which became slate coloured, crumbling and readily bored about 6½in. deeper. This condition persisted to 2ft. 6in. below the surface, but no solid slate rock was suspected from soundings made with the crowbar several inches deeper.

Brigg's Red May on Apricot Stock.

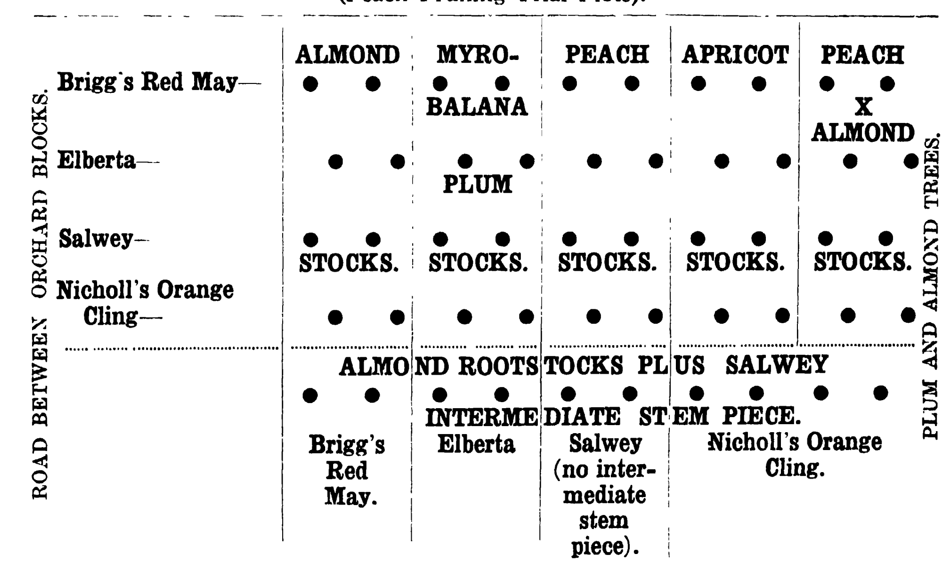
Along the upper and western portion carrying trees on apricot and peach x almond stocks, 9in. of brown clay loam covered a dark red, fairly tough clay layer 14in. thick. At this depth, yellow gritty marly clay followed for 15in., and persisted from 38in. below the surface without any immediate evidence of rock. Towards the lower eastern portion where trees on almond and plum stocks grew, 13in. of the brown loam covered a layer 6in. thick of rather tough red clay. Below this, for 6in., a somewhat dry, stony formation, only breakable with the aid of the crowbar, continued, and at this depth, *viz.*, 25in., the solid, but not very hard native slate rock stratum was located.

This land generally gives one the impression that owing to the effects of many years of clean tillage, combined with the erosive action of the run off of a fairly heavy rainfall, the surface loam has become very impoverished in important elements of fertility, depreciated in texture and reduced in depth.

The large root systems developed from many of the stocks—particularly those from the almond—as indicated by the main root crowns shown in the accompanying illustrations, were found to have spread chiefly between the annual ploughing depth of 5-6in., and the 10in. or 12in. lying immediately below that cultivated layer. In other words, they have not, to any appreciable extent penetrated far below the depth originally disturbed by the subsoiling plough preparatory to planting the trees. In the opinion of the writer, this land in its present condition requires considerable amendment in texture and enrichment in plant foods before it could be deemed to be first class peach growing land.

As the attached sketch plan shows, the peach trees were set out over this area at 20ft. apart on the equilateral triangular or septuple system, forming five longer rows running east to west along the slope. One of each of these four longer rows was devoted to a separate scion variety, whilst the fifth and lowest row carried two trees only of each of these four varieties. Five of the different rootstocks were placed in groups occupying the transverse rows which were formed when the trees were taken in alignment at right angles to the slope of the land. In the sketch plan, these groups are separated by broken lines running in a zig-zag direction across the four long rows. The combination stocks—Salwey stem-piece superimposed upon almond rootstock—occupied the whole of the fifth or lower long row.

SKETCH PLAN OF PLANTING TRIALS CONDUCTED 1910-1930, BLOCK D.
(Peach Pruning Trial Plots).



It will be noted, therefore, that in each of the four long rows, there were two trees of each of the four scion varieties under test on almond, Myrobalana plum, and peach; and one tree of each of these varieties on apricot and peach x almond rootstocks, respectively. In the fifth and lowest of the long rows, there were two trees of each of three of the scion varieties planted, whilst the fourth variety—Salwey—was not double worked. In consequence of this, the crop yields and growth data collected from this variety form simply a replication of the performances of those trees of Salwey on almond rootstock shown in row 3 on the plan in the group occupied by almond rootstocks on the left-hand side of the plot. The single

trees of each of the four scion varieties worked on apricot and peach x almond stocks respectively were included largely for observation purposes —the former stock being locally reputed to be useless, and the latter, as far as the writer's knowledge extended, was quite untried in this climate.

The combination stock, in which Salwey was first worked on to the almond seedling rootstock to form an intermediate stem-piece on which other varieties were to be budded, was adopted because local nurserymen had claimed that this hardy variety displayed a high degree of compatibility with the almond—just as certain varieties of pears are used as intermediates between the quince rootstock and scion varieties of other more desirable kinds of pears which individually lack affinity with that tree. The writer, having had no personal acquaintance with instances where this procedure had been applied to peach tree propagation, readily included it into these trials.

Nicholl's Orange Cling on Apricot Stock.

Influence of Rootstock on Trunk and Branch Development.

It is to be regretted that progressive measurements of growths of trunks and limbs were not collected from each of these trees during the course of the trials. General observations, however, respecting the behaviour of the different varieties on the various rootstocks were frequently made by the writer and the orchard manager during the earlier years following upon the establishment of the plot. It soon became patent to the most casual observer that certain of the rootstocks must inevitably fail in spite of every effort made to establish and protect them.

In 1930—20 years after the date of planting them—so many of the trees had apparently passed their period of useful crop production that it was decided to terminate the trial. With a few noticeable exceptions, these peach trees had gradually declined, and during recent years, large dwindling framework limbs of a number of them had been cut back or wholly eliminated. This is readily detected in several of the accompanying illustrations reproduced from photographs which were taken of the trees

soon after the above decision had been reached. The photographs of the trunks, however, were not taken for several years after they had been grubbed and stored away for demonstrational purposes at the rear of some out-buildings on the orchard premises.

It may be stated here that, contrary to what is deemed desirable with many other kinds of fruit trees, the peach must, to maintain a prolific cropping condition, be kept at a high standard of vegetative activity. Slackened growth not only results in intermittent cropping, but the quality of the fruit also tends to decline rapidly. When grown in loams of average depth overlying stiff clays or marly subsoils, unirrigated peach trees have usually passed the zenith of profitable fruit bearing in this State at about 20 years after being planted. Where the soil is deep, rich, and freely drained, high production may be continued for a longer period, more especially if the trees have been efficiently pruned from the outset, and water is available for irrigation purposes. Peach trees, however, are frequently retained long past this stage, largely, it is believed, because their croppings have not been consistently recorded.

Brigg's Red May on Peach x Almond Stock.

These trees received throughout the course of the trials what has been deemed to be standard tillage and pruning treatments, but no manure of any kind was applied to the land. These cultural treatments have been described in the report on "Rootstocks for Pear Trees." The usual dressings to ensure average immunity from the attacks of parasitic fungus and insect pests were regularly and carefully applied during each year. All of the larger wounds made when pruning, had been immediately

covered with a coating of thick white lead paint. In spite of these precautionary measures, the entry of wood destroying fungi which create the condition commonly known as "Dry Rot" was not wholly prevented. More particularly has this been the result wherever the almond rootstock was used.

The general observations made relative to the behaviour of the different varieties of the peaches when grown on the respective rootstocks may be stated as follows:—

Almond (Hardshell) Rootstock.

It has been claimed by local growers that the Brigg's Red May variety grew successfully on this stock and produced fruit of better colour than when budded on to the seedling peach stock.

The small volume of evidence presented by the trees of this variety grown in these trials has been to the effect that during the first few years after planting they grew well, but at a very early stage began to display signs of the existence of serious incompatibility between the rootstock and the scion variety in the form of the development of masses of extruded tissue around the stem where the junction between stock and scion was located. Notwithstanding this, the limbs continued to extend until the trees reached what may be termed a normal size. About the tenth year—as the crop data also indicates—they had passed the meridian and began to decline towards the sorry condition depicted in the type of tree shown in the photograph of this variety, which, when grubbed was found to have all of its heartwood reduced to a spongy mass permeated throughout by the mycelial growths of the "dry rot" producing fungi.

The Elberta, as indicated by the illustration of a typical tree, developed to normal proportions and as the tables of production show, cropped quite well up to the time of the closing of the trials. When the trees of this variety were grubbed, and the limbs sawn off, the heartwood in some of the main arms was found to be destroyed by "dry rot" fungi and must have collapsed very soon under the strain of a heavy crop of fruit and foliage. This yellow fleshed variety would appear to display a closer affinity with the almond rootstock than did the white fleshed Red May. The above statement, however, requires to be taken with some reservation as the abundant extrusions of calloused tissues around the point where the stock and scion met showed that the union between the scion variety and the root system was being maintained only under increasing difficulty.

The late ripening greenish-yellow fleshed variety, Salwey, as previously stated, was deemed to possess greater compatibility with the almond rootstock than did any of the other varieties. The evidence, in so far as these limited trials can show, appears to lend some support to this contention. Viewed from the basis of tree development and fruit production, the promise is encouraging. The external manifestations of the degree of affinity between rootstock and scion variety take the form of a somewhat increased girth on the part of the stock. The lessened presence of masses of disrupted wood tissues would, it is considered, show the existence of an increased compatibility or capacity to fuse, between the functioning tissues of these two erstwhile separate entities which, in combination, form the complete tree, than has been noted in any of the foregoing varieties. The trees made up of this combination were fairly productive, but had certainly begun to decline at the time the trials terminated.

The behaviour of the yellow fleshed clingstone variety Nicholl's Orange Cling, in respect to the almond stock may be summed up in that the trees grew rapidly into large specimens and produced crops somewhat intermittently—as is the habit of the variety generally in this climate. Their fairly good condition at the end of the trials is evidenced by the last crop being the heaviest they had borne throughout the 14 years they had carried crops. Their stems, however, became very badly calloused around the point of union between stock and scion. When the trees were grubbed, the cores of the sawn off limbs were found to be permeated with "dry rot" fungi, indicating an advanced stage of weakness not revealed in the external appearances of these limbs.

It has been assumed that this apparent dislocation and waste of plant building material which is so abundantly produced in the vicinity of the junction between the scion varieties and the almond rootstocks particularly, arises from some, as yet unexplained, difference between them which it is attempted to cover by the use of the terms "incompatibility" or "lack of

Elberta on Peach x Almond Stock.

affinity." Whether it is the effect of histological, chemotactic, or purely genetic differences, future research may reveal. In a country such as this, where almond and peach trees in particular, are quite frequently affected by the disease known as "crown" or "root gall," one wonders whether this great diversion of the elaborated sapwood in the vicinity of the grafting line on the tree stems may not be aggravated greatly, if not sometimes actually due to the soil inhabiting organism which, it is claimed, causes the "crown" and "root gall" troubles. As this point of union between stock and scion is usually located only a couple of inches above the ground surface on the stem of the ordinary nursery tree, the organism should readily find an entry to the sap vessels before the rough wound often made in removing the top of the budded rootstock has had time to become completely enveloped in the growth of the healing callus of the young tree.

Myrobalana Plum Seedling Rootstocks.

With one solitary exception in these trials, this rootstock proved a failure as a stock for peach trees. In more recent years, it appears to have been similarly classed in both Europe and America. Wickson in "California Fruits and How to Grow Them," Fifth Edition, page 275, after recommending the St. Julien plum as a stock for peaches grown in moister soils says, "The Myrobalan has been used to some extent, but experience generally does not favour any plum stock for the peach, and our largest propagators have abandoned its use."

Hedrick in "The Peaches of New York," issued in 1916, page 148, writes: "The Myrobalan plum, very commonly used for nearly all cultivated plums, was at one time recommended for the peach, but turned out to be very unsatisfactory, and is now practically never used."

The ridiculously small trunk measurements quoted in Table I. and the restricted development of the branch systems, generally of the varieties worked upon it—as seen in the accompanying illustrations—are, with the above exception, representative of its best efforts in the plot devoted to this rootstock.

In some instances, the trees died early, and were replaced by others, but the three diminutive specimens of Salwey, Elberta, and Nicholl's Orange Cling—those of Brigg's Red May having died several seasons previously—represent what remained in 1930 of those planted in 1910.

It is unfortunate that no photograph was taken of the other tree of Salwey variety grown on this stock before the limbs were sawn off, and the butt grubbed. As the photograph of its butt indicates, this tree not only assumed normal proportions in its limb and branch growths, but the union between the plum stock and the scion variety of peach worked upon it, left little to be desired. This line of union had been buried several inches beneath the soil surface, and the writer and the orchard manager both assumed the reason for its superior development would prove to have been due to the scion becoming self rooted.

For this reason, the Manager of the Orchard (Mr. R. Fowler) was asked to have it very carefully removed, and to scrutinise closely the buried portion of the tree when the plot was being cleared. This was done, and the assumption that the Salwey had been growing on its own roots, quite disproved.

When the cropping performances of this tree given in section 6 of Table IV. are carefully noted—its diminutive colleague shown in our illustration helped but very little—the excellence of the affinity which must have existed between the rootstock and the scion variety may be more fully appreciated. At the time of its removal, this tree was in a perfectly sound condition in root and branch, equalling the best preserved of the trees grown on the peach seedling stocks.

When the whole of the trees in this peach stock trial plot were grubbed, the large holes made in removing the boles were left open for many months to permit aeration of the soil to take place. Some of the remaining roots of the almond stocks freely sprouted shoots around the exposed sides of the excavations. The roots of the Myrobalana plum stock on which this Salwey tree had grown so well, did likewise. These plum stools were carefully removed to the nursery during the following winter, and are now being propagated in quantity with a view to being further tested as a rootstock for different commercial varieties of peaches. The facility with which these offsets strike roots in the open nursery beds has been already well demonstrated under the conditions prevailing at Blackwood. Incidentally, it is mentioned that the foliage and young shoots of these rootlings bear a close resemblance to the growths of the plants of Malling Selection No. 9 of the Myrobalana plum stock which is growing close by them in the nursery.

Apricot Seedling Rootstocks.

The trees of Salwey and Brigg's Red May grown on this rootstock were extremely restricted in development—as a full length picture of the latter and illustrations of the trunks of both clearly show. A photograph of the tree of Nicholl's Orange Cling and of the enlarged view of the trunk of same, conveys a correct idea of the comparatively normal development achieved by this variety on apricot rootstock. The smoothness of the line of union between scion and stock is very clearly shown in this latter phase of the picture. Although one or two large limbs had been removed, the absence of "dry rot" in them, as well as in the trunk, should be acceptable as further evidence that the union had been at least a reasonably efficient one in so far as the effective operation of the conducting vessels in both stock and scion were concerned in this particular tree.

Salwey on Peach x Almond Stock.

The tree of Elberta had made fairly good progress on the apricot stock, and its gross yields reached a trifle over 20 per cent. more fruit than that of the Nicholl's Orange Cling on the same rootstock. This, when the comparative cropping habits of the two varieties are taken into consideration, is not an unexpected quantity. Although the trunks and limbs of this tree were sound at the time of its removal from the plot, the large and obliquely placed cornice-like section of embossed tissue which encircled the trunk at the place of junction of stock and scion made one dubious respecting the chances of longevity possessed by such a combination.

Peach x Almond Rootstocks.

Although this was an untried rootstock for the peach tree in this State, it had evidently not escaped the vigilance of the Californian peach growers. Wickson in "Californian Fruits, and How to Grow Them," page 275, Fifth Edition, refers to a "so called peach almond," and from his lucid

description of its fruits, little doubt is left respecting its close relationship with the type of chance hybrid used in these trials under the above designation.

He states it has been little used in California, probably because the straight-out use of peach and almond seedling stocks, which were generally available, had been adopted there with satisfactory results. He dismisses the matter with a brief, but commendatory remark to the effect "that the seedlings when budded to peaches produced good trees."

The evidence of the photographs presented herein of Brigg's Red May, Elberta, and Salwey trees grown in these trials on this stock in the cases of the two first-named varieties at any rate, corroborates Wickson's contention.

Brigg's Red May on Salwey on Almond Stock.

The enlarged views of the trunks of four varieties under test leaves little doubt that this stock forms a better union with the peach scion than is achieved by either the almond or apricot. It would seem as if the infusion of some genetic characters of the peach into this stock has apparently almost removed the cause of the failure of the conducting vessels of the almond rootstock to connect smoothly with those of the peach scion worked upon it.

With the exception of the Salwey variety, the trunks and limbs of the trees worked on this stock were perfectly sound and free from the attacks of "dry rot" fungi at the time of their removal from the land. The tables of figures relative to crop yields indicate that all of the varieties of peach trees grown on this stock, excepting the Nicholl's Orange Cling, bore consistently, though not heavily. The evidence, such as a trial on a very

limited number of trees can offer, would appear not unfavourable to testing this type of rootstock further, especially under climatic and soil conditions which may be somewhat dry for the peach seedling rootstocks.

Salwey on Almond Combination Rootstocks.

The illustrations of the trees, and of the enlargements of the trunks of Brigg's Red May and Elberta, and of that of Nicholl's Orange Cling also, indicate that this combination did not, during the earlier years, tend to restrict strong developments in either roots or tops of the varieties worked thereon.

As the girth measurements of the trunks set out in Table I. show in the cases of Brigg's Red May and Elberta, the short stem piece of Salwey wood was ultimately quite engulfed in huge masses of extruded calloused tissue, presumably from the almond stock. In the case of the Nicholl's Orange Cling, this feature is conspicuously absent, although both the almond rootstock and the Salwey stem piece grafted upon it have a definitely larger girth than the stem of the scion variety—showing to a certain degree that the movements of the sap stream had not been all that could be desired.

When the tops were removed and the large limbs sawn through, it was found that excepting a thin outer shell, those of the Brigg's Red May were consumed by "dry rot" fungi—whilst the limbs of the Elberta were apparently quite sound, and those of Nicholl's Orange Cling only slightly affected by these wood rotting agents.

The crop yield data shows that all three varieties had cropped consistently, but not heavily when worked on this intermediate stem of Salwey inserted between it and the almond rootstock.

Peach Seedling Rootstocks.

Owing to its greater compatibility—arising presumably from its closer genetic position—this rootstock has been accepted the world over as the most suitable one on which to grow all varieties of peaches wherever the environmental conditions of the orchards are not directly inimical to the well-being of the peach tree. As the above conditions, though not ideal, are nevertheless, reasonably favourable to the peach tree at Blackwood, this stock has been viewed as a standard around which the others used in these trials have been grouped for the purposes of comparison.

The illustrations of the trees of the four varieties worked on peach rootstocks, together with the close up views of their respective trunks, leave little doubt that in healthy development they compare more than favourably with any of the trees grown on any of the varieties of other species of prunus or combination of same as used in these trials.

The gradual merging of the rootstock into the basal part of the evenly tapering tree stem indicates that no serious obstruction or lack of compatibility has been displayed when the conducting vessels of the seedling peach stock and scion variety met. The data collected after the trees had been grubbed and the limbs sawn up, showed that in every instance the wood was sound and free from the operations of "dry rot" producing fungi.

The cropping data indicates that whilst only two of the varieties on this rootstock yielded the greatest aggregate weight of peaches per tree at the time of terminating the trials, the average good health of the trees of all four varieties on the peach rootstock held out greater promise of continued high production, than did those of any other stock under test.

Peach Rootstock Trials, Blackwood Experiment Orchard, 1910-30.

* Included under Almond Seedlings in this table as explained in the text following.

Influence of Rootstock on the Production and Quality of Fruit.

The cropping data set forth in Tables II. to V. showing the annual yields of each of these varieties of peaches when grown on the respective rootstocks have been quoted in detail of first and second grade fruit to enable those interested to note not only their gross production, but the consistency or otherwise of each variety in respect to the quality as well as the quantity borne from year to year.

The fruits classed as first grade were those measuring more than 2$\frac{1}{4}$in. in diameter, free from any serious blemish or disease and conforming in shape and colour with varietal characteristics. The second grade covered all fruits not reaching the above standard and included windfalls.

An analysis of these tables shows that the croppings of three out of the four scion varieties utilised in the trials were very unsatisfactory when they were grown on the Myrobalana plum stocks. The Brigg's Red May

Elberta on Salwey on Almond Stock.

trees proved an absolute failure; the Nicholl's Orange Cling only a trifle better. Those of the Elberta, though slightly more productive than the two foregoing sorts, were still negligible, whilst the yields from one of the trees of Salwey—to which reference has been previously made—were extraordinarily consistent and heavy.

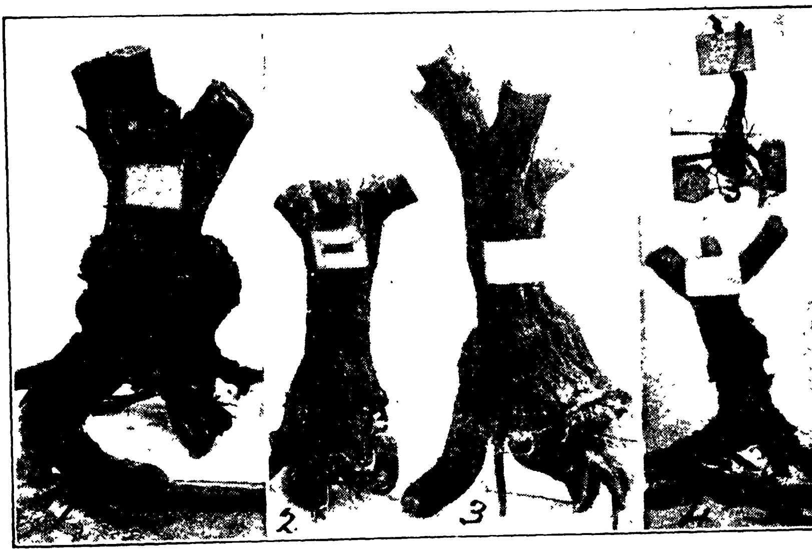
The apricot has also proved a complete failure as a rootstock for Brigg's Red May; almost so for Salwey, and only fairly good for Elberta and Nicholl's Orange Cling in so far as crop yields are concerned.

The crops of Brigg's Red May on almond stocks have not been satisfactory, but from Elberta trees they have approximated within 25 per cent. of those carried by this variety on peach seedling stocks. The gross yield per tree of Salwey when worked on almond stocks was good and approached within 30 per cent. of the average carried by trees of this sort on both peach seedling and Myrobalana plum. The Nicholl's Orange

Cling trees on this stock produced the greatest weight of peaches harvested from any of the four varieties, being 1 per cent. heavier than that borne by the trees on the peach seedling stocks.

The average yield of the Brigg's Red May trees on peach seedling stocks was 20 per cent. less by weight than was recorded from the single tree of this kind grown on peach x almond rootstock, but 14 per cent. more than was carried by the same variety when grafted on the Salwey on almond (combination) stock, and 67 per cent. more than those produced by trees on almond rootstocks.

The Elberta trees on peach stocks yielded the greatest aggregate weight of fruit produced by this variety on any of the rootstocks used in these trials, it being slightly over 25 per cent. more than when this variety was grown on almond stocks, and 47 per cent. greater than was harvested from the single tree of it on peach x almond rootstock.



1. Nicholl's Orange Cling on Almond Stock.
2. Nicholl's Orange Cling on Peach x Almond Stock.
3. Nicholl's Orange Cling on Salwey on Almond Stock.
4. Elberta on Apricot Stock.
5. Salwey on Apricot Stock.

The trees of Salwey worked on peach seedlings are recorded to have individually yielded ½lb. more of peaches in 16-years' crops than did others of this variety worked on Myrobalana plum, a trifle more than 30 per cent. in excess of those grown on almond, and some 62 per cent. more than the trees on the peach x almond rootstocks. Nicholl's Orange Cling trees on peach stocks bore approximately 1 per cent. less peaches by weight than did those of that variety when grown on almond stocks, but carried 29 per cent. more than those of the same sort on the Salwey on almond (combination) and 51 per cent. more than its fellow on apricot stock. The single tree of Brigg's Red May grown on peach x almond produced more fruit than the average per tree of this sort grown on any other rootstock. It was practically 20 per cent. more than was carried by trees of this sort on peach seedling and 31 per cent. heavier than was collected from the trees on the Salwey on almond (combination), which was the only other stock in these trials on which this variety produced any appreciable quantity of peaches. The production of peaches by Elberta trees grown on peach x almond rootstocks was about 47 per cent. less than from the same variety on peach

seedling, and about 30 per cent. less than from those on almond stocks. It exceeded the yields of this variety on the other stocks by approximately 48 per cent. in the case of the Salwey on almond (combination), and 43 per cent. in respect of the trees of it on apricot roots. The gross yield of the Salwey trees on this peach x almond stock was exceeded by those on both peach seedling and Myrobalana plum rootstocks by approximately 79 per cent. in each instance, and by 45 per cent. in the case of the trees on almond stocks.

The Nicholl's Orange Cling tree on this stock bore a few pounds of peaches over about seven seasons from 1917 to 1923, and then declined slowly, and ultimately died.

The Brigg's Red May trees on the Salwey on almond (combination) averaged 31 per cent. less than the tree on the peach x almond, 14 per cent. less than those on peach seedlings, and almost 62 per cent. more than those on the almond stocks.

The Elberta trees on this combination (Salwey on almond) bore approximately 70 per cent. less than on the almond, 78 per cent. below those on peach seedling, 58 per cent. less than the tree on peach x almond, and slightly over 26 per cent. less than that on apricot stocks. Their yields exceeded by 79 per cent. the extremely poor crops gathered from this variety from trees grown on the Myrobalana plum stock.

As the Salwey was not reworked again on its own stem piece in this combination stock (Salwey on almond), its production of fruit cannot be considered as comparative to that of the other three varieties, and has, therefore, been transferred to the test of this variety on almond rootstock.

The trees of Nicholl's Orange Cling on the combination stock yielded nearly 30 per cent. less fruit than when grown on almond, 29 per cent. less than the trees on peach, and 31 per cent. below the trees of the same sort on apricot rootstocks respectively. The crops of this variety on peach x almond and Myrobalana plum stocks were quite negligible in both instances.

In respect to the quality of the fruit produced on the peach trees in these trials, the percentages of first grade peaches borne by each of the different scion varieties grown on the respective rootstocks are presented in Table VI.

The highest percentage of first grade peaches calculated from the aggregate yields of all varieties on any particular rootstock, were harvested from the trees worked on almond rootstocks. There is some evidence in these figures in support of the popular contention that high quality fruits are obtained in an inverse ratio to the heaviness of the yields of the trees. Several of the rootstocks on which all of the varieties consistently show light yields display this feature. The apricot and Salwey on almond combination stocks may be cited in this category.

The consistently high percentages of first grade fruits produced on each of the varieties when grown on the almond stock is more outstanding than is the case of the trees of the same varieties when worked on peach rootstocks. This may be partly accounted for by the fact that there were four trees of each of the reputedly heavy bearing Salwey variety worked on almond stocks. This variety (Salwey) has also, throughout these trials, borne high percentages of first grade peaches from all of the different rootstocks, including even from the Myrobalana plum—which latter instance actually elevated it to a position above the other varieties.

It was—as elsewhere stated—one outstanding tree of Salwey which, by its growth and production of heavy crops of first grade peaches on this stock, has given rise to hopes that it—the particular plum stock—may yet prove of value to peach growers for use when planting peach trees in the heavier and wetter soils of the cooler districts of the State.

The trees in these trials were grown at a planting distance of 20ft. apart on the equilateral triangular system, which allows 125 trees per acre area clear of headlands and roadways. This distance proved to afford quite ample space for the proper development of the trees under the climatic and soil conditions prevailing in the Blackwood Experiment Orchard.

The cropping data quoted in pounds of fruit in Tables II. to V. inclusive set out the total annual yields, and not the quantities actually marketed. These figures were accumulated with unrelaxed care by weighing and grading the fruit from each tree—or from the ground in the case of fallen fruits—throughout the whole cropping period of each variety grown on each respective rootstock.

Taking these figures of the gross yields and transposing them into bushels, each of 45lbs. weight of fruit, the following is an indication of what might be expected to be harvested from an acre of peach trees of similar cropping capacities to the varieties used in these trials during a period of 20 years, dating from the time of planting. This information could, of course, only be directly applicable to districts in which climatic and soil conditions approximate to those prevailing at Coromandel Valley, and it is assumed that the various cultural treatments as described in the preceding report on the Pear Rootstock Trials are annually applied throughout that period of time.

Estimated Annual Yields Per Acre.

Brigg's Red May—Representing the Early Ripening, Shy Bearing Varieties of Dessert Peaches. Averaged Over 16 Years of Cropping.

In the small Table VII., the production of fruit from these trees of representative types of peaches has been reduced to simple units. The gross production per tree of each variety grown on each of the respective rootstocks is set out, together with the average crop produced per tree over its full period of cropping on all stocks. The final column at the right-hand side shows the average annual production per tree throughout that period. Reduced to this form, some of these figures appear to be almost unbelievably low. It will be observed, however, that from the trees grown on two of the rootstocks, *viz.*, Myrobalana plum and apricot, the returns from most of the varieties have been almost negligible. From three out of four varieties grown on the former stock, the crops have ranged from nil to very light. On the last-named stock, the production of fruits from two varieties may be similarly classed.

It is admitted in plots of this kind, wherein very limited numbers of units of each variety of tree have been used on each kind of rootstock included in the trials, the crop yield data can only be accepted with very great reservations when drawing comparisons between the various stocks undergoing trial. There is, however, data presented here from a series of trials which have extended for a period of 20 years from the planting of the trees and embracing cropping periods ranging from 14 to 16 years as displayed by the respective varieties.

From the data tabulated herein, there does not appear to be any marked difference displayed between any of the rootstocks tested in so far as hastening or delaying the arrival at the cropping stage of any of the varieties grown on them. This statement has reference only to those of the stocks on which the scion varieties grew and developed trees of reasonably normal proportions.

There is one noticeable feature which indicates that in no case where the trees bore—even if only poor crops—did any rootstock alter the comparative cropping habits of the representative varieties grown on them. For instance, Brigg's Red May, which is truly representative of the earliest ripening, but very shy bearing dessert varieties of peaches, has not been induced to set better or more regular crops than are obtained from it, or the members of its class, when grown on peach seedling stocks in commercial orchards or private gardens in this State.

The Elberta variety throughout these trials has, on all stocks, shown up to better advantage in so far as crop yields are concerned, than its fellow heavy bearing type—Salwey—which failed on the apricot, and cropped but very indifferently on the peach x almond stocks.

The Nicholl's Orange Cling had a reputation in this State of being later in reaching the bearing stage, and of proving a somewhat intermittent—if not altogether alternate season—cropper. These characteristics are discernible to a fairly marked degree in the data collected in this trial from trees of it growing on the majority of the root stocks.

If one may venture to arrive at conclusions formed from the observations of tree development and the cropping evidences described herein, it would be to the effect that nothing has been revealed in these small trials which indicates that the seedling peach is likely to be superseded by any of the species or varieties of the genus Prunus included in these trials of rootstocks for peach trees.

Whether the selection of seeds from varieties of peaches known to produce vigorous healthy seedlings will ultimately become practicable of adoption, or whether attempts will be made to segregate and perpetuate by segmentation clonal types of selected seedlings, remains for future experiment and research. Thus far, however, the peach, as distinguished from its close relative, the plum, appears to have proved an indifferent subject whenever submitted to ordinary economic large-scale methods of vegetative propagation.

DAIRY AND FARM PRODUCE MARKETS.

MESSRS. A. W. SANDFORD & CO., LIMITED, reported on 1st July, 1935:—

BUTTER.—The frequent showers of rain received throughout June were sufficient to keep the feed going in the dairying districts of the South-East, Hills, and Lower North, but in the Mallee country and Mid-North the conditions are still very backward indeed, and it is disappointing that they have not had good heavy rains in those parts. Cream production in the aggregate, however, through June showed an improvement in quantity and quality, and provided rains are received in the parched areas the tonnage manufactured this season should be satisfactory. Local values continued steady, but the London market improved, so that, under the Equalization Plan, the price for butter fat to the farmers was increased. Present rates are:—Choicest creamery fresh butter in bulk, 1s. 2¾d. per lb.; prints and delivery extra. (This price is for local sale only, and under the quota system the equalised price manufacturers will receive will be 1s. 0½d. per lb., on which basis payments to cream suppliers will be calculated.) Separator lines, from 8d. to 11½d. per lb. for choicest; stores, 6d. to 8d. per lb. (These prices are subject to equalization levies.)

CHEESE.—The turnover in this commodity was well up to the average, both local and Westralian buyers purchasing steadily, and with increased production now showing, exporting has commenced, the first shipment having gone forward by the *Orari* on 27th June. Values are:—Large and medium, from 9½d. per lb.; loaf, from 10d. per lb. at store door, delivery extra; semi-matured and matured, 11d. to 11½d. per lb.

EGGS.—As was expected, a seasonal increase in the quantities of eggs was noted, and with Sydney ceasing to buy, recourse had to be made to packing for export to Britain, and small quantities are being prepared for shipment to relieve the market. Values in consequence came back during the month to nearly export parity, and at present are:—Ordinary country eggs, fair average quality, 9d. per dozen net; long distance rail or shipping eggs lower. Selected new laid clean eggs, full-sized, 11d. to 1s. per dozen net.

BACON.—The turnover in bacon was well maintained throughout the month, and the consumption, owing to the cold wintry weather in June, was quite satisfactory. The lower prices ruling for eggs also assisted in the greater demand for bacon. Ample supplies were marketed by manufacturers each week and rates at present are:—Best quality sides, 9½d. to 9¾d. per lb.; middles, 10½d. to 11d.; heavy middles, 9d. to 9½d.; rolls, 8d. to 8½d.; hams, 1s. 1d. to 1s. 2d.; cooked, 1s. 2d. to 1s. 4d. per lb.

ALMONDS.—Strong demand continues for almonds in shell, but kernels are temporarily dull of sale, but will no doubt improve shortly. Rates are:—Softshells and Brandis, 8½d. to 9½d. per lb.; hardshells, 5d. to 5½d. per lb.; kernels, 1s. 9½d. to 1s. 10½d. per lb.

HONEY.—There was no material alteration in stocks, these being much greater than demand will absorb, and market is sluggish at:—Prime quality clear extracted, 2½d. to 3d. per lb.; lower grades, 1d. to 2d. per lb.

BEESWAX met with ready sale from week to week at quotations, being 1s. 4d. to 1s. 4½d. per lb.

LIVE POULTRY.—Auction sales are held every Tuesday, Wednesday, Thursday, and Friday at our sale rooms, which are in every way the best equipped in South Australia. Good catalogues were submitted at the sales throughout the month, and demand was well sustained. We advise consigning. Crates loaned free on application. The following are prices realised:—Prime roosters, 3s. to 4s.; nice-conditioned cockerels, 2s. 6d. to 2s. 10d.; fair-conditioned cockerels, 1s. 10d. to 2s. 5d.; chickens lower. Heavyweight hens, 2s. 4d. to 3s.; medium hens, 1s. 10d. to 2s. 3d.; light hens, 1s. 5d. to 1s. 8d.; couple of pens of weedy sorts lower. Prime young Muscovy drakes, 3s. to 3s. 10d.; young Muscovy ducks, 2s. to 2s. 7d.; ordinary ducks, 1s. 3d. to 2s.; ducklings lower. Geese, 2s. 6d. to 3s. 6d.; goslings lower. Turkeys, good to prime condition, 8d. to 9½d. per lb., according to quality; turkeys, fair condition, 6d. to 7½d. per lb., according to quality; turkeys, poor and crooked breasted lower. Pigeons, 4½d. to 5d. each.

POTATOES.—New season's, 12s. per cwt.

ONIONS.—Brown Spanish, 8s. 6d. per cwt.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on June 26th, there being present Messrs. A. J. Cooke, A. M. Dawkins, F. Coleman, S. Shepherd, Hon. A. L. McEwin, M.L.C., J. W. Sandford, H. N. Wicks, Professor A. J. Perkins, Dr. A. E. V. Richardson, and H. C. Pritchard. Apologies were received from Messrs. R. H. Martin, A. J. A. Koch, and J. B. Murdoch.

LIFE MEMBERS.—Life membership of the Agricultural Bureau was conferred on Messrs. E. Hart (Carey's Gully) and A. B. Ferguson (Arthurton).

NEW BRANCHES.—Conditional approval was granted to the formation of Branches at Karte (Men's and Women's), and Brimpton Lake. Approval was also given for the formation of a Women's Branch at Mudamuckla, with the following ladies as Foundation Members:—Mesdames W. H. and A. C. Watson, G. H. Noske, W. J. Riencke, L. and S. W. Burner, J. Kreusler, P. Flaherty, C. H. Kuhlmann, and S. J. Ettridge, Misses G. Hunter, D. Ettridge, K. Flaherty, E. Hosking, E. and M. Burner, G. Greusler, and M. Dunstall.

BRANCHES TO BE CLOSED.—It was decided to close the Veitch, Big Swamp, Hookina, and Kapinnie Branches.

NEW MEMBERS.—The following names were added to the rolls of existing Branches:— Wirrilla—Rex Kelly, H. Kirk; Mcorook—O. Huddy; Frayville—Edwin Hoffman, J. E. Ramm; Mudamuckla—L. J. Martin; Sheoak Log Women's—Miss Sylvia Dahlenburg; Warramboo Women's—Miss A. A. Sampson; Kybybolite Women's—Mrs. H. S. Naylor, Miss Letty Stevens; Narridy Women's—Mrs. A. Freeman, Miss M. Sandow, Miss A. Threadgold; Sheoak Log Women's—Miss A. Mattiske, Mrs. C. W. H. Dahlenburg; Carey's Gully—H. Hoffman, F. W. Folks, H. J. Folks, A. J. Schulze, H. N. Cook, Lewis Hart, G. M. Hart, A. G. Badenoch, G. H. Halliday, F. Jarrett; Malteo Women's —Miss R. Schwarz; Laura Bay—J. Osman; Chapman's Bore—A. Hill (Foundation Member).

SKELETON WEED.—Mr. Dawkins drew attention to the damage that was being done to wheat lands in New South Wales by Skeleton Weed, and suggested that steps should be taken to guard against its introduction into this State. Dr. Richardson reported that the C.S. & I.R., in conjunction with the New South Wales Department of Agriculture, were making investigations at Wagga concerning the control of this weed. It was decided that Mr. Clarke, Botanist at the Roseworthy Agricultural College, should be asked to contribute an illustrated article dealing with Skeleton Weed for publication in the *Journal.*

Other items were considered in Committee.

PAPERS READ AT CONFERENCES.

DAIRY CONFERENCE, MOUNT BARKER, 9th MAY, 1935.

SOME DAIRY HOME-TRUTHS.

[J. Y. HURD, Adelaide.]

The heavy increase in butter production which has been brought about in recent years by certain economic factors, coupled with the closing of many of our former markets by the forces of economic nationalism which is so evident in many of the nations to-day, threatens to bring about a condition of chaos in the Dairying Industry, especially in our own State with its preponderance of second-grade butter.

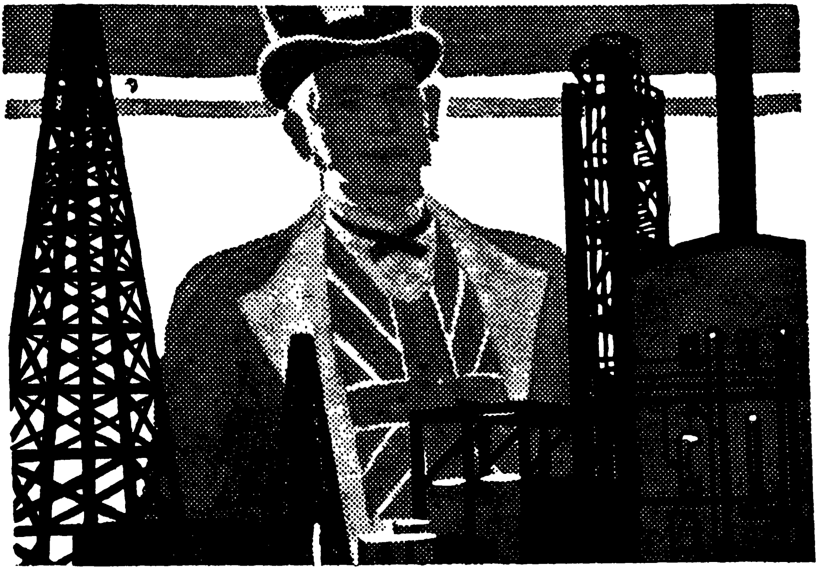
South Australia is not a dairying State, but this does not condone in any way the unsatisfactory attitude of the manufacturers, nor the slipshod, dilatory conduct of a great many of the producers.

In regard to manufacturers, there has been, and still is, too much desire to get cream customers to the detriment of a quality product, or the payment of a better price for a superior raw product. While these conditions go on, farmers cannot be expected to take the interest in their cream that they should.

One of the chief causes of concern to-day to the cream supplier is the payment for butterfat. In payment for butterfat or commercial butter the sum total is the same, but it is difficult to convince the ordinary dairyman that this is so, and this discontent will continue until butter is paid for on the principle of commercial butter. To give an example, if a farmer sends 50lbs. of cream to the factory, and it is of 40 per cent. test, he gets a return of 20lbs. butterfat. He churns 50lbs. of cream and may get from 25lbs. to 30lbs. of butter. This farmer does not take into consideration that he may have from 10 to 20 per cent. of water and salt in his churning, and he immediately comes to the conclusion that the factory is robbing him, and he becomes another discontented supplier. The sooner payment is made for commercial butter the sooner will cream suppliers be contented.

If the supplier is contented then he will take more interest in his product, and many of them to-day are producing cream and milk under very unhygienic conditions. All milking sheds should be built to face the north, to get a maximum of sunlight in them. Every shed should have an impervious floor of either brick or concrete with a 3in. slope from the manger to drain at the outside so that it can be properly washed. If the splashes of milk from milking are allowed to accumulate on the floor, they become a breeding ground for germs. All udders should be clipped around the base of the teats, so that they can be thoroughly washed before milking; an ordinary pair of barber's clippers is the best for this job.

Where cream or milk is left at the wayside to be picked up by lorries it should have proper shelters where it can be kept from the sun, and these shelters should be so constructed as to cause a continual draught to pass through, which has a cooling effect. All cream kept at the farm should be stored where it receives a stream of fresh air. If the weather is hot, a wet bag should be placed around the can, which is easily kept damp by throwing a bucket of water on the bag. In the more thickly populated districts, where several firms are drawing cream supplies, it should be possible for all cream to be picked up by one lorry. By this means it would be possible to get supplies to the factories more often than is the case to-day. Another point to be seriously considered in the economic production of milk and cream is the contentment of the dairy herd, and one of the greatest factors in securing this is to see that every animal is dehorned.



[*Papers Read at Conferences.*]

THE DEVELOPMENT OF THE DAIRY INDUSTRY IN DENMARK.

[L. M. HANSEN, Mount Barker.]

The development of modern dairy farming in Denmark in the last quarter of the nineteenth century was a natural consequence of the altered circumstances of agricultural production, but it was also one of the results of the free trade policy which, contrary to most other Continental European countries, was chosen by Denmark.

Of Denmark's total area of about 11,000,000 acres, about 76 per cent. is utilised for agricultural and horticultural purposes, 9 per cent. is timbered, while the greater part of the remainder comprises areas that are useless for cultivation and agriculture.

In 1861 the number of cows was 757,000; since then the number has been more than doubled, and the average annual yield of milk per cow more than trebled. The total annual output of butter-fat per cow has become four times as high. The increase in the quantity of butter-fat per cow is mostly due to the increased milk yield, but also to the fact that from 1861 to 1929 the milk has become richer. In the former year, a quantity of about 32lbs. of milk was required to produce 1lb. of butter. In 1929 the Danish co-operative dairies on an average used only three-quarters as much, or 23.6lbs. of milk per lb. of butter.

The total output of milk in Denmark in 1929 was over 11,000,000lbs. In the same year the total butter-fat produced amounted to about 410,000,000lbs., corresponding to about 470,000,000lbs. of butter, or about 135lbs. of butter per head of population. The average butter yield per cow for the whole of the country's stock of cows was in 1930 nearly 310lbs. In the same year Denmark's butter exports totalled about 375,000,000lbs., or about 230lbs. for every cow in the country.

CO-OPERATIVE EFFORT.

When the mechanical separator was invented it became possible to establish dairy factories. The result was that a number of privately owned factories were built; but from 1882 the establishment of typical co-operative dairy factories began.

How quickly the co-operative system won its way into Danish dairy farming is seen from the fact that up to 1890, *i.e.*, in the course of eight years, about 700 dairies were established, or nearly as many as in the next 40 years. It is now estimated that more than 90 per cent. of Denmark's 215,000 farmers have joined the co-operative dairies, and these now handle about 90 per cent. of the country's total quantity of milk, and produce about 93 per cent. of the whole butter output, in addition to the greater part of cheese.

That the co-operative principle so decidedly secured the leading position in Danish dairying is the result of several coinciding circumstances, of which only one or two of the most important need be referred to here. As the co-operative dairies from the very beginning were organised in the poorer districts of Western Jutland, they naturally were founded on very democratic principles. In the preceding years the political struggle for equal suffrage was in the foreground, and in this struggle the great majority of small farmers were on the democratic side. At about this time an intellectual and educational movement began among the farming population, and prepared the mind of the farmer for the work to be done in good fellowship and co-operation.

It was considered natural and right that co-operative dairy factories should be organised on a fully democratic basis. Each member received only one vote in all the affairs of the dairy, regardless of whether he had few or many cows, and the endeavours that have since been made to change this very democratic form of management and to allow the influence of the individual member to be determined by the quantity of milk he supplied (the number of his cows) were unsuccessful.

[*Papers Read at Conferences.*]

Another reason why the co-operative system expanded so rapidly was the economic necessity of changing over from grain production to dairies. The milk suppliers—including many thousands of small holders—could obtain the same advantage as the big producers, both with regard to technical handling and quality production and with regard to the marketing of their products.

In the course of time the number of private dairies has steadily declined, and it is characteristic that the so-called estate dairies now, 50 years later, have practically disappeared. In 1914 there were only 16 left, and since then several of these have closed down.

This explains the fact that modern dairy farming requires such a large and costly technical plant that even the biggest farmers have too small a quantity of milk to form the basis of a fully up-to-date and sufficiently economic dairy factory alone.

It appears from the material sent in to the Bureau of Dairy Statistics by the co-operative dairies, that in 1914 the latter had on an average handled 580,000galls., and in 1929, 740,000galls. of whole milk per dairy. According to size they may be divided into the following groups:—

	Number.	Per cent.
Over 1 million gallons of milk	103	13
.8 - 1 million gallons of milk	111	14
.6–.8 million gallons of milk	206	26
.4–.6 million gallons of milk	226	28
.2- .4 million gallons of milk	136	17
Under .2 million gallons of milk	14	2

The factories of the size of .8 to 1,000,000galls. have shown the best returns to the farmers, apparently on account of the shorter collecting radius.

Dairy Instruction.

These factories are spread over all the country, and practically every village has its own factory. All factories receive milk only and the average output per week per factory is 2 tons of butter, and is practically the same from week to week the whole year round. The radius of collecting is about three miles, and this accounts to a great extent for the good quality of Danish butter. The Danish farmer does not believe in having his product spoiled before it reaches the factory. The rapid development of the modern system of dairying brought to the front the problem of theoretical training for staffs of the dairy factories, and in 1887 and 1889, respectively, special dairy sections were established at Ladelund and Dalum schools, and these sections are still being maintained.

Every year these two schools—which are both run as private schools with a small State grant—have an eight-months' theoretical course. The instruction comprises the natural sciences, chemistry, physics, micro-biology, anatomy, and the physiology of nutrition, and also the special subjects such as ordinary dairying, dairy machinery, dairy management, bookkeeping, &c. The course ends with a final examination under public control, on the passing of which the pupils are given a certificate. Students without means may obtain State scholarships while taking these courses. The practical training has always taken place at the factories. At first this part of the instruction was more or less casual, but since 1911 the Danish Dairy Managers' Society (an organisation of dairy managers from all over the country, who, besides working in the interests of their profession, also take great interest in the technical progress of the dairy industry) has had a systematic and organised apprentice period of four years. At the end of their apprenticeship, the young dairymen receive a certificate, after which, as a rule, they work for two to five years as assistant dairymen, and then complete their training by going through the above-mentioned eight months' theoretical course at one of the dairy schools. It is from among these practical and theoretically trained dairymen that the dairy-manager class is recruited.

Mention should be made of the Government's Experimental Dairy, where the work is exclusively for the purpose of promoting technical progress in the dairy industry, while an association embracing the whole country, the Central Organisation of Danish Dairy Associations, takes care of the general interests of the industry.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

1935 PRUNING COMPETITIONS.

McLAREN FLAT.

From a small competition primarily inaugurated with the object of instructing boys and youths in the treatment of fruit trees and vines, the Pruning Competitions annually conducted under the auspices of the McLaren Flat Branch of the Agricultural Bureau have developed into one of the outstanding fixtures in the horticultural activities of the southern districts of the State. On the cessation of the Royal Agricultural Society's management of the Reynella Competitions in 1931, the McLaren Flat Bureau undertook the management of the Competitions, and since that year has managed them with marked success. Mr. Tom Wait, who has been secretary of the Competitions for five years, paid a tribute to the committee which had assisted him. He referred especially to the work of the chairman (Mr. Cyril Robertson). Trophies for the prize winners in the various sections were given by the Royal Agricultural Society, Messrs. J. Ingoldby, Thos. Hardy & Sons, Tatachilla Vineyards, Emu Wine Company, F. Kay, Gollin & Co., Grape Vendors' Association, A. Bruce, L. Townsend, McLaren Vale Fruit Packers, and Mr. and Mrs. E. Hockney. Vineyards and orchards belonging to Messrs. J. Ingoldby, F. B. Wilson, Chas. Elliott, and R. Nottage were placed at the disposal of the Bureau for the Competitions.

VINE SECTION.

H. Storer	76	75	151
A. Powell	72	73	145

Messrs. H. H. Orchard (District Horticultural Instructor) and G. Cox, who judged the spur section, said the chief fault of the pruners was in overtaxing the strength of the vines and leaving three buds on the spurs. Generally speaking, the standard of the work was not equal to that of last year, but that of the winner was outstanding.

Messrs. J. Williams (Viticultural Instructor Roseworthy College) and E. Strout said that in the rod pruning there was a noticeable improvement in the work in the section which they judged. The shaping of the vines, however, was faulty. Pruners showed a tendency to select fruiting rods remote from the wire when more suitable rods in closer proximity to the wire could have been chosen.

CURRANT.

Mr. H. Howard, of Langhorne's Creek, and Messrs. G. Dowdell and N. Low said they were disappointed with the treatment of the currant vines and the cutting left much to be desired; in many instances spurs were left too long. The saw work was definitely poor.

TREE SECTION.

Competitor.	Apricot.	Prune.	Total.
L. Ward	89	87	176
K. Robertson	87	86	173
R. Townsend	85	87	172

H. Eatts	—	82	82

"The pruning of apricots was very even, and all competitors showed a good knowledge of the treatment necessary for this tree," said the judges, Messrs. E. Leishman and C. Pollitt, of the Department of Agriculture. "The work was highly commendable, particularly that of the winner. In the prune section competitors had been a little too drastic on the fruiting wood."

JUNIOR COMPETITIONS.

Boys, 15-18.—Currant—S. Penny, 96; G. Townsend, 90½; E. Penny, 90. S. Penny, rod 93, spur 86 (189); E. Penny, 91, 95 (186); N. Sparrow, 92, 88 (180); O. Wright, 89, 86 (175); G. Townsend, 87, 86 (173); R. Le Poidevin, 88, 80 (168); D. Broughton, 85, 82 (167); F. Stillwell, 78, 83 (161); C. Oakley, 83 s.

Boys, 12-15.—I. Bruce, spur 83, rod 79 (162); K. Guerin, 81, 80 (161); R. Kyloh, 77, 82 (159); I. Chapman, 76, 80 (156); J. Dowdell, 81, 75 (156); J. Warren, 78, 74 (152); W. Elliott, 76, 76 (152); R. Elliott, 76, 70 (146). Spurs only—D. Elliott, 77; L. Stillwell, 77; D. Stillwell, 75; G. Ricks, 70.

Boys, under 12.—Spurs—D. Cox, 81; P. Elliott, 74; N. Chapman, 74; H. Powell, [illegible]; J. Stillwell, 64.

The boys' classes were judged by Messrs. G. Ward, G. Dowdell, F. Schurgott, H. Cox, and L. Sparrow.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall at the subjoined stations for the month of, and to the end of June, 1935, also the average precipitation for June, and the average annual rainfall.

INDEX TO BUREAU REPORTS—*continued.*

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator *v.* Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

SEASONAL REPORTS.

VINES.

At the April meeting of the Greenock Branch, which was attended by 20 members, Mr. H. Helbig, in the course of a report on Vines, said, as a general rule, pruning was not done hard enough because of the very dry conditions which prevailed right from flowering to picking. Ploughing was done earlier than usual and because of the lack of rain only one cultivation was given. Vines were slow in shooting and a very severe hailstorm was responsible for considerable damage. The keen demand for grapes with a general improvement in the wine trade should put growers in better heart for the next season.

FRUIT.

Mr. L. Zimmermann reported that, after a dry winter, Apricots bloomed late in the season and showed a fair crop after flowering for several weeks. Pears flowered heavily, but in many cases failed to set. Apples had an off year. Insect pests were not serious, except in the damage done by Codlin Moth to Apples. Late rains enabled fruit to make a good start, but a dry winter followed. The fruit grown on the drier soils did not make full development. Drying weather was good. Reasonable prices were received for fresh and dried Apricots. The sample of Prunes was fair, but only very poor prices were realised. Early varieties of Peaches filled out well. The sample of Pears was good, due to there being only a light crop. In general, it could be reported that the fruit crop was good, with a marked improvement in prices above those of last year.

CEREALS.

Mr. A. Roenfeldt said that, despite a comparatively low rainfall for the year, many good Hay crops were grown. Generally speaking, late-sown crops gave best results. Crops on good fallow yielded eight bags to the acre. Many heavy crops of Oats were reported in both Hay and Grain. Barley crops were badly damaged by heavy winds. Many farmers were devoting more attention to Peas; sown on stubble land crops of up to 10 bags to the acre were reported. Crops were particularly free from disease. (Secretary, A. Schubert.)

SUMMER GARDENING.

Mr. R. Schulz, one of the young members of the Koolunga Branch, which held a meeting on 15th May, contributed a paper on the subject, "Summer Gardening without Irrigation," in the course of which he stated that properly managed the garden would add very considerably to the revenue of the farm. The soil selected should be one that with good working was capable of retaining moisture. It must be securely fenced. The land must be thoroughly prepared and dressed with stable manue, which should be ploughed in during June. If consolidated by rain, it should be ploughed again and then harrowed before planting. Kale should be planted for feed for cows. Henderson Succession was the best variety of Cabbage; both these crops should be planted in rows 18in. apart during September. Mangolds were also a good feed for cows and did well thinned out to about 8in. apart. For Beetroot the writer recommended Obelisk and Turnip-rooted. A row or two of Pumpkins or Melons should not be forgotten. The best variety of Beans he considered to be Emperor William. Sow the seed in rows about 3ft. apart so that the land can be worked with a horse hoe. Mr. E. Mattischke spoke on the "Care of Hides and Skins." (Secretary, H. Mibus.)

FODDER CONSERVATION.

The June meeting of the Gladstone Branch was held on the 1st of the month. Mr. J. Fisher, in writing on the above subject, said because of recurring drought periods, every livestock owner should endeavour to store fodder during seasons of plenty. Hay was the most popular form of conserved fodder, but it deteriorated in quality the longer it was kept. Sheaved wheaten and oaten straw and cocky chaff were foodstuffs of low feeding quality, but they could be stored for many years, and if fed with a liberal supply of crushed grain would keep stock in good order. Ensilage was the cheapest way to store fodder over long periods and was particularly good for sheep and cows. (Secretary, M. Hoare.)

IMPROVING CREAM QUALITY.

At the meeting of the Wandearah Branch, held on 14th May, Mr. H. Wastell read a paper on the above subject. The writer dealt with the restriction of export butter, the high percentage of low-grade butter produced in this State, the low consumption per head of population, and butter substitutes. Referring to what steps could be taken to improve the quality of the cream Mr. Wastell said bacterial taints were the cause of about 75 per cent. of the lower grade cream that was received at factories. The first step towards reducing this amount was to induce producers to be more careful

so far as the cleanliness of the methods was concerned and to use cream coolers, combined with the sterilisation of milking utensils and separating plant before use. The udders of the cows should be thoroughly cleansed before milking and due regard paid to the condition of the milking sheds to see that floors were clean and properly drained. The speaker invited members to call at the local factory at any time, when he would be pleased to explain any matters of interest to those marketing cream. (Secretary, L. Jacobs.)

FRUIT GROWING.

CITRUS FRUITS.

Mr. J. Arthur read a paper on "Citrus Culture" at the May meeting of the Beetaloo Valley Branch. Holes for orange trees should be dug about 2ft. in diameter and 1ft. deep, leaving the grafting union 3in. above ground level. After the tree had been set in position and when filling in the hole, he recommended mixing some well rotted stable manure with the earth that was to be replaced. Then with sufficient water, the tree should make a good start. The trees should be planted 24ft. apart to provide room for adequate cultivation. Fertiliser in the form of nitrate of soda could be applied for the first year or two, but when the trees came into bearing sulphate of ammonia and stable manure should be applied. Lime also was necessary. Cover crops should be planted between the rows, and for these nothing was better than peas sown at the rate of half a bag with 2cwts. of super to the acre. In the case of big, healthy trees, which always carried light crops, the speaker thought that cincturing would probably induce a heavier setting of fruit. Valencia Late and Washington Navel he thought the best varieties. (Secretary, B. Giddings.)

THE HOME FRUIT GARDEN.

At the meeting of the Booborowie Branch held on 22nd May, Mr. F. Catt, in the course of a paper, said in districts subject to strong winds the provision of a wind-break surrounding the garden was of first importance. For this purpose he recommended either Gum trees or Almond trees. The holes for the trees should be prepared some time before planting actually took place, 21ft. being left between each tree. If best results were to be obtained, thorough cultivation and manuring were necessary. If water was available, the trees should be given an occasional good soaking. If the garden was in a spot moderately well sheltered from frosts, the following trees should do well—Almonds, Apricots, Peaches, Plums, Nectarines, Quinces, and to a lesser degree, Apples. Vines did particularly well, but the fruit had to be covered to protect it from birds. Pruning was necessary to ensure regular cropping. The speaker then gave information relative to the methods of pruning the various kinds of fruit trees. (Secretary, A. Fairchild.)

QUESTION BOX.

Taking the form of a Question Box, the April meeting of the Murraytown Branch was attended by 12 members and visitors. Mr. Tregenza, in reply to a question, recommended 90lbs. of super to the acre for cereals. Mr. Woolford, who had tried the new rubber collar for horses, was not favourably impressed with it. He preferred a sheep pelt as a relief to sore shoulders. Coil springs were also spoken of as being of benefit to relieve the jar from the shoulders. Discussing the profitableness of dairying on the farm, Mr. Pitman believed that it paid to feed the cows during the whole year, but only on products that were grown on the farm. Messrs. Borgas and Joppich supplemented chaff and crushed wheat with linseed meal. The question of the correct time to sow lucerne was also discussed, Mr. M. Scholz speaking in favour of either April or May or a spring sowing. It should not be sown in a cover crop. Mr. Tregenza said he would sow the seed in July so that the young plants would be well established before summer. Mr. Joppich said the soil in which lucerne was to be sown should be very clean. The seed could be mixed with the super and a chain drawn lightly behind the combine to cover the seed. The reason why Florence wheat was not grown more extensively in South Australia, even though it was a wheat of high milling quality, was because it had a tendency to shake, said Mr. W. Scholz. Mr. Pitman, in referring to the question as to the possibility of wheat rising to 4s. per bushel, said that present indications of world's markets did not indicate any permanent increase. Mr. Reichstein forecasted a rise of up to 4s. by July of the current year. (Secretary, E. Pitman.)

OATS V. WHEAT FOR HAY.

The above was the subject of a paper contributed by Mr. K. Masters at the April meeting of the Roberts and Verran Branch. After some years' experience he had come to the conclusion that wheaten hay always opened up in better condition than oaten, principally because mice did not do so much damage to the former. The crops should be cut soon after the flowering stage. From a feeding point of view he favoured

good oaten hay, providing the crop was not cut too ripe. Members, in discussing the paper, generally agreed that oaten hay made the best hay for horses. "Seeding Operations" was the subject of a paper contributed by Mr. A. Ramsey at the meeting held on 14th May. An interesting discussion followed.

FIRE FIGHTING.

Attended by 13 members and two visitors the monthly meeting of the Mount Hope Branch was held on 14th May. Discussing the subject of "Fire Fighting" Mr. A. Myers said the secret of successful fire fighting was in having the district properly organised, so that when word was received of an outbreak no time would be lost in taking steps to combat it. In addition fire breaks should be ploughed. He suggested that a valuable part of the equipment to fight fires would be a motor lorry with a water tank. Mr. H. Adams (District Instructor) addressed the meeting on "Common Ailments of Farm Animals." (Secretary, J. Vigar.)

RECREATION ON THE FARM.

In the course of a short paper on this subject read by Mr. E. James at the May meeting of the Taragora Branch the writer said there was always a tendency for the children of farmers as they grew up to become dissatisfied with farm life and to gravitate towards the cities. In order to overcome that, it was suggested that as much recreation as possible should be introduced in the home. The reading of good books was an education and visits to neighbouring homesteads, where various indoor games could be indulged in, would provide enjoyment for both old and young. Wood carving the writer mentioned as being an interesting hobby and one from which useful articles for the home could be made. Perhaps there was no greater adjunct to home entertainment than the wireless, and with its installation much would be done to create contentment and enjoyment. (Secretary, T. Winters.)

● FULL MOON

SHEEP: THE MAINSTAY OF THE FARMER.

The May meeting of the Laura Bay Branch was held at the residence of Mr. W. Bowell and was attended by 14 members. Mr. A. J. Bowell read a paper under the title, "A Few Jumbled Thoughts." Twelve months ago he expressed the opinion that fairly large holdings stocked with sheep was the method of farm management most likely to assist wheatgrowers in getting out of their difficulties. He stressed the importance of making adequate provision for water and the conservation of fodder if the flock was to be managed successfully. The large holding would naturally have to be cropped for several years to get rid of shoots, and for that purpose he recommended oats. The sheep would also assist in clearing off some of the natural growth. A meeting was also held on 9th April. This took the form of a Question Box. (Secretary, P. Morrison.)

EFFICIENCY AND THE PLIGHT OF THE FARMER.

The above was the subject of a paper read by Mr. R. Spriggs at the May meeting of the Yadnarie Branch. In the first place, he said the lack of finance made it impossible for the farmer to replace his old machines, which, in quite a number of cases, were almost beyond repair. The horse teams were also far below strength, and fences were in a bad state of repair. The best asset the farmer had at the present time was his flock of sheep. He also drew attention to the repairs that were necessary to farm buildings and harness. On the other hand, he believed that too much poorly prepared land was put under crop. A smaller area of good fallow would be more profitable. (Secretary, E. Spriggs.)

A CRITICISM OF FARM MANAGEMENT.

Twelve members attended the May meeting of the Cungena Branch, when Mr. A. Taylor, in the course of a paper, said during the past 12 months the farmer with marked ability in the management of his farm had come out on top in the Cungena district. His first criticism was levelled at the failure on the part of many farmers to store fodder for their livestock during years of plenty. Lack of proper shelter for livestock from severe weather conditions was another point which farmers overlooked. There was a strong tendency to overstock and sheep were kept in the one paddock for too long a period. Pigs were not naturally filthy animals and were entitled to better attention than they often received. Time and money would be saved if the farming plant was regularly overhauled and the necessary repairs made to all implements and harness. To make the paddocks in first-class working order more time should be spent in stone picking. With the institution of bounties many first-class farmers had been spoilt. Growers were inclined to scratch in their crops. He strongly advocated a tightening up of the traces of farm management. (Secretary, A. Voumard.)

INCREASING YIELDS PER ACRE.

Mr. D. McKenzie read a paper dealing with this subject at the May meeting of the Warramboo Branch. To obtain a higher average yield he was firmly of the opinion that it would be necessary to sow more fallow land. If all wheat were sown on fallow it would be possible for the farmer to start a system of rotation. When this latter was done sheep would follow as a natural consequence. They would clean the fallow and add to its fertility. Seed wheat should be pickled with copper carbonate. With smaller areas under wheat on fallow, heavier dressings of super could be applied. The land in the district of Cungena was capable of higher yields, and attention to the foregoing points would, he believed, bring about the desired result. (Secretary, H. F. Chilman.)

Mr. P. Daniel read a paper on seeding operations.

FARM ECONOMY.

The following are the chief points brought out in a paper on this subject read by Mr. T. Earl at the May meeting of the Allandale East Branch. Before cutting chaff, examine the bags and sew up the holes that are almost certain to be present. Provide a mouse-proof stage on which to build the haystack and so prevent damage by mice. Overhaul all implements before taking them into the field. A good grease for the plough can be made by mixing equal parts of mutton fat and coal tar. Graze all paddocks with sheep before commencing ploughing. The super will be much easier to handle at seeding time if it is first put into small butts. When drilling in oats put in a handful of rape each time the grain box is filled. Oil is an absolutely necessary farm requisite; buy it in 2gall. or 4gall. lots and so effect a saving. Endeavour to so arrange the schedule of farm operations that the right job is done at the right time. (Secretary, R. Laslett.)

"Economy lies not so much in rigidly curtailing all expenditure as in spending wisely and putting money into farming operations that would show more profit" said Mr. M. Harvie in the course of a paper which he read at the May meeting of the Appila Branch. Continuing, he said "it was false economy to continue using farm machinery that was badly worn; in the case of a harvesting implement that would be wasteful. Power farming he though was too expensive at the present price of wheat, but the farmer could safely raise a few foals each year. Harness and machines should be regularly overhauled and any repairs effected. A good set of tools would often enable one to do many jobs on the farm that otherwise would have to be taken to a tradesman. He believed that a very considerable saving could be made by farmers if they bought such requisites as cornsacks, twine, &c., co-operatively. Super bags should be washed and used for the storage of cereals that were kept for seed. Vermin in the form of rats, mice, &c., were often a source of waste, and an endeavour should be made to check the damage they caused."

This subject was also discussed by Mr. D. Gregurke at the March meeting of the Wepowie Branch. He believed the best economy consisted in the wise expenditure of the farm finances. It was not always wise to cut down the expenditure on labour, especially at harvest time. Occasional hours spent in the blacksmith's shop often saved considerable waste time in the field. Neither fence nor buildings should be allowed to become so much out of repair that they involved the expenditure of much money to be made effective. (Secretary, E. Roocke.)

SHEEP MANAGEMENT.

Twenty members and visitors attended the May meeting of the Sutherlands Branch, when a paper on the above subject was contributed by Mr. B. Doecke. The first essential, he said, was a plentiful supply of good water, and the troughs should be cleaned out occasionally. If the flock was kept for breeding, purchase the best animals that finances would allow. Yard the ewes with the rams about November; they will then mate more readily than if left in large paddocks. Crutch the ewes about four weeks before lambing. Flocks of approximately 100 ewes will be found most convenient to handle when the lambs commence to drop. For ewes, the best paddocks should be made available, and he stressed the importance of providing shelter for them. When lambing commences, make a regular tour of inspection and assist any ewes that may be in difficulty. Do not forget at this time to lay baits for foxes. Marking should be done when the lambs are two to three weeks old, doing the work early in the morning. To guard against blowflies, crutching would be of material assistance. A good dressing is waste car oil. At all times handle the sheep carefully. (Secretary, E. Schiller.)

SHEEP BLOWFLY TRAPS.

From experiments that he had conducted with traps, Mr. H. Noske, of Wepowie, at the May meeting of the Branch expressed the opinion that it definitely paid to use traps for blowflies. If every farmer was to use traps the trouble of fly-struck sheep would be greatly reduced.

At the same meeting Mr. L. Jasper contributed a short paper, "Sheep on a Wheat Farm." He said of late years sheep were being given more attention on wheat farms. For their district the only sheep worthy of consideration was the large-frame, plain-bodied Merino. For the farmer with a comparatively small flock the making of the clip into too many lines was to be avoided. (Secretary, E. Roocke.)

WHEAT GROWING OUTSIDE GOYDER'S LINE.

"Generally speaking," said Mr. M. Brown, in the course of a paper on the above subject which he read at the May meeting of the Morchard Branch, "landholders outside of Goyder's line of rainfall would be far better off if they devoted more attention to stock and less to cereal growing." He contended that 2,000 acres of land were necessary on which to make a fair living. Of this holding he could crop 300 acres of fallow a year and carry 700 sheep. On a holding of 1,200 acres, he recommended cropping 250 acres and stocking the remainder to its maximum. Mr. P. Schultz also read a paper, "Travelling as an Aid to Agricultural Knowledge." (Secretary, E. Tilbrook.)

IRRIGATING CURRANT VINES.

At the May meeting of the Ramco Branch, Mr. F. Lewis introduced a discussion on the subject, "Watering Currants after 1st January," in the course of which he said, Gordos required more water than Currants. In the case of the former the more vigorous the growth of the vine the better the fruit; just the reverse was the case with the Currant. The Currant vines should not be watered after the New Year until the fruit had been picked. He thought the vines were more easily cultivated if the

Currants were cut back early. Shed returns indicated that growers who did that had had the worst returns. This year he did not cut back and did not water after the New Year and had had the best results. Mr. C. Boehm disagreed; he always watered after the New Year and the fruit, both in regard to quality and colour, was good. Mr. R. Stanley said if the vines were topped too early the fruit would be red. The end vines of the rows made a vigorous growth and did not colour well. At one time he did not water in the New Year, but now he does. Mr. Lewis advocated taking out the end vines of the rows. Mr. Rogers said he watered his Currants, whilst Mr. Lewis did not, and Mr. Lewis had obtained better Currants and finished drying earlier. (Secretary, J. Odgers.)

SOUTH-EASTERN DISTRICT.

ALLANDALE EAST.

13th June, 1935.—Attendance, 12.

Question Box.—1. "What is the best means of ridding land of ferns?" Mr. Butler: Different soils required different treatment. It was essential to keep rabbits out when treating ferns, as they checked pasture growth and gave the ferns a chance to recover. Mr. W. Laslett: Peas had successfully checked ferns on some soils, but if subterranean clover, &c., could be established, cattle would tramp out the ferns. Mr. T. A. Earl suggested dragging a log over the ferns. 2. "Would it pay to sow a half a bushel less per acre and put the money saved into a heavier dressing of super?" Members were of the opinion that it would be a good proposition to use 60lbs. of oats and 100lbs. of super for sowing up till May, and to use the extra half bushel and lighter dressing from then on. 3. "What is the correct depth to plant potatoes?" It was noticed that potatoes planted to a shallow depth were more susceptible to worms, &c. Members thought that about 4in. was about the correct depth. 4. "What is the best way to keep seed potatoes?" Seed kept well when stacked beneath pine trees, and it was thought that the best means of keeping seed was to keep it dry and let it have as much air as possible. 5. "What is the best time to sow early potatoes?" For garden sowing they could be put in about June, but for paddock sowing it would not be advisable to put them in before September. 6. "Does it pay to put super on all summer fodders?" Mr. S. H. Butler had used super on one-half of a paddock of maize last year but could not notice any difference from the part that had not received super. Members thought that super would not be very effective on summer fodders, except in wet summers, unless put on the ground in the spring. (Secretary, R. T. Laslett.)

KYBYBOLITE (Average annual rainfall, 22in.).

March 19th.—Attendance: 21.

The Cultivation and Management of Our Old Clover Paddocks.—Paper by Mr. J. M. Wray:—"The phenomenal change which our soils have undergone since the advent of scientific treatment by sowing Subterranean clover and top dressing the pasture with superphosphate has brought about an entire change in the management of our farms. The old order of things has passed away; the constant cropping of cereals carrying 1 sheep to 3 acres was common, whereas 3 sheep and more to the acre is now quite a commonplace thing. I find it quite difficult to explain just exactly, or to get complete strangers to conceive just what certain fields were like 26 years ago. However, this very welcome change which has taken place, and of which we are justly proud, because we all have done something to help to bring it about, has in my belief brought us face to face with new difficulties which deserve our most serious consideration. We have been constantly following the improvement of pastures by increasing annually our flocks and herds, whereby our fields present to us at this time of the year more of the sheep yard or cow yard type (whichever stock we have), instead of pasture paddocks. It is this aspect, which presents a most unhealthy as well as an unsightly appearance, which has led me to bring this subject before you, and I solicit your co-operation of thought and expression of opinion that we might help one another and the district generally in dealing with these new problems that confront us. I have been trying during the past year or so to satisfy myself as to a method. The first thought was—grow wheat. A field of about 20 acres was chosen, and as the rain fell early in the autumn we ploughed it, then put the harrows over it at intervals of a few days five times before the seed wheat was sown with about 112lbs. of 45 per cent. superphosphate. The crop was the heaviest that I had so far grown; it fell flat on the ground, and we had great difficulty in getting 9 bags to the acre. The price per bushel was low, and the result was that it did not pay; but I learned that, apart from the poor monetary return, the heavy crop of wheat had seriously impoverished the soil that I had built up, and I am convinced that if

you want to keep your soil in good growing condition you must leave the growing of wheat alone. On the other hand, a crop of oats cut for hay, sown in early July, had no serious ill effects upon the soil. Some time ago I decided to purchase a sundercut to go over the ground in its dry condition and at the first rains, and have used it with great results. The experiment has consisted only on small paddocks up to 20 acres and less. The method is to sow 1½bush. of oats to the acre before or after the sundercut, with 112lbs. of 45 per cent. superphosphate. In 1933 we treated an 18 acre paddock, the rains coming early, and the results were so gratifying that 2 additional paddocks, one of 3 acres and one of 20, and the original 18 acres were put in for feed last year (1934), resulting in the bromes and clovers and Algerian oats making a wonderful mixture of clean, fresh feed off practically clean soil.

Owing to the thick coat of droppings, caused through heavy stocking, we have been seriously troubled with the Cockschafer beetle, a small grub that makes its appearance in early and mid-winter, working through the waste on the surface and destroying hundreds of acres of what should be beautiful pastures. Now this grub does not work or live where the sundercut has thrown the soil over the droppings. As we had considerable loss of pasture in 1933 through this beetle, we noticed that where it had been it did not return, and we bared the pasture off more than usual, until the surface was well kicked up by the hoofs of the sheep, thus leaving no cover, and causing a looseness. The beetle gave us practically no trouble last year. This, of course, can only be done by hand-feeding, which again brings another feature of pasture management.

The gathering in of meadow hay is well known and appreciated; also the chaff feeder, which is found to be another great asset which enables a farmer to eat his paddocks bare, and thus get the full benefit of his previous top dressing, and also gives the sheep an opportunity to walk the burrs out of the soil. Loosening the top surface also creates a dust that assimilates the droppings and lets the sunrays get right on to the soil. This gives nature a chance to clean up before the next heavy pasture makes its appearance. Care must be taken to have plenty of reserve fodder on hand in case the season proves to be a sluggish one at the beginning. This bareing of the fields also gives the sheep an opportunity of getting their hoofs on the real turf, and coupled with the extra exercise the sheep have to make, grows a better hoof, and gives it greater resistance against foot disease.

The cultivation and management of our old Subterranean clover paddocks is making more work, and will continue to do so. The day of sitting down while the wool grows on the sheep's back is past and gone. There is much more to be said. I have only touched on one or two things. Our paddocks are too large in the main, and in the near future smaller paddocks will be the order of the day. What a wonderful plant this Subterranean clover has been to us? It not only provides us with succulent fodder that can be grazed, but provides us with hay, and while doing this it is secretly storing up grain of high fattening strength to carry the stock through the autumn.'' (Secretary, A. S. Shepherd.)

Home Gardening.—The following paper was read by Mr. W. D. Starick at the April meeting:—''If you want to prepare a place for a Home Garden Site, see that it is situated on the east to north-east side of the home. To have any success in growing vegetables for the table you must have it sheltered from the south-east to westerly winds. You have mostly hot winds from the north-west, but that is far easier to combat than the cold frosty winds. Do not have the plot sheltered from the early morning sun.

Preparation of Soil.—I prefer soil of a sandy nature, deep sandy loam, anything from 3ft. to 8ft. deep, with a clay bottom. Clay too near the surface makes the soil too cold during the winter months, and is bad for drainage as well. Iron-stone bottom dries out too quickly and needs too much watering during the summer months. Clay holds the water too long and causes water-logging, which can be overcome by trenching.

Many people make a great mistake by carting away tins, wire, iron, broken glassware, stones and bones, which are most essential to the home garden. This also applies to those who have heavy soil too; do not expect to do this with the whole of the plot which you have selected, only a piece at a time. First of all burn everything. The bone naturally burns up. Bag that up when cold and put aside. The reason why it should be burnt is that it has a better chance to decay and partly dissolve. In a year or so you will be able to grow any class of vegetable of a good maturity, tender, and sweet, and it will take some beating if wanted for show purposes. Dig your trench 2ft. deep; care should be taken to put the surface soil by itself. The width of the trench should be wide enough to be able to walk comfortably in it. Now place your bits of old burnt iron and broken stone or burnt up glass, then some clay; say 2in. of iron, 4in. of Clay, then about 3in. of burnt up tins and bits of wire, then some wood ashes saved from the fireplace, then very little of the clay, and lastly your good soil on top. It would not hurt if you mixed some of the wood ashes and burnt bone with it. The bone needs to be crushed if it is too lumpy.

Seeding Operations.—When sowing seeds of root vegetables, *i.e.*, carrots, parsnips, beetroot, turnips, and swedes, always have some well-rotted farm yard manure which has been heaped up for say about six months, and has been constantly disturbed to kill all the rubbish that grows in it. For root vegetables manure must not be lumpy. Fresh manure is practically of no use to root vegetables, for rubbish grows before the roots' seeds are ready. Spread this manure over the soil. When you prepare the soil for root vegetables, see that you have previously grown lettuce, cabbage, cauliflowers, peas, onions, spinach and leeks. By no means grow root vegetables where potatoes have been grown or any kind of tuber. Root vegetables do wonderfully well where onions, shallots, leeks and garlic have been. The roots will grow all right but they have a bitter taste when cooked if grown where pumpkins or melons have been. Grow onions or peas first, then you will have no after effects. The same applies to tomatoes. You can grow tomatoes after cabbages. Do not plant tomatoes after pumpkins or melons. When preparing soil for root vegetables make beds of about 3ft. wide. The length of the beds depends on the power of water you have to water with. With windmill power by hose or gravitation 12ft. is quite long enough. Do not sow carrots and parsnips in one bed; always sow a full bed of each variety and you will have better results and grow more vegetables in the same bed. Always have your beds 4 to 6in. high or have a drain cut through to that depth. See that the footpath is not too high, for you will use the drains also as footpaths. There may be a rise of about 3in. in the main footpath, but no more than the drains of the beds you have made. The reason for the 3ft. beds is for air, drainage in the winter, and to throw weeds in during the weeding time for them to die. The same applies for the summer; it helps to keep the earth cool when watering on a hot, windy day. I am no believer of watering with a sprinkler on hot windy days, but only when it is calm and not too hot. Always have the beds wide enough to plant 2 rows of cabbages or cauliflowers 6in. apart, or else 3 rows of lettuce or 3 rows of root vegetables or onions. When digging the beds always see that you dig the old drain in. Never use the same drain twice; make half of the bed go each way. Plant piemelons down the paddock on some well worked fallow, and watermelons at home, because of inoculation, as they inoculate very easily. The rows of root vegetables need to be from 8 to 12in. apart.

Cabbages, lettuce and onions do well on very rich soil, but cauliflowers should be planted on unmanured soil, and fed afterwards with liquid manure, an occasional salt bath, and lime and ground oyster shell grit. Cauliflowers will grow where all other plants will die. If you know of some place where there is plenty of mineral in the ground, such as magnesia, plant a crop of cauliflowers in the usual way, manure it, &c., and you will find it will do wonderfully well. The best time for planting root vegetables is from August until the end of October and a late planting from the middle of February until the first week in April. A small sowing of turnips may be done after the middle of June until April of the following year.

When the sowing of cabbage, cauliflower and lettuce is to be made in nursery beds, do not have the beds too rich, but just manured lightly. When they are planted out into the beds (have them richly manured) they will go ahead right away. Nothing is worse than for cabbage or cauliflower plants to go back after planting. They should be a deep green with no yellow or blue tinge. The same applies with the growing of celery, but this plant differs from all others and takes longer to come to maturity—about 9 months or so. Do not plant out in a bed, but in a trench 12in. deep, with well rotted stable manure dug in, with some surface oil mixed through, and 3in. of good soil on top of that again. Plant the celery about 2 or 3 plants wide and about 3 or 4in. apart, depending on the width of the trench. Celery needs a lot of attention, as it has to be earthed up while it is growing in order to grow good, tender, and sweet celery. If grown otherwise it becomes bitter very quickly. Celery does not like "wet feet," and the lighter the soil the clearer the celery.

Asparagus takes about 2 years before coming to maturity. It is cut about 7 to 9in. under the soil. This plant takes a lot of attention, so you can understand why celery and asparagus are expensive when handled over the counter." Secretary, A. S. Shepherd.)

BLACK SPRINGS.

"Farm Management" was the subject of a paper by Mr. E. Seigert at the monthly meeting held on June 11th. He recommended sowing oats or barley at the opening of the season in order to provide greenfeed for stock. The next operation was to keep the fallows free from weeds either by cultivation or by sheep, which were good scavengers and would also add fertility to the soil. The seed wheat should be graded and dry-pickled as soon as possible after harvest. Farmers should breed their own horses, because a young team could withstand a hard day's work when required. Care should be taken of mares in foal, but they should be worked right up to the time they were ready to foal. A foal should be well cared for after weaning, because a stunted foal would not make a good horse. Cows, pigs, fowls and sheep would help in the upkeep of the farm. When each machine was finished with it should be thoroughly overhauled, repaired where necessary, and placed in a shed instead of being left at the mercy of the weather as was often noticed on farms. (Secretary, K. H. Dunn.)

GREENOCK (Average annual rainfall, 21.57in.).

10th June.—Attendance, 18.

CARE OF THE BREEDING EWE AND MARKING OF LAMBS.—In the course of a paper on this subject, Mr. R. E. R. Lang stated that he preferred a large-frame Merino ewe of good wool quality, *i.e.*, wool of fairly fine texture and of fair staple. Well bred ewes should be chosen, otherwise one would not get good quality wool or a good quality lamb. The best age to breed from a ewe was when she was rising four-tooth. Breeding from a younger ewe would result in a percentage of lambs being lost, because the young ewe would not take care of her lamb as well as would an older ewe. Also where a flock was worried by foxes a young ewe would not fight as well as an older one. Another point against breeding from young ewes was that some lambs might be

lost at lambing, especially if the ewes had been mated to rams whose progeny were subject to large shoulders. *Feeding.*—Breeding ewes should always be kept separate from the other sheep. They should be placed in the best available paddocks near to the homestead, so that they could have as much attention as possible. A frequent change of paddock was advisable, because if they were kept in the one paddock the feed became stale and the ewes would not do so well. Ewes should always be kept in good condition, because a ewe in low condition would not yield good wool or a good lamb. Where feed was not plentiful it would pay to hand feed them on hay-chaff and oats. A suitable ration was about 4lbs. of chaff and 2lbs. of oats per sheep. Hand-fed ewes would give a much better percentage of lambs and would be much stronger and better able to rear the lambs. Sheep nuts were also very good for hand feeding and the ewes did well on them. They were very easy to feed, for it was only necessary to run out a trail of nuts for the sheep to pick up, no troughs being needed. *Crutching and Shearing.*—The shearing of the ewe should be carried out in as short a time and as carefully as possible, taking care not to unduly knock the ewe about and not to leave her in the yard for a couple of days without feed. Ewes should be turned out as soon as possible after shearing, and into a good paddock —not a poor one—so that they could get a stomach full in a short time. They should never be turned out at sunset or losses would occur because of the cold. If the sheep were turned out in time to have a feed before night fell there would be very few, if any, losses. When shearing ewes the legs and crutch should be well cleaned in order to avoid trouble from flies, otherwise the wool became damp and would irritate the sheep, as well as draw flies. It would also mean a loss of wool, because badly stained or very dirty wool was not of much value. Ewes should be crutched just before mating time and again just before lambing. If that were done there would be very little trouble and all the wool would be saleable. Ewes should be crutched again before shearing. The practice of crutching ewes three times a year would result in a saving in trouble from flies and a saving of wool. When crutching prior to lambing every care should be taken not to damage the ewe. *The Mating of the Ewe and the Class of Ram.*—The writer preferred the Border Leicester or Southdown ram because it gave a fast-growing lamb of good quality and shape. The age of the ram should be about the same as that of the ewes mentioned above. The rams should be mated with the ewes in December and left with them until about six weeks before the lambing season. Yarding the ewes every night during the first fortnight the rams were with them would ensure a better percentage and also a more even lambing. If rams were too fat when mated with the ewes they would be a little lazy in working. When yarding ewes during the mating season the dog should not be used unduly so as to excite and frighten the ewes unnecessarily; nor should the dogs be tied too near to the yard or the sheep would become restless and nervous. When the rams were taken out they should be kept separate from the ewes and yolked, or else aprons should be put on them, so that if they found their way in among the ewes during lambing season they could not become a nuisance to the ewes. By mating the ewes in December the lambing would occur during the beginning of May or the latter part of April. With the lambing season occurring early in May, the lambs would be ready for marketing in early September. *The Lambing Period.*—It was advisable to go round the flock each morning and evening to see that all was in order. Dogs should be kept out of the paddock as much as possible during the lambing period, because they disturbed the ewes and lambs and often caused a ewe to leave her lamb. In districts where foxes were troublesome the yarding of the ewes when lambing would be found to result in a great saving and would even pay for the expense of building a yard. Where a yard was built it was advisable to make it fairly large so that the ewes and lambs might have ample space. The entrance gate should be large in order to avoid the sheep being crushed. When letting out the ewes in the morning the gate should be opened and the sheep left to go out at their will. It would be found that they would go out more quietly than if hunted out. *The Marking of the Lambs.*—The yards to be used should be cleaned out, all old refuse being swept up and taken away in order to lessen the likelihood of disease. After cleaning the yards should be sprayed with a disinfectant, such as milk-oil fluid. There should be two yards, one for catching and the other to take the lambs after marking. Drafting the lambs from the ewes before marking was recommended, because it would save much time and the ewes would not be damaged so much. A small yard for the catching would save much unnecessary running both for the lambs and for the man. A good, sunny day should be chosen for marking. The weather was often the cause of losses, for if marking were done on a cold day the lambs would become very stiff and possibly die. On the other hand, if the day was hot one might have trouble with excessive bleeding, which might also cause losses. Ewes and lambs should be yarded about 1-1½ hours prior to the time of starting to mark, which should be not later than 10 o'clock in the

morning and should finish not later than 4 o'clock. Turning out ewes and lambs at this time would give them time to mate up and have a feed before nightfall. Of the several methods of marking the use of the knife was most common and was fairly good. The knife should have a good blade; a real marking knife was preferable. The use of a knife with a bad edge would cause trouble to the person using it as well as to the lamb. There should be a rail erected on the division fence between the two yards so that the lamb could be seated firmly. The marker should be provided with a tin containing some antiseptic so that he could sterilise his knife after each lamb by dipping it in the tin, in order to prevent spreading a disease from one lamb to the next. It would save time if there were two catchers to each marker. The lambs should not be caught any other way than by the leg. Catching by the side or back would injure the skin and cause unnecessary pain to the lambs. The lamb should be held firmly by both hind legs, the legs being drawn well up towards the shoulders. The body of the person holding it should be a backrest for the lamb. If such a method were used, it would be much easier for the marker. When letting the lamb down, it should not be allowed to drop, but should be let down in such a manner that it would land on its legs. A dab of Stockholm tar on the places which had been marked was a preventive of flies and disease. Ear-marking the lambs would help one to distinguish between the sexes when drafting, the wether lamb being marked on the right ear and the ewe lamb on the left. After the ewes and lambs had been turned out into the paddock the next thing to be done was to clean up all refuse from marking, cart it to a heap, and burn it. If left about the yard it would attract flies and might cause disease. The yards should then be disinfected and the rail which was used for marking should be washed with disinfectant. The next day the sheep should be examined to see that all the lambs had returned to their mothers. If possible, it would be a good plan if lambs and ewes were moved to a fresh paddock. If any seemed rather stiff and were lying down, it was advisable to drive the flock slowly around the paddock in order to work off the stiffness from the lambs. The lambs should be all right in a few days, and if care was taken during the marking very little trouble should be experienced. The best age for marking was about one month. If the lambs were left until much older, trouble was often experienced after the marking. (Secretary, A. Schubert.)

TRURO (Average annual rainfall, 29.95in.).

Meeting held 17th June, 1935. Attendance, 13.

PIG RAISING was the subject of the following paper by Mr. J. Miller.—"The farmer who raises pigs must also be prepared to keep at least half a dozen milch cows on his farm, for it is impossible to rear young pigs successfully without the aid of skim milk as part of their daily ration. Of course, there are hundreds of pigs reared where the sows and their litters receive practically no skim milk, but they are always more or less stunted in growth and rough in appearance. For the average farmer I would suggest the keeping of three sows, and these should be so worked that when No. 1 sow has a litter ready for market, No. 2 should be about due to farrow, and No. 3 should be half way through her period of pregnancy. If a larger number of sows is kept they should also be regulated on the method mentioned, as by so doing sows with their litters can be given all the available skim milk and better attention, and a better average market price can be obtained throughout the year.

In selecting young sows for breeding purposes, they should be obtained from big litters if possible, be well grown with plenty of length, and have from 12 to 14 teats. If given good treatment they will be sufficiently developed at the age of eight months to be mated, so that they will have their first litter at about 12 months of age. If a sow proves herself a good, prolific breeder and rears most of her young pigs, do not be hasty in disposing of her on account of age. Some sows are quite good breeders up to eight years of age. On the other hand, if a sow has only small litters, or perhaps has good litters, but is careless and kills half by lying or tramping on them, the best place for her is the market. There is no better time for disposing of the young pigs than off their mothers at the age of from six to eight weeks. Always endeavour to have them in good condition, sleek in coat, and with plenty of bloom, and not, as is often seen in the markets, razor backed, pod bellied, and hairy. This latter type seldom brings a good price.

If you are a breeder of pigs in any number, do not attempt to rear them into porkers or baconers. Leave that to the man who is not a breeder. When the young pigs are taken off their mother, they still require skim milk as part of their ration to retain a good quick growth, which means that if a breeder tries both to breed and rear, he has not sufficient milk and all become more or less stunted. Of course, for the farmer who only breeds from one sow, the position is altogether different.

The work of castrating young pigs should be done at the age of four weeks. Some breeders neglect this work until the pigs are more than twice this age, which is a big mistake, as the pigs develop a coarseness which they carry throughout, and which is easily noticeable to the experienced buyer.

Sows during their idle period can be grazed on barley or other green pasture when this is available, with just a little grain given to keep them in good strong condition. During the summer, when practically no green is available in our district, a sow should be given a little bran prior to her farrowing. This helps to keep the sow in a healthy condition. For the first two or three days after having pigs she should be fed very lightly—a little skim milk and warm water with a small quantity of bran added is sufficient. After the first week the quantity can be increased, and pollard or other crushed grain such as wheat or barley can be given. Whole grain is not very suitable for a sow with a littler.

If a breeder has cement floors in his breeding pens, a false bottom made of soft wood should be provided for the portion of the floor which is under cover. A cement floor without some protection is too cold in the winter-time and will cause serious trouble to the farrowing sow. A railing about 8in. from the floor and the same distance from the wall should be erected in the breeding pen. This helps to protect the young pigs and prevents the mother from lying on them. Galvanized piping is very suitable for this purpose. Always see that your pigs have plenty of good bedding, as it is as essential as good feeding. A pig is a dirty animal, but he likes a good bed. A small pen should be attached to the breeding pen with a small outlet so that the little pigs can be fed by themselves when they are old enough to take feed. Do not on any account attempt in-breeding (close-breeding), as such troubles as small litters and deformed weak pigs will result. The question of the best breed of pigs to rear is a difficult one. We all know that the popular breed of to-day is the Large White Cross, but what will be the most popular in five years' time is difficult to forecast. We must endeavour to breed the type of pig which is most readily sought after and will bring the most money on the market.

When taking young pigs off their mothers wean them gradually for two or three days prior to selling. If they are left on the mother until morning of sale, taken to the market and sold, this may be very detrimental to the sow, as when rearing a litter the milk flow is at its full height, and such trouble as calloused udders is likely to occur if young ones are not weaned gradually. A sow should receive the same consideration in this respect as a cow or a mare." (Secretary, L. S. Davis.)

MALTEE.

21st March.—Attendance, 11.

THE MODERN DRILL.—Paper read by Mr. V. Schwarz:—"It is just 20 years since the combine was introduced into Australian agriculture, this being the name which the farmers promptly gave to the combination of the grain and fertiliser drill with the spring-tine cultivator. Both units of the combination were invented and developed in older countries, but the combination of the two was undoubtedly an Australian idea, and the first sample issued for its field tests in 1915. As is usual with improvement in farm machinery it was the invention of a practical former, in this case R. A. Squires, of Quirindi, New South Wales, who objected to making one coverage of his paddock with the spring-tine and another with the hoe drill when the two jobs might be done at the same time. At first much difficulty was experienced in making and attaching satisfactory sowing "boots" to the spring-tyne, and another great trouble was to make conveyor tubes to take the grain from the hopper to the boot which would not strain and break when the spring-tine encountered and jumped over stumps or stones. *Invention of Conveyor Tubes.*—Again a practical farmer came to the rescue with the invention of the tapered two-piece telescopic rubber tube. These resist all the shocks that develop in rough paddocks, and will last indefinitely if only the farmer will put them in a cool, dark place when they are not in use. When these minor troubles were righted the "combine" was quickly accepted by the wheat-growing community, and the hoe drill became almost a thing of the past. This remark, however, does not apply to the disc drill, which is still in use in all country where an excess of surface rubbish impedes the work at seeding time. The first attraction of the combined drill is that it is cheaper in capital cost than the two implements which it displaces, and further it saves double work for horse and man by working over a given area once only instead of twice, as in former practice. The advocates of this system make greater claims than the above, and are bold enough to assert that earlier germination and an increase in yield are achieved. Most gardeners, as well as farmers, have an unshakeable belief in the advantage of sowing seeds on a firmly compacted surface, and a properly adjusted tyne drill does that. In such a position the seed receives more moisture for germination purposes than when it has both loose soil under and over it. The covering of the seed by the "combine" certainly helps towards increased yield, because no seed is left on the surface for the birds. The sieving action of the tines has the effect of leaving the larger lumps of soil on the surface and shaking the finer particles down on to the seed. This places the clods where they will best break down by weathering, and it also helps to resist wind driftage of the top soil if there is a lengthy period after sowing. *Scattering of Seed.*—One great advantage of the tine drill is that it does not pack all the seeds along one straight, narrow channel as did the hoe drill. On the contrary it scatters them to the extent of 2in. on each side of a centre line. This makes for a better spacing of the seed and probably induces better tillering. In this connection it is interesting to know that experiments were conducted at the Waite Research Institute last year, in which the Australian combined drill was tested against a so-called precision drill from overseas. The result was in favour of the Australian type. In recent years no changes of importance have been made in the design of the combined drill. Standards have been reached, and one generally adhered to in respect to the range of seed and fertiliser which may be sown. The arrangement of the tines in four ranks appears to have been standardised, but it is noticeable that some makes have the sowing boots on the centre ranks, while in others they are attached to the two rear rows. Mostly these implements are used for sowing wheat, oats, and barley, but to a lesser extent they are used to sow peas, beans, millet, and other seeds. For sowing lucerne and

other small, round seeds an additional attachment is needed. This is a small box placed at the rear, and containing sowing devices which are miniature replicas of those used in the large grain box. The combined drill leaves the soil in ridges, and the grains are in rows 7in. apart. Some farmers prefer this from the anti-drifting point of view, but for those who prefer to smooth off the soil, there is available a light type of harrows which may be dragged behind the drill and does not add excessively to the draft. Around seeding time the combine is often used in place of a cultivator, and its first sowing task for the year is often that of drilling in oats on the wheat stubble. (Secretary, E. Schwarz.)

MANGALO (Average annual rainfall, 14in. to 15in.).

AUTUMN FEED.—The following paper entitled, "Can Mangalo Farmers Increase Their Income from Sheep by Providing Autumn Feed?" was read by Mr. F. Coles at the April meeting:—"Mangalo was first known as a hundred in 1907—28 years ago. Since that year about 80 per cent. of the arable land has been permanently cleared and brought under cultivation. During the process the farmers have learned from observation the habits of the natural grasses and of grasses which have come into the district as a result of cultivation, together with the effects on these grasses of the climatic conditions—rain, temperature, and wind. Quite naturally farmers made use of their observations by introducing sheep into the district. Figures taken from the statistics of the hundred of Mangalo point out that this animal has become increasingly popular with the general development of the district, until to-day I believe that farmers look to the sheep for at least 50 per cent. of their revenue. The undermentioned figures clearly illustrate how sheep have increased:—Sheep—1913-14, 25; 1918-19, 1,421; 1923-24, 2,836; 1928-29, 4,685; 1933-34, 7,972; compared with wheat acreage—1913-14, 3,943; 1918-19, 3,983; 1923-24, 3,728; 1928-29, 9,164; 1933-34, 8,679. But however valuable the sheep has proved as a source of income we must realise there are limits to the carrying capacity where natural grasses form the main feed. It will be agreed that during the spring and summer, between grass and stubble, there is usually enough sheep feed to keep the flocks in good condition, but in the late autumn and early winter there is a decided shortage in the supplies of paddock feed, and it is this annual shortage which plays such an important part in the carrying capacity of our farms. Is it possible to strengthen this weakness, and if so, in what way? In the first place it should be decided that the ultimate objective of any attempt to make good this shortage of feed must show a result for a direct financial gain over and above its actual cost if it is to be adopted. Also that if there is a risk about the method to be adopted being successful, then it must show a much bigger return than can be expected from natural feeding, or it should be rejected without further consideration. There are several avenues through which income may be derived from sheep, viz., wool, fat lambs, or fat wethers. But before this aspect is considered, the possibilities of providing the feed must be searched. In my opinion only two methods lend themselves to our purpose in Mangalo—sowing oats in the autumn or hand feeding from stored feed. In some respects sowing oats promises to serve well. Firstly we can produce the seed on the farm. It can be sown when the land is dry and when the team is more or less idle. Before this sown grain can be of use to the sheep rain must fall and fall early enough in the year to cause a good root system to become established, thus giving considerable growth and feeding off qualities before the cold of winter comes. Because of the expense of this work we must expect a longer grazing period than from natural grass. We know from experience that if oats do not get away before the middle of May their growth is slow, and in fact worthless to produce a bulk of early feed, and even if we use quick-growing varieties we are not helped much, because they will seldom stand feeding off. Since early rain is vital to this project, let us see what the prospects are. The only way to get at this is to gauge what has occurred in the past, and so I have drawn up a chart from the records at the Mangalo Post Office taken over a period of 18 years, showing the totals of rain for every 15 days during the months of March, April, May, and June. The net result shows an average of 41 points for March, 78 for April, 145 for May, and 166 for June. During the 18 years, in six years, or one-third of the time no rain fell during March, and in two other years the gaugings were under 20 points. In three years, or one-sixth of the time, no rain fell in April. Taking the chart all round, together with the number of days in which the rain fell, it would seem risky to attempt to get early feed by sowing oats. This conclusion also indicates that fat lambs cannot be raised successfully in Mangalo. We are told lambs must arrive early to catch the season; they must be fed on a great bulk of succulent feed, and it seems these ideals cannot be attained because of the absence of rain at the right time. Of course, oats could be sown early to chance early feed, and if it failed the oats would not deteriorate in the ground, and when the winter rains came they could be allowed to grow and mature, and the grain reaped and stored. In autumn this grain could be hand fed. But this type of feed will not produce fat lambs, and

my experience has been that it is far too expensive to produce wool. My conclusions are that Mangalo farmers must decide that this autumn shortage of feed cannot be substituted economically, and we must therefore be content with a less ambitious programme of carrying only such sheep as can be kept on the natural grass even though in some years some feed goes to waste. (Secretary, R. J. Turner.)

O'LOUGHLIN.

March 21st.—Attendance, 9.

HANDLING THE HORSE.—Mr. E. Lutz read the following paper:—"There are many ways of handling horses, of course, but I shall deal with young horses, that is to say, from a foal till broken into work. On ordinary farms all breeding mares have to take their places in the team, generally at harvest time, when the foal is about three months old. This is when I consider a foal should be handled first, as it has to be separated from its mother when she has to go to work. Most farms have a loose box, or small yard to shut the foal in but in some instances it is a very poor one, which soon teaches a foal to crawl, &c. Although done on very few farms, I am a firm believer in tying the foal up, where it cannot walk around. It will pull back for a start, but very soon will become used to it. This is when it should be petted and got quiet. Do not start to quieten it from the wrong end; when it is finished pulling back, put your right arm over its neck, and with your left, rub over its nose gently, slowly working up its face and over behind its ears. By doing this several times he will soon get used to you. When quiet about the head, gradually work back around his hind-quarters. Always bear in mind to keep close to him, not giving him a chance to kick you. After you have him quiet, so that he can be caught anywhere, catch him and you will find that you can lead him with the rope round his neck up to the post for tying.

When harvest is completed and the mare turned out, the foal should not be touched again until ready to break in. If petted too much he becomes sneaky and cunning. *Breaking in a Horse.*—I do not favour breaking in a horse at harvest time when a little over two years, as this is rather young, and with hot weather you are more likely to damage his shoulders. I favour the latter end of seeding, and then only short half-days. The previous handling of tying up when a foal now plays a great part, as he will be caught with very little trouble. Tie him up, and if quiet as before, put the winkers on and bit in, and leave him for a day or so, that he may become used to them, then take him out in the open and make him travel round, first one way and then the other. When you think he is sufficiently mouthed, have a pair of reins and drive him around, and at the same time teach him words of command. When this is satisfactory, you can put him in the team along with other quiet horses, and no trouble will be experienced. He is not likely to pull back, this having been taught him when tied up as a foal. Many ropes, couplings, winkers, &c., are saved by this method of handling; also there is no need for assistance when handling a horse in this way.. This I know from experience, as I never have assistance when breaking in my young horses." (Secretary, E. R. Pfeiffer.)

PINKAWILLINIE.

April 17th.—Attendance, 9.

Mr. W. Hutchins read the following paper entitled "Dry Pickling of Wheat":—"I propose to deal with the importance of seed wheat pickling as a preventive of diseases in wheat, such as takeall, flag smut, loose smut, and bunt. I wish to deal mainly with the advantages of dry pickling, but at first I will deal briefly with solution

or wet pickling. One of the disadvantages of pickling seed with solution is the fact that the germination is adversely affected, also the initial growth, and in many cases this has caused farmers to weaken the known effective strength of their solutions. Such a practice, whilst overcoming the disadvantages mentioned, has had the effect of increasing the bunt infection with proportionate loss, and in addition considerable inconvenience is caused by the fact that wet-pickled wheat must be sown immediately after treatment. It is claimed that both bluestone and formalin solutions lessen the vitality of the seed, and so pickling with these solutions must be done during seeding time, thus leading to waste of time or working late at night after a hard day's work.

Now, however, there is a method of pickling with a fungicide in dust form which has overcome these disadvantages, and which is more popular each year. The use of finely powdered copper carbonate cannot be too strongly recommended, for it does not affect the vitality or germination of the seed, nor does it delay germination or initial growth. Indeed, the germination appears to be improved by about 2 per cent., a result confirmed each year for a period of three years in tests in Victoria. Whilst many tests have been carried out to find the exact quantity of dust which should be used with every bushel of seed wheat, I feel that this is really a matter for further experiment by the user. Seed which is badly affected with bunt spores may require more dust than comparatively clean seed, but generally speaking 1¼ to 1½ozs. of dust containing not less than 50 per cent. of metallic copper is safe and effective. To ensure maximum yields pickling is essential, and the correct method must be adopted, otherwise the whole operation will be valueless.

In conclusion, I will briefly deal with the disease and how to detect it. A bunted head of wheat has a peculiar odour, not unlike that of rotten eggs. The grains at first sight appear to be intact, but closer inspection shows them to be replaced by spherical bodies called smut balls, containing a mass of black powdery dust enclosed in a tough skin. Each smut ball is capable of producing millions of seeds every year, any one of which may infect a wheat plant. It is most important that the grower should realise this fact, and since the smut seeds are carried to the crops on the wheat grain, any bunticide that will destroy them without injuring the wheat will result in a smut-free crop. (Secretary, L. F. Freeth.)

FARM BOOKKEEPING.

[By C. J. Whillas, Green Patch.]

Whilst not insisting that bookkeeping is necessary to successful farming, some simple system could be used to advantage, and from a practical standpoint it is well worth while. The keeping of financial records can be commended on the following grounds, viz., it shows the farmer how he stands financially with others at all times, and thus places him in a strong position in the settlement of any dispute; it places his affairs before him in terms of profit and loss, so that he is not working wholly in the dark; it enables him to compare one year's work with another, as well as the different activities of a farm; it enables taxation returns to be filled in without trouble.

Complicated cost accountancy such as is used in a large manufacturing concern is not applicable to the average farm. Operations are on too small a scale to warrant the cost. Farm operations overlap so much that correct apportionment of wages and stores would be difficult. Also, it is almost impossible to keep a correct account of many matters that influence the real profit and loss of many farm activities such as soil fertility, increase or decrease due to grazing, cropping, or top-dressing, &c. In fact, most farm activities are too complex for close recording both in regard to costs and returns.

It is, however, possible to keep simple account books that will prove quite useful to the average farmer. Before any farmer can attempt to keep his own books it is essential that he has a fair knowledge of the principles governing same. Therefore he should, unless he already has the knowledge, study the subject through textbooks or otherwise. Such a paper as this can only deal lightly with the subject. A few remarks on bookkeeping generally are necessary before touching farm bookkeeping specially. The objects of bookkeeping are: "To record

correctly in books, transactions involving the transfer of money or money's worth; firstly, in so explicit a manner that at any subsequent time the exact nature of such transaction can be readily perceived, and secondly, that such transactions shall be so classified that at any time the total results can be readily ascertained." If time and labour were of no object, bookkeeping would be fairly simple, but it is obvious that the cost of keeping accounts of any given business must not exceed the benefits derived therefrom. It is mainly the short cuts that make modern bookkeeping so complicated. In old-fashioned bookkeeping—and it is still the custom in many countries—there were only two books, viz., the journal and the ledger, the journal containing in chronological order a record of all and each transaction just as they occur, and the ledger a segregation and classification of these transactions under their correct headings. The sales and purchases book now used are only types of journals arranged for saving time and labour, and the cash book is only a ledger account kept separately for convenience. The terms "credited by" and "debited to" can easily be followed thus. Every entry is a transfer—one place or party is the giver and the other the receiver of whatever money or meney's worth is being transferred. The giver is always "credited by" and the receiver "debited to" the amount of the transfer. (In single entry only one side of the transaction is recorded, and results only show what one owes or what is owed.) Double entry records, both sides of all transactions, so that the farmer's affairs are recorded both externally and internally. Therefore by dividing one's affairs internally into so many convenient sections each transaction recorded in double entry books will show the other party Cr. by, and a section of your own affairs, whatever is being transferred, Dr. to, or *vice versa*. Double entry thus enables a tally to be kept of the financial position with others, to classify and analyse one's own affairs and as the total of all the debits equal the total of all the credits, the clerical accuracy of the work can be checked.

A complete system of double entry would not suit many farmers, as it would take too much time. Also farm work unsuits one for the careful and methodical entering and posting necessary. Good results can be obtained with much less bother. It is not possible to devise one short-cut bookkeeping system that will be suitable for every farmer, for conditions may differ greatly. I will try to outline a simple system that should suit many, the working conditions necessary being that the farmer shall square up all accounts, both in and out, at the end of the financial year, and that he shall pass all his money transactions through his bank account. In this case an analysis of the credits and debits shown in the bank account over the year, in conjunction with the increase or decrease shown in the balance-sheets at the start and the end of the year, will supply all the figures necessary to draw up profit and loss accounts of his different activities.

Under the conditions mentioned above the bank pass book can be taken as the starting point for his main books, and his payments—that is, cheques drawn—will be his expenditure and bank "pay-ins" his receipts. The question of squaring up at the end of the year may be out of the question, but of late years a farmer's credit is generally restricted to secured loans and his sales are mostly on a cash basis.

It is most important to look after sales and receipts. A simple way to do this is to use a rough day sales book—any book having a date column, a particulars, and a money column will do. Enter details of every sale as they occur, leaving sufficient space below each sale entry to enter when and how paid. Some farmers keep records of their daily money transactions in their working diary. This is not advisable, and it will save a lot of time and confusion if a separate book is kept for recording sales and receipts. As for his purchases, a file of unpaid and one of paid accounts should answer in most cases. For the more certain collection of the money due from his sales, other than spot cash sales, and for keeping records of money owing him, the farmer should at the end of each month, or more often if necessary, make out from his sales book duplicate invoices or statements of amounts owing to him, mailing the original to the debtor and keeping the copy as a record of the position.

We will now deal with the farmer's main account books. For these he will require a ledger and two cash analysis books. The ledger will be used only for end of the year statements, balance-sheets, bank or cash account, totals of year's receipts and payments, and profit and loss accounts. The most convenient form of ledger for these purposes will be one with journal ruling, *i.e.*, one having a double money column on each folio. The analysis books will be used, one for analysing the receipts and one for the payments. Analysis cash books contain a date column, a particulars column, then a number of money columns. They are standard stock and can be had up to thirty money columns. The number of money columns required will depend upon the number of sections required for the money transactions being analysed. The use of such books is known as tabular bookkeeping. Its use gives results that would require a tremendous amount of time and labour in posting, &c., under ordinary methods. In the case of the farmer's books the practice of using this system can be followed by studying the example below from an imaginary farmer's receipts analysis book. It will be noted that each receipt is first entered in the bank column, then cross-cast horizontally across the book and entered under its correct heading.

The farmer's financial year should coincide with the income tax year from July 1st to June 30th. The first step in starting a set of books is to draw up a balance-sheet of the position at the start of the year under review. Land values should be put in at cost, *i.e.*, the cost of the land plus improvements minus a depreciation of the improvements unless they are maintained in as good order as when constructed. If the land has to be put in at an estimated value put it a

little below current values. Plant can be put in at cost, less a yearly depreciation. For the careful farmer, 5 per cent. per annum should be ample for plant depreciation. Livestock put in at about market rates, but without much variation.

The undermentioned transactions are those of a farmer whose affairs are not very complicated—one who confines his activities to cropping cereal crops and sheep, and who does most of his own work. His working horses are part of his plant. Should a farmer have other activities the receipts and expenditure can be dealt with by having the necessary extra columns in the analysis books.

The affairs for the year ending June 30th, 1934, will show the following statements, viz., "Balance-sheet as on 30/6/33," "Balance-sheet as on 30/6/34." "Receipts analysis book" show the first few entries of the year, method of heading the analysis columns and of cross-casting the cash amounts. "Totals of payments analysis for the year" show the headings that will be used in the payment analysis book: "Totals of receipts and analysis for the year," "Bank account," "Crop account," and "Sheep account for the year; "Profit and loss account for the year," also a "Statement showing how the year's profit balances with the balance-sheet surpluses."

In the receipts analysis book the analysis columns are headed under three main headings, viz., Crop account, Sheep account, and Sundry account; then the Crop and Sheep accounts are still further subdivided into the definite products of each activity. The Sundry account is for any receipts that will not come under the other headings. With the receipts the choice of analysis headings is simple. But with the payments it is another matter. In fact, it requires a double analysis to give satisfactory results, first as regards the use made of the payment and second as regards the nature of the payment. The first analysis is required in order to arrive at the cost of the farmer's different activities, whereas the second is mainly for income tax purposes and to show the farmer how much he spends on various items. The payment analysis book will be used for the first analysis. The analysis columns will be headed *General account*, subdivided into household, private, car costs, interest, taxes, &c., and general expenses; *Crop account* subdivided into wages, supplies, repairs, and transport; *Sheep account* subdivided into sheep purchases, wages, supplies, repairs, and transport; *Property account* subdivided into wages and supplies; *Plant account* and *Sundry account*. The *General account* is necessary, as it would be very difficult to charge the items that will come under it direct to the other accounts. It is really an overhead account. At the end of the year the total expenditure shown in General account must be apportioned out to the other accounts. To fix the ratio that each other account will take is a matter of judgment dependent upon the labour put in and the use of the land for each activity. The farmer's own wage is included in the General account under the Private section and part of the Household section. The direct working cost accounts such as Crop account are subdivided into wages, for all labour used; supplies, repairs, for all accounts paid for any repairs on maintenance either for improvements or plant that can be considered due to that activity and transport payments for railage, freight, cartage, or any transport charges, on any supplies required for cropping, or for the transport of any products of cropping. *Sheep account* is split up in a similar way, with an extra column for sheep purchases. *Property account* is for the cost of the land and any improvements thereto, and is subdivided into wages and supplies. Maintenance of improvements should not be charged to this account, but should go direct to the working accounts. *Plant account* is only for new plant added. Maintenance and repairs must not be charged to this account, but to the working accounts.

In entering up the analysis book the farmer will take the entries direct from his passbook, starting from 1st July of each year. The Credit entries will be the receipts and the Dr. side the payments. Each item will be cross-cast and entered

under its correct analysis heading. At the end of the year, he will take the totals, which should, of course, check up with the bank totals. He will then take stock and draw up a balance-sheet for the end of the year. He is now in a position to draw up Profit and Loss accounts of his different activities on the lines shown in the example.

Regarding the second analysis of payments I mentioned above, this is not required for the Profit and Loss accounts, and is therefore not over important, but for income tax purposes it is necessary to segregate one's payments into a great number of sections—too many for a tabular cashbook. The simplest way to get at it is to make out lists on separate sheets of the cash amounts under as many headings as are found necessary. For Wages, every employee will require a separate list. Supplies—a separate list for every kind of item. Repairs will require at least the following: blacksmithing, saddlery, garage costs, plant parts, tractor parts, fencing material and building material. General expenses—stamps, telephone charges, insurances, rent, rates, taxes, bank charges, interest and travelling expenses, household and private expenses.

A statement in the ledger should then be made of the totals under each heading showing the results of the dissection of the payments in this way.

EASTERN DISTRICT.

KANNI.

March 30th.—Attendance, 9.

QUESTION BOX.—Among the questions discussed was the query, "Does bluestone lose its strength if held for 12 months?" Mr. F. Hoad believed it would not be affected. "What is a good grass to sow for feed when natural grass has dried off?" Wimmera rye grass, native grass, and other species were recommended. The question of holding a local wheat crop competition was discussed. (Secretary, E. H. Schulze.)

SUTHERLANDS (Average annual rainfall, 10.84in.).

April 4th.—Attendance: 14.

SEEDING OPERATIONS.—The following paper was read by Mr. V. H. Weis:—"Since the beginning of the depression, and the relatively low prices for wheat, farmers have undertaken to sow large areas in order to meet the overhead expenses. Although the modern implements employed on the farm to-day make it possible to sow large areas, it certainly would be advantageous to the industry to reduce the acreage, and pay greater attention to the preparation of the soil and the sowing of the seed. It does not seem to be fully realised that the farmer who takes reasonable care to sow the seed on a well-tilled fallow naturally increases the chances of receiving a good yield per acre, whereas the farmer who makes it his policy to endeavour to scratch in every available acre surely reduces the chances of securing a good average yield. Nor does it seem to be realised that it is both simpler and cheaper to handle 1,000 bags of wheat produced on 250 acres than from 500 acres. It should be unnecessary to stress the fact that land should not be brought under wheat too often, and particularly the mallee areas, which should not be cropped with wheat more frequently than once in three or four years, and where the land is very light, at even greater intervals. Every farmer should have a definite crop rotation, because it not only increases the mean yield per acre, but also increases the stock-carrying capacity of the farm, and in these times of economic depression and the continuing low prices for produce, every farmer must endeavour to increase the mean yield per acre, and take from the land what it can actually produce, or, in other words, he must increase the production per unit. It must be realised that the best time to increase the mean yield of wheat per acre is the period preceding seeding time. Seeding in reality is the beginning of the next year's profit, and the successes depend largely upon the methods adopted.

THE BENEFITS OF FALLOW.

There is one practice which has enabled farmers to continue growing wheat in the unfavourable conditions, both economic and climatic, and that is the recognised practice of sowing wheat on land that has been treated as carefully tilled bare fallow. Fallow operations should in most cases be completed in the month of August, the soil being stirred to a moderate depth of from 2 to 4 inches, the main purpose being to conserve the moisture of the winter rains and stimulate weed germination. Those who delay fallowing operations because they are afraid of ploughing up the bits of feed that are about are usually doing so at the expense of the succeeding year's wheat crop. Whether the fallow should be harrowed immediately after ploughing or whether it should be left in a rough state until the rainy season has elapsed is a matter depending upon local weather conditions. It certainly is true that any attempt to reduce heavy soils to a fine tilth during the rainy season would result in compacting the soil, which would have the result of throwing off rather than allowing the moisture to penetrate into the ground.

Weed growth can effectively be controlled by cultivating, and at the same time creating a surface mulch. The number of tillage operations required will depend much upon the circumstances which prevail, but maintaining the surface mulch will permit any rains which fall during the summer months to sink into the soil readily instead of running off, or being held near the surface to be rapidly evaporated. Fallow soil normally contains more moisture at seeding time than stubble ploughed soil, but the difference is not so great as is generally supposed. An experiment has been carried out at the Waite Research Institute to ascertain the moisture contents of fallow and of stubble to a depth of 3ft. at normal seeding period. The result was that fallow contained 1.5 per cent. more moisture, which is equivalent to a little more than half an inch of rain. This appears to be of small importance compared with the serious lack of nitrates in the stubble-ploughed soil.

Although the precise chemical and physical changes which take place in the soil during the process of bare fallow are incompletely known, investigations have shown that fallow soil normally contains considerably more nitrate nitrogen at the end of the fallow period than at the beginning. Another important factor of the cultivated fallow is the preparation of a good seed-bed, which should consist of 1½ to 2ins. of loose soil mulch resting upon a firm, well consolidated sub-surface layer. It remains to be

added that the tillage of soils that are in a dust-dry condition should be avoided as much as possible, and particularly so if the soils are light in texture. Under those conditions it is usually beneficial to run sheep on the fallows to cope with weeds, and thereby help to consolidate the soil, and so create a firm seed-bed. As the result of the compacting of the seed-bed, either by cultivation or by sheep, the amount of moisture per unit volume is increased, with the result that the young roots can obtain the moisture more readily.

The Selection of Seed.

The production of pure seed wheat is a factor which does not receive the maximum amount of care on most of the farms in the grain-growing districts. It is commonly found that a variety contains as an admixture seed of all the common varieties that have been or are grown on the farm, varying, as they chiefly do, from early to late maturing, and it can be well imagined what results can be obtained from such wheat if chosen for seed. It remains to be added that the yield per acre will also be comparatively lower than would be the result from pure seed, because, as frequently happens, the strangers are of a low-yielding variety, or are the outcome of varieties that have never been adapted to the soil and climatic conditions of the district. Most strangers are introduced into a variety through the careless handling the seed receives on the farm. The neglect of cleaning out the drill when going on to another variety is one cause, or stripping two varieties of wheat on to the same floor, or grading wheat which has as an admixture a variety with large grains. The machine retains the large grains, and thereby increases the proportion of strangers. The presence of barley in wheat crops is also a matter which deserves attention, because in average years it will be noticed that barley has considerably more ears per plant than most varieties of wheat, and, if permitted to accumulate to such an extent, the wheat will become unfit for market. The only sure way of keeping a variety true to type is to grow the wheat in widely-spaced rows, and hand-pick all strangers, or hand-pick a certain area of the standing crop. These are the only ways whereby barley and other inferior matter can be completely eliminated, and the grower is then sure of the quality and trueness of the grain.

Suitable Varieties.—No amount of fertiliser and no system of cultivation or crop rotation will produce maximum yields unless the variety of wheat grown is well adapted to the soil and climate of the district. Wheat variety trials have demonstrated the wide differences in yield between varieties of wheat grown in the same district. One variety may yield well in comparison with a standard variety in one district and poorly in another district. For example, Gluyas, one of the highest yielding varieties in the low rainfall mallee areas, is at Roseworthy Agricultural College inferior to other and better adapted varieties. Whatsoever increase in yield is secured by using better varieties is obtained at no greater labour or monetary cost than is required to grow a poor yielding variety. Variety trials could be well conducted at each individual farm. By introducing a few new varieties each year the farmer could ascertain which is the most suitable variety, and in addition it would also stimulate interest in the value of varieties and in experimental work in general. Owing to the varying seasons it would be necessary to conduct these trials over a period of years, so that each variety is thoroughly tested The most suitable varieties to grow in the mallee areas are early maturing with a high yielding capacity. Such varieties would yield a high proportion of grain to straw, possess moderate tillering ability, and be resistant to prevalent diseases. For the more fertile districts the most suitable variety should be a mid-season to late maturing, with a high capacity.

Deterioration of Seed.

In the grain growing districts there appears to be a strongly held belief by some farmers that wheat which is grown continuously on the one farm leads to rapid deterioration of productivity, and if the variety is to be persisted with, it then becomes necessary to secure a change of seed. This is so highly regarded by some growers that they frequently change their seed, and always purchase seed to be used from outside sources. They maintain that by securing seed from a more fertile locality, where the yields have been much higher than in their own district, the wheat tends to be more vigorous and prolific, and must naturally under all circumstances substantially increase the yield of the crop. For that reason they would never think of using seed that has been grown on their own farm for a number of years, and would not even use seed grown in their own district.

Carefully conducted investigations have been carried out on this matter in many of the grain growing countries, and the result of this test proved that without a single exception the seed grown on the farm continuously gave greater results than seed of the same variety which had been secured from another locality. At Roseworthy College, Gluyas and King's Early have been grown continuously for over 30 years, and reports show that both varieties are more vigorous and prolific now than they have been at any time during that period. Where ordinary reasonable care is taken with seed, there is no necessity to secure a change, but it can be selected year after year from the same strain that has been grown continuously on the farm. If, however, seed is deteriorating to such an extent that it requires replacement of seed from another locality, it shows that ordinary care has not been taken with it and that the deterioration is the result of neglect and of the handling it receives on the farm, but it is not due to the continuous growing on the one farm.

Grading the Seed.

It will be noticed that wheat taken direct from the harvesting implement has much foreign matter associated with it, and will not run through the seed drill at the desired even pace. Bits of straw or even a mustard pod, will pass through the revolving wheels, be sucked into the seed cups, and place themselves in such a position as to prevent any grains from passing. The result is unsown rows where weeds make rapid growth.

The mustard seeds fall out of the pod, and are sown with the superphosphate, receiving encouragement for vigorous growth and spreading. It must also be remembered that these seeds do not necessarily germinate the year after they are shed, but may lie dormant for varying periods, and start into life among later crops.

It should be unnecessary to stress the fact that cracked and small or shrivelled grains are not successfully removed by the harvesting machine. Although these grains take their position when passing through the seed cups, very few if any ever germinate. If the germinating powers are poor then under average conditions it will produce comparatively weak plants, which have a very poor tillering capacity and naturally reduce the thickness of the crop and the number of ears per acre. In order that the seed wheat be free from all inferior matter it should be graded, or if a grader is not available the seed should be put through the hand winnower a second time, using the small zinc sieve. By keeping it level and fairly full of grain, most of the inferior matter can be floated off. Through grading the farmer assures himself of a good plump sample, which will run through the drill freely, and has a high and rapid power of germination and growth. It will produce strong plants with a high tillering capacity, and being large seeds it will give higher yields and also produce a larger proportion of large seeds than are produced from small seeds.

Pickling.

The world-wide importance of bunt or stinking smut as a factor detrimental to wheat production, and its great antiquity as a cereal disease, necessitates the treatment of seed wheat. Smut if not combated causes more loss to the Australian wheat farmer than any other fungus disease. If seed is not properly treated, this disease will affect up to 50 per cent. of the crop, and thus rob the farmer of half his profits.

The disease not only causes reduction of yield through the grain being displaced by spores, but the value of the grain generally for milling purposes is also materially affected. There are two distinct treatments available for the prevention of smut, viz., dry dusting with copper carbonate and wet pickling with bluestone (copper sulphate) or formalin.

Dry Pickling.

Dusting the wheat grains with copper carbonate powder at the rate of approximately 2ozs. per bushel has proved a comparatively satisfactory control for smut, provided the seed is not seriously affected. Through dusting the wheat with 2ozs. of copper carbonate per bushel, practically all the fine impalpable dust is taken up and held by the small brush at the end of each grain of wheat. Adequate provision should be made to sieve off any surplus powder that is not actually adhering to the grain. It is the free powder that causes most of the trouble in the drill, and it is advisable to give the drill a few turns with the handle to make sure everything is running smoothly. The dry pickling may be done at any time of the year and the wheat stored until required for seeding. It must be remembered when using dry pickle that a certain amount is liable to escape into the air where it remains suspended. To breathe this dust for a considerable period of time causes the throat to become dry and parched, and this may be followed by a certain amount of indisposition, therefore it is recommended that the farmer should pickle in the open and stand on the windward side of the machine.

Wet Pickling.

The use of bluestone as a pickle is obsolete in many districts, on account of the poor germination resulting from seed treated with this pickle. Where this wet method of combating smut is still used, the solution should be made by dissolving 1½lbs. of bluestone in 10galls. of water. Reinfection may take place immediately the solution is dry, as the pickle is only effective while wet.

If formalin is to be used care should be taken that a quarter per cent. solution is used, *i.e.*, 1lb. of formalin to 40galls. of water. Though formalin if correctly used does not hinder germination as much as bluestone, it has been proved that the seed should be sown within two days of pickling to secure the best results. When using wet pickles the pickling can be done by immersing the seed into the solution or by turning it with the shovel. It will be found that by immersing the seed, smut balls will rise to the surface and can easily be removed. Care should be taken to leave the seed in the solution for at least 3 minutes.

The Use of Artificial Fertilisers.

The use of artificial fertilisers plays an important part in increasing the productivity of cereal crops, and a proper system of manuring is only a profitable business proposition. To take out of the soil more than is returned to it must result in impoverishing the land sooner or later, and is equivalent to living on one's capital. In South Australia the two major soil deficiencies are water and phosphate, and, over a limited area, nitrates. If sufficient rain falls, then maximum yields can be obtained by applying phosphate, but on the other hand, if the rainfall and the phosphate content are sufficient and there is a deficiency in the nitrate content, then greater yields will be obtained by applying nitrogenous fertilisers. Manurial experiments carried out at the various experimental farms in the mallee areas, both in South Australia and Victoria, have proved that wheat sown with superphosphate showed a maked increase in yield over non-manured plots and continued to respond more liberally as the manurial dressings became heavier. The direct effect of the heavier dressings in promoting the growth of natural grasses in stubbles is also important, as it increases the stock-carrying capacity of the farm and the fertility of the soil.

It is generally recognised that 1cwt. of superphosphate supplies only sufficient phosphoric acid into the soil to produce what would be considered a fairly good wheat crop. A good dressing of manure is therefore essential to keep up the standard of fertility rather than let it diminish, and on poorer soils it is imperative in order to give the land an opportunity to produce a good crop. The advantage of sowing the superphosphate with the wheat becomes more marked as the season progresses, because it accelerates early growth and maturity, and lowers the water requirements for grain production. The increased yield obtained by applying soluble phosphates is mainly due to the increase in the number of ear-bearing tillers, since the number of

grains per head and the size of the grains are always identical in the produce from the manured and unmanured areas. Liberal dressings of superphosphate tend not only to give the maximum yields of wheat possible on the rainfall, but make it possible to secure the extra yield under ordinary conditions, with very little extra expense.

With regard to nitrogenous fertilisers, it must be remembered that the greatest returns will be received through applying it to stubble soil, as practically all the available nitrogen has been exhausted by the previous season's crop. Hence the nitrate nitrogen content is rarely sufficient to meet the requirements of a good cereal crop, and the application of nitrogenous fertilisers to the stubble-ploughed soil removes one important limiting factor.

SOWING THE SEED.

There can be no hard and fast rule laid down for the commencement of seeding, as this is entirely controlled by seasonal conditions. Experiments, however, have proved that the best period for seeding is after the autumn rainfall; the soil is then at its best, conditions are ideal, and by spring the crop will be far enough advanced to benefit from the warmer temperatures. Through the advancement of modern machinery it is possible to adjust the sowing dates to permit better germination of weeds, and these can then be effectively dealt with in the earlier stages. It also results in the production of crops with a better balance of grain to straw and enables greater production to be obtained on a given rainfall.

The advent of the combine has also shown a marked increase in the yields of cereal crops. The chief reason for the great success of the combine is that it cultivates the land more thoroughly and effectively than did the old-time cultivating implements, because the tines are spaced closer together, and if fitted with wide points, the cultivation actually overlaps, and it is therefore impossible to miss weeds and leave any soil untilled. Another important reason is that by more scientific sowing it actually increases the average yield. It is generally recognised that wheat, together with the fertiliser, should be sown on a level, compact subsurface, and covered wih a mulch of finely pulverized soil. Experiments that have been carried out on this matter prove that the moisture oozes by capillary attraction or surface tension to the surface of compaction, but that the dust mulch stops it from rising further, and so prevents loss of moisture by evaporation.

Although the depth of sowing has little effect on the root system of the plant, it is considered that to sow approximately 1½in. below the surface is satisfactory, and by placing the seed with the superphosphate on the compact subsurface it will derive the most benefits from the available moisture, which hastens germination of the seed, ensuring early growth and giving the crop every opportunity for healthy development in the early stages.

Amount of Seed per Acre.—The quantity of seed to be sown per acre is a matter which receives a great deal of discussion among some farmers, but it is a matter which naturally must be left to the farmer's own discretion. No farmer should be induced to sow more seed per acre just because his neighbour is doing so, but a wheatgrower should be convinced by no other theory than by experimenting over a period of years on his own land. Much, however, depends on the seasonal conditions which prevail, and it must be remembered that if the season is early, then less seed should be applied per acre than if the season is late. By applying an extra amount of seed per acre in late seasons, the grower practically assures himself of a thicker crop, because the wheat plant does not stool to such an extent as it does in more prolific years.

Harrowing.—Harrows give the farmer an implement which is light in draught, covers much width per stroke, and stirs the soil, which helps to conserve moisture. Harrowing after seeding is essential, but should not be proceeded with until four or five days after sowing, as this enables a further germination of weeds, which will be readily destroyed by a stroke with the harrows. After heavy rain the dust mulch tends to run together, and unless the mulch is renewed, much of the valuable moisture is lost. Harrowing after seeding will leave the surface smooth and even, and will ensure perfect covering of the seed and leave a workmanlike job. If the crop comes away strongly and tends to grow rankly, a stroke of the harrows will check growth and encourage stooling.

SPACING THE WHEAT PLANT.

Any observant wheatgrower who walks over his paddocks of wheat shortly after the seed has germinated must be impressed with the irregular spacings of the seed from an ordinary seeding implement. Although these machines are designed to space the grains as uniformly as possible, they are inefficient machines in this respect. It will be noticed by careful observation that there are spaces of approximately 12in. where not one grain of wheat has fallen, whereas on the next 12in. there will be more than a dozen plants. All this may be found in the same drill row. Although the wheat-

plant tillers more profusely at the wide spacings, it does not produce sufficient tillers to compensate for the shortage of plants. The annual yield would be greatly increased by using a seeding implement which spaced the grains more uniformly. Even with our present implements more even spacing could undoubtedly be obtained by keeping the feed cups and working parts clean and in good order.

CONCLUDING REMARKS.

The following analysis of the factors affecting seeding operations show that although considerable progress has been made, there is still a wide scope for further improvements to be made by the rising generation. I fully realise that you are already familiar with much that I have had to say, even with the least palatable portions of the address. But I would like to add that throughout the preparation of this address I have tried to keep steadily before me what seemed to be in the best interest of the industry and the grower.

The wheat Industry brings in more revenue to the State than any other product, and it appears likely to remain our principal product for a long time to come, and despite the speeches that have been thundered down upon the growers from public platforms to grow less wheat, our State wants not less but more wheat. It must also be borne in mind that unless those directly responsible for the growth of wheat work their holdings not only for private gain but for the requirements of the community as well, and furthermore that by reaping 6bushs. to the acre when it is both technical and economical for farmers to have produced 9bush. or 10bush., they are not only wronging those immediately dependent upon them, but also the community and the industry. Hence to be a successful wheatgrower the farmer must possess more than physical strength and an ability for manual labour, which were among the farmer's greatest assets in the days gone by, but in addition must have a knowledge of the principles of agriculture; he must know how and when to work his land, the variety of wheat most adapted to it, the fertiliser which ensures the best results, and the most suitable time to sow seed. These are the factors that eventually lead to growing better quality wheat and returning higher average yields. (Secretary, E. R. Schiller.)

PINNAROO (Average annual rainfall, 14.54in.).

12th April.—Attendance, 14.

HOW TO BREAK A COLT.—Paper read by Mr. C. H. B. Ross:—"To break an unbroken colt, have a good yard, and a good strong rope about 40ft. long with a loop about 2ft. 8in. long. This long loop is advisable as it gives a double rope round the horse's neck instead of a single rope where the short loop is used; it also prevents the horse from choking, as the end of the long loop will not pull over the knot tied in same. Have a stick about 10 or 12ft. long, bamboo preferred for its lightness and less danger of injuring the horse. Drive the horse into a corner and pat him with the stick till he gets used to you, all the time watching the horse's eye, patting the horse all over his body and head. When the horse allows the stick to be put over his head without taking much notice, put the loop of rope over the end of the stick, allowing enough rope to make a large enough sling to slip easily over the horse's head. When the sling has been secured over the horse's head, see that it is well up on the head with the knot of the loop well under his throat. Have your assistant take the end of the rope round a strong post about 18in. above ground. This height will give less strain on your post, and also help to prevent the rope from getting between the horse's ears,

which is dangerous. Have the horse fairly close to the post, say about 6ft. Have your man hold the other end of the rope by taking it around another post, making it easy for him to hold as the horse is pulling against him. By no means tie the rope until the horse has had a few good pulls. After the horse has stopped straining on the rope, approach him from the left, about level with his shoulder, with your hand extended, watching his eye all the time; pat him, talk to him coaxingly and give him to understand that you are his friend. Get a leather headstall without a bit. Undo the noseband, also unbuckle headstrap. Approach the horse with the headstall in your extended hand and let the horse feel the headstall with his nose. Slip the headstrap over his head, rubbing him with your hand gently all the time. Buckle the headstrap. Do the same with the nosestrap. Now get the bit, slip your hand under his chin, buckle the bit on the off side first, grab the bitstrap on the nearside, press your thumb against his gum, and slip the bit into his mouth and buckle up. Get a light strap; the hames-strap of buggy harness will do. Slip the strap into off side of bit ring, pass under chin to bit ring on near side and buckle so as just to allow the bit to play freely in the horse's mouth. This is to prevent the horse pulling bit ring into his mouth; also it is easier for the man on the end of the reins when the horse is untied. The horse is now fully haltered. Put a good rein on the rear bit ring. Let your man slacken the tie-rope, gently slacken the loop and take it off the horse's head. Now let the horse move around in the yard with the rein on his near side. Let him feel the rein gently at first, then make him move around in a circle to the left. Approach him, pat him, show him that you are his friend, but be firm with him, also give him to understand that you are his master. When the horse reins fairly well to the near side, put the rein on off-side bit-ring, and make him circle around to the off-side for a while. Then put a rein on each side and make him stop and start to your command. This should be enough for the colt's first lesson. Tie him up to a strong post at the manger with a bowline knot, so that it may be untied without trouble. When you think that your horse is sufficiently trained to be put into the team, put him on the near side. Have a quiet horse next to him with a light rope doubly tied in a small loop just below the horse's hame hook. Put a rope halter over the colt's leather headstall, and tie it into the loop of the hames of the horse next to him, just long enough to prevent the colt pulling on the rope halter when coupled up. When you have the colt fully harnessed, keep a spare rein on him for the first round or two, but being tied to the other horses' hames the colt has very little chance of getting away. I favour putting the colt on the near side of the team. If anything goes wrong you can get to him; all buckles are on the near side, and he has not the chance of loafing by letting his end of the swing rest against the double swing, which he has if put in the middle of the team.

To be a good horseman one must be fearless, be a lover of horses, and have unlimited patience. Use the open headstall for breaking young horses. I condemn the winkers altogether until the horse has worked for a time. If you happen to get a bad one to break, or a kicker, tie up the near front leg by putting a loop around his fetlock. Pass the rope over his withers and pull it through under his girth. Lift his leg by pulling up, and let your assistant take up the slack of the rope. Pass it over the body again and under his girth, and you have him at your mercy. Let him caper around the yard on three legs. Keep pulling his head to the left, or else the rope over his withers will work back over his body. Let him kneel and struggle until he is fully exhausted. Trim his tail and feet while you have him tied and you will find that you have full control over him without the horse doing himself any harm." (Secretary, H. L. Badman.)

SOUTH AND HILLS DISTRICT.

FRAYVILLE.

At the monthly meeting held on 13th June a paper on "Pigs as a Sideline" was read by Mr. O. Rosenzweig:—"I intend to first deal with types of pigs, and, secondly, with their feeding. It is not intended to discuss all breeds of pigs, but it would be an advantage to the industry if many of the breeds were wiped out. This would enable a more uniform type to be produced and help gain the confidence of the overseas buyer. This is most important, as the Abattoirs requirements are, roughly, 1,000 pigs a week, so that when this is exceeded, as it has been during the last couple of years, breeders must produce what the overseas buyer wants and insists on. The pigs must be of even type and correct shape, and they must be given such food as will make them capable of producing the kind of bacon that the consumer desires.

The breeding of pigs of the type in demand is the most important factor, and that means the difference between profit and loss. At present the buyer of bacon pigs is looking for a pig with a long, deep middle, light shoulders, and good hams, the first in importance being the middle. The hair and skin give a fair indication of the firmness and quality of the flesh. The pig with coarse hair and wrinkly skin will probably yield coarse, dark flesh. Hairless skin usually denotes too much lard. The pig should not taper from shoulder to hams. It should be as wide there, and preferably wider than at the shoulder. White pigs are preferred. The breed recognised all over the world as the best bacon producer is the Large White.

Methods of Keeping Pigs.

There are two methods of keeping pigs—in the sty and in the open air. I should certainly recommend the latter method. Not only is there a saving in labour, but the pigs must be healthier. For the open-air method of keeping pigs it is necessary to have proper paddocks. I have a paddock and recommend a barbed wire fence which is about 44in. in height and consists of nine wires. In the long run it is the cheapest. Put your posts 12ft. apart; bore an inch hole 3in. from the bottom, then 3½, 3½, 4, 4, 4, 5, 5, 6, and 6in. This is an extra good fence. You can fasten in crimped droppers as you require. I have only one in the middle, and I should say that is all it requires, as pigs will not go near such a fence.

Feeding.

Barley comes first among the grains as a food for producing first-class pork or bacon, and, in conjunction with skim milk, forms an ideal food. Wheat as a food gives fair results. Feeding trials I have carried out with wheat and barley mixed show that pigs make quicker gains. When killed and dressed and allowed to set, the pigs fed on the wheat and barley mixture show a firmer fat than those fed on wheat alone. A crusher is the thing in which to prepare the food in a man's spare time. Mix wheat and barley, and then grind. When a pig attains the weight required by the curer, and is in good condition, it should be marketed, even though the market is dull. It is a mistake to wait for prices to rise. A pig may lessen in value, for there is no sale for over-fat bacon.

In these times of depression pig raising is a valuable sideline. Regarding low prices for grain, these last few years back we have had a fair amount of wheat under f.a.q. Three years ago I had 69 bags of wheat weighing from 150lbs. to 160lbs. a bag. There was no sale for it, so I bought 18 little pigs at 1s. 6d. each and 12 at 2s. 6d. (a total cost of £2 17s.). I fed them the 69 bags of wheat and 60 cases of apples, topped them off with 15 bags of crushed barley, and took them to the Abattoirs, receiving £83 9s. 7d. On top of that I had two pigs to kill for myself. In such ways as this the pig is able to convert into profit many products that would otherwise be wasted.

And, for the export trade in particular, the Large White or the Large White crossed with the Mid-York sow. Export buyers prefer the white breeds because of the better colour and conformation of the dressed carcass.

To make pig raising fully profitable it is essential to breed or buy the right type of pigs." (Secretary, H. H. Ramm.)

The Farm Horse.—The following paper was read by Mr. W. Faehrman at a recent meeting:—

To maintain the strength of his team the farmer naturally has to either buy additional horses or breed from his own mares. The latter is by far the most satisfactory, not only because of the high price which is now being paid, but because a purchase made at a sale ring is very often disappointing. Therefore I will first deal with the breeding of farm horses.

Unfortunately in the past there has been a tendency on the part of farmers to breed from any class of horse that would produce a foal, and the result is that quite a number of horses seen on farms to-day cannot be classed as a suitable type of farm horse.

The most popular type for farm purposes to-day is the Clydesdale, and for general all-round farm work can be recommended as capable of doing any job on the farm. The point to be emphasized as far as breeding is concerned is to secure the service of the very best sire available in the district. He should be of a square build, short but not flat ribbed, flat boned, sound on all legs, and, if possible, staunch and quiet. If possible choose a pedigreed horse—this is a guarantee that his breeding is good. Failing that, he should have a certificate of soundness.

Selecting a Sire.

Too much care cannot be exercised in selecting a sire, and bad points should not be overlooked, because the offspring are likely to have the same faults as the parents. It pays to breed good stock. A few of the reasons are:—A ready sale, attractive appearance, good and reliable workers.

There are several important matters which should not be overlooked to ensure a suitable mare becoming a successful breeder. A mare should be mated for breeding purposes at an early age—I should say from three to four years of age.

In many instances a mare, unless bred from when young, proves very unreliable as she grows older. An overfat mare is not usually a good breeder. If a mare has been worked down at seeding or fallowing time and has a worn-out appearance, it is wise to let her rest until later in the spring and then mate. If at all possible try to mate a mare on her first period after foaling; this is usually on the ninth day. A mare during in-foal period may be worked at almost any farm work right up to within a fortnight of foaling with benefit to the mare, as it will keep her from becoming overfat, but she should be so placed in the team that enables her to do her work without jerking. Avoid squeezing and crushing when driving through gates. Never use short swings which will allow the chains to rub the abdomen. A week before foaling it is advisable to separate mares from other horses. When the time of foaling is due I do not consider it advisable to put the mare in the stable and keep a constant watch, as this often disturbs and excites her. It is better to keep her in a small paddock and watch her from some distance. If any sign of difficulty is shown, immediately summon somebody competent, because a little assistance at the critical moment may mean the life of both the mare and the foal. Perhaps the greatest and most serious trouble the horse-breeder has to contend with is retention of the after-birth. In such cases a veterinary officer should be summoned immediately. I have read that three times as many horses die from this as from all other complications of foaling.

If a mare is required to work during the time she is suckling a foal this can be done after the foal is eight weeks old, but the mare should not be separated from the foal more than three or four hours. It is not advisable to allow a foal to follow the team, as it will probably prove a nuisance and is likely to be injured. Never allow a foal to suck when the mare is heated, as this may cause the death of the foal. A foal should be weaned at from four to six months old. It should be shut up in a yard with free access to water and be fed regularly on good nourishing food. Bear in mind that feeding is half the breeding. At 2½ to 3 years old a colt is ready for breaking in. When breaking in young horses always be kind and gentle, yet firm, never losing patience.

Feeding.

Feeding is one of the most important items of horse management, and the farmer must use his own discretion to a great extent. The manger should never be filled and then left till empty before being refilled. Each horse should receive just as much feed as he will reasonably clean up. Under natural conditions the horse is a bulky feeder, and under working conditions bulk is essential to his feed, and even where concentrated feeding is resorted to, the admixture of chaff prevents over hasty feeding and promotes digestion.

The stomach of a horse is small, and severe labour cannot be carried out on a full stomach, therefore feed should be small and concentrated. Oats, whole or crushed, rank as one of the best grains for horses. Always water the horses before feeding as well as after. It will not hurt him at all if he is used to it, even if he is hot. The walk in from the paddock will in most cases have cooled him down sufficiently.

To prevent sore shoulders never forget to groom down severely, as this is as necessary as a well-fitting collar. Keep all collars clean by scraping off any sweat and dust which may have accumulated. I prefer the short hames. The long hames tend to spoil the collar by pushing it out of shape and pinching the top of the horse's neck.

If it is not cold and rainy we have found it to advantage to turn horses loose at night, leaving the stable doors open and then feeding with hay in a shed a little distance from home. This enables them to roll and rub themselves, also making the

strawing of the stable unnecessary. When hitching up see that trace chains are both the same length, swings the right width, and there will be little trouble with sore shoulders.

When horses have been turned out for some time they should be worked short hours for a few days. Never work late at night, but start early and knock off early at night. Give the horses a short spell every round to allow to cool down a little. Do not expect eight horses to do the work of ten. An old saying has it, "the horse is the farmer's best friend."

The farmer, who should be a lover of horses, should not send his old horses to the sale, but should shoot them. This certainly is the most humane ending for these old and noble servants.

MILANG.

At a meeting held on 15th June, Mr. B. Casley read a paper entitled "Farm Conveniences," in the course of which he said that the rearrangement of fencing would often add to returns by reducing labour where cows were the main concern. Fencing could be erected in such a way that the rotational grazing of an area could be properly carried out, while labour was reduced to a minimum. The size of the paddocks must be governed by the fertility of the soil or by the nature of the farming operations. Adequate water supplies for stock had an important bearing on successful grazing. Cemented brick tanks and troughs were recommended because of their resistance to saline water. Tanks and troughs were easily and cheaply made. A trough to hold 600galls. had cost only £5 18s. Suitable yards should be made for handling and loading calves, lambs, or pigs. A permanent race should be built for loading calves; it was advisable to make it strong and broad enough to carry cows. For the repair and upkeep of implements a suitable set of tools should be kept. A large saving in repairs, &c., could be made if suitable tools were available. A suitable makeshift for a forge blower could be made from an old separator by soldering 3 or 4 wings to the bottom of the bowl and guiding the draught to the fire by means of a funnel. The part which went under the fire should be of piping with the end plugged and holes bored in suitable places. A soldering outfit and some carpenter's tools would be very useful. A very good job could be made of dehorning a young calf, say 2 months old, by cutting off the bud with a ¾in. chisel and afterwards searing with a red hot iron. A rope-maker was a handy tool. Mr. Casley made all his own rope from sheaf bands. He also described a method of making a ditcher from 2 railway sleepers, which would make a drain 15-18in. deep and would cover half a mile a day if 4 or more horses were used. (Secretary, L. E. Yelland.)

TWEEDVALE (Average annual rainfall, 35.97in.).

May 16th.—Attendance, 18.

Vegetable Culture.—Mr. H. Schapel, in his paper on the above-mentioned subject, pointed out that in the first place all seeds should be true to type, ground should be well dressed with stable manure in preference to other manures, and should be watered before the seeding, as watering after the seed was sown would harden the ground. In preparing land for a crop the ground should be well worked, ploughing in plenty of grass, and cultivating twice before planting. Onions should be planted 10in. x 3in. apart, the ground being kept loose after planting. Cauliflowers should be planted 2ft. 6in. x 2ft. and watered every other day, and they should be ready to cut in 8 to 10 weeks if manured with super and bonedust. Swedes should be grown on new ground. They did well on land which was not very fertile, such as gravel or stoney land. Turnips would grow almost anywhere. Carrots needed deep soil. The ground should be manured with artificial manure the year previous to cropping with carrots. Lettuce should be planted 10in. x 6in.-8in., using stable manure or sulphate of ammonia. Plenty of water is required in order to make them crisp. Beetroot, Egyptian Turnip Rooted was the best variety.

Times for Planting.—Cauliflowers and cabbages in November to February for winter crops; onions, April was the best time to sow the seed and transplanting should be done in August and September; carrots, September and October; lettuce, in the spring; turnips and swedes, October to February; garden peas, September to February, every two or three weeks; beetroot, any time of the year. One thing which gardeners should not overlook was to plough land two furrows deep, as that would bring down the weeds, and they would not give much trouble. (Secretary, B. Schapel.)

MOUNT COMPASS.

The annual meeting was held on 6th June, when there was an attendance of 170, including members and their friends, representatives of neighbouring branches, and Departmental Officers. The Chairman (Mr. A. S. Kidman) said that 11 meetings had been held during the year, with a total attendance of 590, or an average of 53. Field Days accounted for 5 meetings, and 7 meetings were held in the ordinary way. The subjects treated by Departmental Officers, members, and visitors in addresses and demonstrations were "Tobacco Growing," "Station Life," "Side Lines," "Visits to Eastern States and New Zealand," "Handling and Classing of Wool," "Sheep Shearing," "Pig Breeding and Management," "Progress of Jersey Herds," "Pastures Suitable to the District," "Manures and Manuring," "Potato Growing," "Field Trials of Implements for Swamp Lands," "Soils and Clearing Land for Pasture Establishment". A visit had been made to Roseworthy College, and several members had visited Branches in the district, and other Branches had visited Mount Compass. Successful competitions had been conducted for girls (flower growing), and for boys (potato growing). Other activities of the Branch included the recognition of the district as a meteorological station, the establishment of a daily mail service, assistance to officers in the collection of information on potato diseases, supervision of grass plots, and instruction to school boys on grass cultivation and potato culture. Arrangements were being made to hold a senior potato competition. In the State Meadow Hay Competition—open to all comers—Mount Compass members secured first, second, and third places. At the Royal Show, cows and sheep from the district obtained numerous prizes, including two champions. The lambs which secured first prize in the export lamb competition were bred in the district and on many occasions during the year, consignments of sheep and lambs from Mount Compass topped the Adelaide market.

The prizes won by Miss Betty Jacobs and Don McKinley respectively, in the flower and potato competitions were presented during the evening, and a musical programme was supplied by visitors from Victor Harbour. Mr. H. Womersley, Entomologist at the Adelaide Museum, gave an instructive address, illustrated by lantern slides, on "Biological Control of Insect Pests".

In thanking the Committee for the support of its members during the year, Mr. Kidman paid a special tribute to the excellent work of the Secretary (Mr. Chas. E. Verco).

LAURA BAY.

Meeting held June 11th. Attendance, 10.

WHAT CAN WE MAKE OUT OF YEAST DOUGH?—Paper by Mrs. A. J. Bowell:—"There are lots of ways of using up yeast dough if you have a little over after you have put the dough into tins for bread. You can make a nice little yeast cake by adding a little butter, sugar, currants, or sultanas, and a little nutmeg to flavour. Put these ingredients in according to the size of the cake; this will be ready to bake when the bread comes out of the oven. This cake is nice while it is fresh.

Baked Apple Dumplings.—Some morning when you are baking bread, save a small piece of dough when you are putting it in the tins. Put aside until you are ready to cook it, perhaps for tea. Then take the dough, and roll out and spread it two or three times with some nice dripping. Have some apples peeled and cored, or you can leave them whole, with cores out. Then roll out the dough pastry, and cut in sizes required for apples; wrap around apples, putting a little sugar and cloves with the apples. Put the dumplings into a piedish or a deep cake-tin. Then take 2 tablespoons of sugar, 1 tablespoon of butter, ¾ cup of boiling water, and pour over the dumplings, and bake for 1 hour until a nice brown.

This dough pastry is nice over fruit pies, or for tarts, but should be eaten while hot and freshly made. Just the plain dough is nice, dropped in small lumps into the stewpot. It is nice and light. Or you can leave a piece of dough on a plate, and just before dinner slide it off the plate into some boiling water, and there you have a dumpling, and you can serve it up with golden syrup and cream. Alternatively you may have it with meat and gravy. It can also be put over the top of any meat and gravy that is cooking in the saucepan for dinner." (Secretary, Mrs. W. Burke.)

MILLICENT (Average annual rainfall, 29.76in.).

The meeting held on 21st June was attended by nine members, the subject being "Favourite Winter Dishes." Mrs. W. Varcoe, Mrs. Bryant, Misses I. Fensom and K. Hutchinson submitted the following recipes:—

Mock Fish.—Beat 1 egg, grate 1 large potato into egg, add pepper and salt, and fry in spoonsful to a golden brown.

Salmon Dainties.—Take 1lb. salmon, 1lb. boiled mashed potatoes, a little chopped parsley, 1 teaspoonful mustard, a little vinegar, a beaten egg, a few breadcrumbs (if necessary), a little flour, fat for frying. Turn out the salmon into a basin, pouring off the liquid into a cup. Add the potatoes to the salmon, and mix well until the mixture is stiff; if too moist, add some breadcrumbs to absorb the moisture. Divide into 12 pieces and sprinkle with flour, make into round balls, and fry in plenty of fat until a golden brown. Add the teaspoon of mustard to the liquid from the salmon; then mix with a little chopped parsley the beaten egg and the vinegar. Stir over fire until thick. Pour the sauce over the salmon cakes and serve.

Treacle Pudding.—Half cup sugar, ½ cup dripping, 1 large tablespoon of treacle. Mix all well together, or dripping and treacle may be rubbed into flour instead. Add rather more than ½ cup milk, then 2 cups flour sifted with 1 teaspoon of soda, and a good dessertspoon of ginger. Steam 2 hours.

Gem Pudding.—Six tablespoons flour, 2 tablespoons sugar, 1 small tablespoonful cinnamon, 1 small teaspoon of soda, a pinch of salt, a piece of dripping the size of an egg. Mix all together with a little milk, then add 2 teaspoons of jam. Boil 2½ hours.

Scotch Broth.—¼lb. pearl barley, ¼lb. split peas, soak overnight. Place ½lb. best neck of mutton in a roomy saucepan, cover with cold water, add a level tablespoon salt. Simmer for 1 hour. Take 2 or 3 leeks or a small onion, 2 carrots, white turnip, and a small tender cabbage, chop up finely, and add to broth. Boil 1 hour. Quarter of an hour before serving add 1 handful of finely chopped parsley and 1 grated carrot.

Potato Pie.—Cut 2 large rashers of bacon finely. Peel and slice thinly 3 or 4 potatoes, also cut one onion into very small pieces or thin slices. Sprinkle some of the bacon in the bottom of a piedish. Add alternate rows of potato, onion, and bacon. Add salt and pepper dissolved in 1 tablespoon of boiling water. Cover with a good short pastry crust and bake quickly for 10 minutes, then slowly for almost an hour. Before serving add 1 cup milk or cream. Serve hot.

Breakfast Dish.—Cut up 2 large onions and boil in 1 cup of water. When cooked add 1 pint of milk; season with salt and pepper. When boiling, thicken with 2 heaped tablespoons of flour and 1 heaped tablespoon of "Oysterene" mixed into a thin paste with a little milk. Serve hot on slices of buttered toast.

Meat Pudding.—Of course, steak and kidney make the nicest meat pudding, but I often use any meat I have on hand, such as part of a leg of mutton, or any beef without bone or fat. Over the meat place a layer of onions and sprinkle with salt, pepper, flour, and thyme. Repeat until the basin is nicely filled, then 3 parts fill the basin with water. Make a crust with flour, suet, a little rising, and salt. Place on top and tie a cloth over. Steam for not less than 3 hours.

Date Pudding.—Take 2 cups of flour and sift with 1 teaspoon of carb. soda; add ½ cup sugar, 1 cup chopped dates (or any other fruit will do), 2 tablespoons of butter dissolved in ¾ cup of boiling water, and lemon to taste. Mix well and boil in a cloth for 2 hours. (Secretary, Mrs. H. J. Hutchesson.)

MONARTO SOUTH (Average annual rainfall, 14in. to 15in.).
Meeting held on 15th June. Attendance, 19.

DRIED FRUIT AND VARIOUS WAYS OF USING SAME was the subject of the following paper by Mrs. F. W. Liebelt.—"Australian fruits are dried under ideal conditions in full sunshine, and consequently retain most of their original flavour. Jams and chutneys made from dried fruits can be excellent additions to the larder It needs little more than the re-absorption of water to restore dried fruit to its original form. Here, then, are some recipes, both for jam and chutney, that I have chosen. They will doubtless appeal to women who, through rush of work, or perhaps sickness, have missed making any particular preserve earlier in the season. Apricots are cheap and make a very nice jam that is often considered better in flavour than that made with fresh fruit. Apricot jam is made as follows:—1lb. of dried apricots, 3 pints cold water, 3lbs. sugar, and a few almond kernels (if liked). Wash the fruit and then steep in the water for 24 hours or until fruit is plump and soft. Then pour into the preserving pan the liquid and fruit and bring to boil and boil for half an hour, stirring from time to time. Next add sugar and blanched almond kernels and bring to the boil again; boil for 20-30 minutes, or until a little will set when tested on a cold plate. Bottle and seal down at once. This jam sticks quickly, so stir almost constantly.

Peach jam is very nice and quite inexpensive if made with dried fruit. Take 1lb. of dried peaches, 4 pints of water, 3lbs. of sugar, juice of 2 lemons, 1oz. or 2ozs. of blanched almonds. You may, of course, omit the almonds, but if you have no lemons, substitute ¼ teaspoon (level) of citric or tartaric acid, otherwise the jam is inclined to taste insipid. Wash the peaches, cut them into three or four pieces, and soak overnight in water. Next morning rub off some of the skins and boil in the steeping water 20-30 minutes. Now add the sugar, the lemon juice (or acid) and the almond kernels, and boil briskly for another half hour, or until a little will set when tested. Bottle

and seal at once. Then there is an easily made apricot chutney that is very nice. Take 1lb. dried apricots, enough water to cover, 1lb. brown sugar (or more if liked), 2 teaspoons salt, 2ozs. whole ginger, ¼ teaspoon cayenne pepper, ¼ teaspoon cinnamon, 2 pints vinegar. Soak apricots in water overnight or until soft. Cook in the same water next day until almost mashed; add all the other ingredients (the ginger in a muslin bag) and simmer gently for about 1 hour, or until of the right chutney consistency. Botle, cork, and seal down. These, of course, are only a few ways in which dried fruits can be used to fill an empty larder. Once the idea is grasped many more people will use dried fruits where fresh fruit is out of the question.'' (Secretary, Mrs. F. W. Liebelt.)

O'LOUGHLIN.

Meeting held June 13th, 1935. Attendance, 11.

A MEATLESS MEAL.—Mrs. S. Trewartha read the following paper:—It is often a woman's worry as to what to prepare for the next meal when there is no meat in the house, for this often occurs in the summer months. This problem is perhaps not so great on a farm and with plenty of eggs, potatoes, and onions on hand. I am always pleased when some of my friends tell of how to do up a meatless meal, but it needs to be substantial, and, therefore, strength-giving for the men on the land. I have now jotted down some recipes that I have found appetising when one has to prepare such a meal. *Egg and Onion.*—Take 8 large onions and after peeling them, slice and fry in a little butter until a nice brown. Beat 6 eggs, to which add a cup of milk, also pepper and salt to taste. Then pour over the onions and stir over the fire until the eggs are cooked, as when scrambling them. *Potato Patties.*—One can also add beaten eggs and milk to mashed potatoes. Make this into a batter consistency and fry in the same way as the above recipe. *Potatoes and Eggs.*—After preparing potatoes for cooking, slice them on a vegetable slicer. Beat eggs and add to the sliced potatoes. Flavour with pepper and salt. Drop spoonfuls into boiling fat and fry. Other somewhat similar dishes are curried eggs, macaroni cheese, mashed potatoes and lettuce salad, and the usual fried eggs on toast or fried bread. (Secretary, Mrs. J. S. Foggo, *pro tem.*)

WEPOWIE (Average annual rainfall, 12.46in.).

A recipe afternoon was conducted at the meeting held on 19th June, 12 members being present. The following were among the recipes submitted:—

EGGLESS AND BUTTERLESS CAKE.—*Boiled Cake.*—Put in saucepan 1 cup sugar, 1 cup water, 1 cup currants, 1 cup sultanas, nutmeg and spice, a few almonds, and a little peel, 2 teaspoonsful treacle, ¼lb. dripping, and simmer for 15 minutes. When cool stir in 2 cups S.R. flour, ½ cup plain flour, ½ teaspoonful carbonate soda. Bake slowly for 1½ hours. This recipe was considered very economical at the present time, when eggs are fairly scarce.

The following recipe for biscuits is also made without eggs:—*Short Bread Creams.*—¼lb. butter, 2ozs. icing sugar, 2 small cups S.R. flour. Cream sugar and butter, add flour, mix to a soft paste, break off piece the size of a marble, press slightly flat with a fork so as to form little squares on the top. Stick together with butter icing.

Tomato Sauce.—12lbs. tomatoes, 1lb. apples, 1lb. onions, 1½lbs. sugar, ¼lb. salt, 1oz. allspice, ¼oz. each cloves, mace, and cayenne pepper, 1 quart vinegar, boil three hours. If too thick add more vinegar. Add a little ginger if liked.

The following recipe for shaving cream has been made and found very good:—*Shaving Cream.*—1 small packet Lux, 6 cups boiling water. 2 tablespoonsful olive oil, little perfume. Beat together until well dissolved. Keep airtight.

Custard Creams.—A biscuit recipe with custard flavouring; ¼lb. butter, 4 tablespoons sugar, 4 tablespoons custard powder, 1 cup flour, 1 egg, 2 tablespoons baking powder, and a little milk. Bake in moderate oven for 10 minutes. (Secretary, Miss E. Roocke.)

WILLIAMSTOWN WOMEN'S (Average annual rainfall, 27.77in.).

June 5th.—Attendance, 6.

ODDS AND ENDS.—Paper read by Mrs. Hamilton:—When your lamps smoke badly and you think it necessary to buy new burners, try burning the burners for half an hour in water to which has been added a quantity of soda, removing from the water while hot, so that they may be easily dried. This thoroughly cleans them, and your light will be as bright as when burners are new. When vegetables are wilted, add the juice of a lemon to a pan of cold water, and let them stand in it for an hour; they will be almost as fresh as when gathered. This is especially good for lettuce, spinach, celery, and parsley. Sew a safety pin on the outside of your ''rag bag'' and as you add a piece of material to the bag, clip off a bit and put it on the safety pin. A glance will tell you just what the bag contains and you will be saved the trouble of hunting through the entire contents.

EGGLESS RECIPES.—*Eggless Biscuits.*—Three cups plain flour, 1 cup butter (or ¾ cup of good clean dripping), 1 cup sugar, ½ cup milk, level teaspoon carb. soda, a little essence. Put milk and sugar on to boil and when boiling add the soda and stir well, then set aside to cool. Rub butter (or dripping) into flour and add pinch of salt. Beat sugar, milk, and soda mixture and add to the flour. Add essence. Knead and roll out and cut into shapes and bake for about 10 minutes in a quick oven. Eat either plain, or one-half iced or spread with jam or lemon butter, and the other half placed on top and iced. *Black-fellows' Cake.*—Boil together ½ cup of raisins, ½ cup currants, ½ cup sultanas, ½ pkt. mixed spice, 1½ cups water, 1½ tablespoons butter, 1 large teaspoon carb. soda, and 1 cup sugar. After coming to boil, take off fire and cool. Add 2 cups S.R. flour (the mixture should drop easily from spoon); bake in moderate oven for about ¾ to 1 hour. This cake is excellent if cooked in large log tins and better if kept a couple of days before cutting, although it can be cut straight away if desired. *Eggless Pudding.*—Six ounces flour, 1 tablespoon sugar, 1 teaspoon carb. soda, heaped teaspoon jam, 2ozs. butter. Rub butter into flour and add sugar and jam, mixing well. Mix soda into half teacup warm milk; add to mixture. Immediately pour into greased basin and put greased paper over the top. Steam 1½ hours. Serve with a sauce. (Secretary, Mrs. G. E. Cundy.)

AGRICULTURAL BUREAU CONFERENCE.

The several Women's Branches located in the western districts of Eyre's Peninsula held a Conference at Ceduna on the 3rd of July, when over 60 members attended. The arrangements were made by the Laura Bay Branch, and Mrs. W. W. Bowell presided.

In conjunction with the Conference the Laura Bay Branch conducted an exhibition of cooking and needlework, which was capably organised by the Secretary, Mrs. R. W. Burke. The entries made an attractive display, and were closely inspected by visitors during the day. The judges were Mesdames L. E. Trebilcock, I. Allport, and C. Lutz.

The General Secretary (Mr. H. C. Pritchard) addressed the Conference on the work of the Women's Branches, outlining the manner in which their meetings should be conducted and indicating proposed work for the future.

Miss V. Barnett read a paper on needlework and Miss L. Blumson on laundry work.

Mr. H. B. Barlow (Chief Dairy Instructor) spoke on dairying on the farm, inspected the displays of butter at the exhibition and pointed out faults in manufacture.

BISCUIT RECIPES.

[Supplied by members of the Kybybolite Branch.]

Bubble Macaroons.—4oz. butter, ¾ cup sugar, 1 egg (well beaten), 1 large cup S.R. flour, 2 cups rice bubbles. Drop in spoonsful on greased slide. Bake in slow oven.

Peanut Drops.—¼lb. butter, ½ cup sugar, 1 egg, pinch salt, 1 cup S.R. flour, ½ cup chopped peanuts. Drop in spoonsful on greased tray and bake in a moderate oven.

Cocoanut Biscuits.—¼lb. each flour, cornflour, sugar, butter, des. cocoanut, 2 eggs, 1 level teaspoon cream tartar, ½ soda, vanilla essence. Beat butter, sugar, and eggs together. Add flavouring, flour, cornflour, rising, and lastly cocoanut. Roll out and cut into shapes. They may also be put in spoonsful on oven slide.

Foam Biscuits.—½ cup milk, 1 cup each sugar and butter, 3 cups flour, ½ teaspoonful soda, vanilla essence. Rub butter into flour. Bring sugar, milk, and soda to the boil, and when it foams cool slightly, then add to flour and mix. Roll out very thin, cut into shapes, and bake in quick oven.

Scotch Shortbread.—4oz. castor sugar and 13oz. flour sifted together, 8oz. butter, ½ teaspoon salt. Stand basin containing butter over saucepan of boiling water until quite liquid. Pour butter slowly into sifted sugar and flour, working into a stiff dough. Turn on to floured board and press very well together until quite free from cracks. This may not be accomplished at once. Use the knuckles to knead. Roll into several small rounds about ½in. thick. Prick well with a fork. Slide on to an oven tray which is covered with a piece of greased paper. Bake for ¾ hour in a moderate oven, decreasing the heat gradually after it has set firmly. It should be very pale in colour, not brown.

Ginger Biscuits.—2 cups flour, 1 cup sugar, pinch of salt, 2 eggs, 4 tablespoons butter, 2 tablespoons golden syrup, 2 dessertspoons ground ginger, 2 small teaspoons baking powder. Sift flour, ginger, and baking powder well, cream butter, sugar, and salt, add eggs singly, beating well, then syrup, lastly flour, &c. Rub on well greased oven slide in very small teaspoons; cook in moderate oven for about 10 minutes.

Honey Pusher Biscuits.—Sieve ½lb. flour with pinch of salt, 1 teaspoon cream of tartar, and ½ teaspoon of soda. Beat 4oz. of sugar with 4oz. of butter or good dripping to a cream; add 1 egg and beat again; add 1 dessertspoon honey and beat well together. Gradually add the flour and powders and squeeze of lemon and mix well. Put through pusher and bake in a moderate oven.

Cream Biscuits.—1 cup each cream and sugar, 2 eggs. Beat together until sugar is dissolved, then sift in 3 cups self-raising flour. Divide mixture if different varieties are needed. *For Plain Biscuit*—Flour with any flavouring and roll out thin. Bake until golden brown. *For Orange*—Sandwich flavour orange rind and juice and when cooked fill with orange filling. *For Chocolate Creams*—Flavour with chocolate or cocoa and fill with vanilla cream. *For Lemon Bars*—Flavour with lemon rind and juice. *For Sugar Buttons*—Small pieces of mixture rolled into a ball and dipped in sugar.

Raisin Biscuit.—2 cups S.R. flour, 1 cup each sugar and cornflour, salt, 2 eggs, 1 cup butter, about 4 teaspoons milk. Sift flour, salt, and cornflour, rub in butter. Mix beaten eggs and milk together and add to flour, using just sufficient to make a stiff biscuit dough. Roll out thin and cut into rounds. Bake in a moderate oven 15 minutes. When cold spread with filling. Put two together and ice top. *Filling*—Mix together ½lb. seeded raisins, 2oz. chopped nuts, and make into paste with lemon and orange juice.

Orange Cream Fingers.—Cream 2 tablespoons butter with ½ cup of castor sugar, add 2 eggs, beat well and then sift in ½lb. plain flour to which has been added 1 teaspoon cream of tartar, ½ teaspoon carbonate of soda, and pinch of salt. Mix to dough and roll out and cut in thin fingers. Bake in quick oven 10 minutes. *Filling*—Three tablespoons icing sugar, 1 tablespoon (large) butter. Add piece of ½ an orange and warm over fire.

Slugs or Cocoanut Biscuits.—¼lb. butter, 3oz. sugar, ½lb. flour, 1 tablespoon cocoanut, 1 egg, 1 teaspoon cream of tartar, ½ teaspoon carb. soda. Cream butter and sugar, add eggs and cocoanut, and lastly flour and rising. Roll 12in. long in cocoanut, &c. Bake about 10 minutes in a moderate oven.

Date Dainties.—1½ cups of flour, 1 teaspoon cream tartar, ½ teaspoon carb. soda, pinch salt, ¼lb. butter, ½ cup sugar, ¼lb. dates, and 12 walnuts, 2 eggs. Sift flour and powders, add sugar, then rub in butter. Beat eggs and add to mixture, then dates and nuts and mix well. Place in spoonful on buttered slide and bake 10 minutes.

Cocoanut Biscuits.—½lb. S.R. flour, pinch salt, 3oz. butter, 6 good tablespoons cocoanut, 1 egg (1 or more tablespoons milk if needed), 3 tablespoons sugar. Sift flour, put in sugar and salt, rub in butter, add cocoanut. Mix to dry paste with egg, roll into small balls and flatten. Bake from 15 to 20 minutes. (Secretary, Mrs. M. Kekwick.)

SWEETS.

[Recipes supplied by Miss Patterson, Warramboo Branch.]

Cocoanut Candy.—2 cups sugar, ½ cup water, 2 teaspoons cream of tartar, 2 drops vanilla, ¾ cup cocoanut. Boil for 5 to 10 minutes, put in cocoanut and then stir until white.

Cocoanut Lollies.—2 cups sugar, ½ cup milk, ¾ cup cocoanut. Boil 5 minutes, pour out and stir until creams. When cold cut in squares.

Uncooked Sweets for Emergencies.—Fondant from icing sugar used in various ways (ginger, dates, and almonds)—*Date Balls*—Dates soaked and mashed with cocoanut. Uncooked sweets do not keep, must be fresh. Cocoanut macaroons a good substitute. Beat whites of 2 eggs with 5oz. sugar until stiff enough to hold shape, stir in 2oz. cocoanut and bake in tiny cakes until dry. Gelatine is very useful and convenient for sweetmaking, particularly Turkish delight and snowballs.

Turkish Delight.—Take 3oz. gelatine soaked in 1 cup of water for 20 minutes, put into saucepan with 1½ cups water and 2lbs. sugar. Boil 15 minutes, stirring all the time. Flavour with lemon and citric acid, colour some with cochineal. Pour into plates to cool.

Snowballs.—1oz. gelatine, 2½ gills of water, 1lb. sugar. Soak the gelatine in 1½ gills of water for at least 20 minutes. Boil the sugar and the rest of the water (1 gill) for 10 minutes, then add the soaked gelatine and water and boil for 10 minutes more. Turn all into a large basin and beat until cool and stiff. Form into balls with fingers while still slightly warm. Cover with chocolate and cocoanut.

Butter Scotch.—4 tablespoons butter, 2 tablespoons golden syrup, 2 tablespoons milk, 1 tablespoon vinegar, 1 tablespoon cold water, 12 ozs. sugar. Boil together for 5 minutes or until brittle when dropped into cold wate.. Put almonds on buttered plate and pour over the mixture. Let set until cold.

Snowballs.—Soak 1oz. gelatine in 1½gills (12 tablespoons) of water for 25 minutes. Boil together 1lb. of sugar and 1 gill of water for 10 minutes until dissolved, add soaked gelatine to water, and boil 10 minutes longer. Turn the mixture into a big basin and beat until it is cool and stiff. Form into balls with the fingers while it is still slightly warm. Dip them into a chocolate coating and finally roll them on a dish sprinkled with desiccated cocoanut. To make chocolate coating, take 2oz. unsweetened chocolate, a few drops vanilla, and a little hot water—a very little at a time as you need it. This should be melted and snowballs dipped in it.

Cocoanut Ice.—2 cups fine white sugar, ½ cup milk, ¾ cup desiccated cocoanut, a few drops vanilla and red colouring. Heat sugar and milk together and boil for 5 minutes, stirring all the time. Then add the cocoanut and boil for another full minute. When flavouring and colouring is liked, add it with the cocoanut. Remove from the fire, and as it cools beat well (a wooden spoon is good) until it goes creamy. Pour quickly into a wet dish or on to waxed paper to set. Cut into pieces. (Secretary, Miss J. P. Patterson.)

TOMATOES AND THEIR USES.

[Mrs. W. Woods, Wirrilla.]

The tomato is grown extensively in summer, and is appreciated by everyone during hot days. When the housewife is at her wit's end to know what to prepare, if there are tomatoes in the house, one can rely on having a cool meal when the men come in from the paddock. If a hot meal is preferred, a tomato pie can be served with roast beef or mutton, made as follows:—Butter a dish and fill up with alternate layers of sliced tomato, sliced onions and bread crumbs, with a little butter or dripping on top of last layer of crumbs and bake to a nice brown.

Another Recipe.—Dip three or four tomatoes into boiling water for a minute or so. Dry and remove the skins, cut in slices, season with pepper and salt. Mix 3 tablespoons breadcrumbs and 2 tablespoons grated cheese together. Place tomatoes and bread-crumbs and cheese alternately in a greased pie-dish, having crumbs for the last layer. Put 1oz. butter in small pieces on top of dish and bake 20 minutes.

Before serving the hot roast and vegetables, serve tomato soup, which is made as as follows:—2lbs. tomatoes stewed for 15 minutes in 1 gill of water, strain through flour sieve. The more pulp forced through the better and richer will be the soup. Return pulp to saucepan. Add an equal quantity of milk, butter size of walnut, pepper and salt to taste, and when heated a thickening of flour or cornflour, and 1 teaspoon sugar. Boil gently for 5 minutes,

Bottled Tomatoes are useful for making tomato soup during winter, when soup is more appreciated than during hot weather. They are simply done: Scald the tomatoes with boiling water, press them tightly into the bottles, put on the lids and clips and put in sterilizer. Fried tomatoes are also very tasty, cut them in slices, sprinkle with pepper and salt, and fry until cooked.

Tomato Toast.—Chop up a little bacon and put into a small saucepan to cook with a small piece of butter for a few minutes, then add two or three tomatoes which have been skinned and cut up, and a little pepper. When tomatoes are well cooked, break in 2 eggs and stir well. When thick enough, put on the pieces of buttered toast. Another similar recipe is to put on three or four good sized tomatoes with pepper and salt and when cooked add 3 beaten eggs, stir well, and when done serve on toast.

Tomato Cheese.—Two fair sized tomatoes, 2 or 3 small pieces of cheese (that have got too dry for table use), 2 tablespoons of milk, a little pepper and salt. Cook in small saucepan 2 or 3 minutes and serve on toast.

Tomato Nest Eggs.—4 large firm tomatoes, 4 eggs, a little grated cheese, salt, butter, pinch cayenne if wanted. Wipe the tomatoes and cut a large slice off the top, scoop out the pulp, season inside with cheese, salt and cayenne. Place tomatoes on a greased slide and carefully break an egg into each one, Place a little butter and cheese on top and replace lid. Bake in a quick oven until egg set. Serve on rounds of buttered toast.

Stuffed Tomatoes.—½oz. bread crumbs, 1oz. butter, 2 level tablespoons chopped parsley, 2 teaspoons grated cheese, 1 level tablespoon chopped onion, salt, pepper, browned crumbs, 1 level tablespoon thick gravy or sauce. Mix all except cheese and browned crumbs. Scoop out some of soft part of tomatoes and fill with mixture, putting a little cheese and browned crumbs on top, bake till done.

Cold meat chopped finely and flavoured with nutmeg can also be used and served on fried bread or toast. Tomatoes can also be stewed with a little butter, and seasoned. Cook for 20 or 30 minutes, add a tablespoon of vinegar and serve with roast meat,

Tomato Sauce should not be made with tomatoes that have been picked after a rain, and if the sauce is made later in the season, the tomatoes are inclined to be watery, thus making the sauce very thin. Tomatoes should be firm and not over ripe to get the best results for sauce making. Following is a good recipe:—12lbs. tomatoes, 3 cups vinegar, 6ozs. salt, 2ozs. garlic, ½oz. each cloves and mace, 2 cups sugar, 2 large apples, ¼oz. cayenne, 1 large onion. Boil all together for three hours, then strain through a sieve. Before putting on the tomatoes, scald and skin them. (Secretary, Mrs. W. Jones.)

KINDERGARTEN WORK.

[*Paper contributed by Mrs. Sandercock (Belalie) and read at the April meeting of the Wirrabara Branch.*]

The word "kindergarten" is made of two German words meaning the child's garden. The training of the child's mind can be likened to the growing of seeds in the garden. Its thoughts and fears have to be gently cared for to produce the right foundation for adolescence. Like to the soil in the garden, the atmosphere, which is the environment of the child, is where the seeds of its thoughts grow. It is this atmosphere that a kindergarten teacher must create for her little learners.

The teaching of the young children has undergone a great change. The teaching of the children in the younger grades was not made so interesting as it is now with the latest methods. In these methods the teacher indirectly controls her class although she is not in the foreground. It was discovered that the children learned more quickly through their senses and they liked to create in their own small way. The first material the children were given to use was something with which they were all familiar, that is, their clothes. Frames were made on which materials were tacked and tape sewn to them. From these tapes the children learnt to tie and from that to using buttons, hooks, and fastening press studs. Then came the sense of touch. For this exercise the child is blind-folded with a bandage provided by the teacher and is given a board on which rough and smooth paper is pasted. He feels the paper, saying rough or smooth, as it is touched. From this simple exercise the more difficult ones are given, such as several pieces of rough and smooth on the board which have to be touched. The final sense of touch is given by allowing the child to feel sand-paper letters—a, m, p, etc.—thus setting the foundation for the teaching of reading and writing. The child of to-day has a more highly developed sense of touch in the tips of its fingers than we of the older generation.

The Sight.—The child is given a set of colours, having two of each colour in it. He must pick out the colours and place them in their correct pair. A little more difficult exercise is for him to arrange several colours such as blue, green, yellow, &c. These range from the lightest of blue to the deepest. H is required to place each colour in correct position, having the lighter shades merging into the dark shades. Then blocks are given by which the child finds the largest and builds upon it till the smallest is reached. Pictures are also used in the development of the sight. Allowing the chi n to tell what is seen in a picture is the fore-runner to composition. From this t the children learn when in Grade I. to look at a word and hear it pronounced recognise it when seen again.

Many interesting lessons can be given to develop the sense of hearing. So are taught collectively. One fascinating game which the children like to ringing of the bell from different places in the room. One child rings an whose face is hidden, points to the direction whence he thinks the sound set of material used by the individual child is the pairing of tins containi quantities in them to give out the same sound when shaken, such as equa of sand, wheat, stones, peas, &c. These have to be shaken and placed in use of the piano is one of the finest exercises for the development of the Children are taught to combine rhythmical steps with tunes on the piano. Simp steps such as march, run, skip, &c., also a chord for stopping work; a bar of music to return to their seats. An efficient kindergarten teacher can give most of her orders from the music which she plays on the piano. When learning the sounds such as a, e, t, &c., a teacher shows them the letter and tells them what it is they hear and are able to recognise the letter and sounding of it when next shown to them.

The sense of taste does not directly help the child in his school life as the three before-mentioned. Although in the kindergarten class lessons are given to test the

child's power of taste. Such a game is to have a cup each containing milk, w cocoa, raspberry, &c., for the child to taste which he must name after sipping the, li

The sense of smell is similarly dealt with by letting the child smell such thin soap, butter, ink, chalk, &c. These make very interesting games for the children love to play them. In the kindergarten class half of the period is set lessons bu other part is free period. All the exercises described and many others are plac cupboards and the child is allowed to choose his work. After he has finished h still until the teacher sees that the work is correct. He may then pack it awa start on another. The first step learnt in the teaching of writing is by an inset. are made out of wood and cut in different shapes such as a circle, oblong, square, diamond, &c., a small knob is placed in the centre for the child to handle it places this inset on his board, draws the shape with chalk and fills it in with s strokes. When he can master this with chalk he is given a blank book and co pencil in which to work an inset. After this comes the feeling of the sand letters a, c, i, then the writing of these letters in chalk on the blackboard, and the use of the pencil. The object of all kindergarten teaching is to allow the freedom of expression.

Mrs. Cugley read a paper, "His Majesty the Baby." (Secretary, Mrs. A. M. Cu
